$$H_k(T) = \sum_{j=0}^{\lfloor k/2\rfloor} D_{k-2j}, \qquad \langle e_0, H_k(T)e_0\rangle = \begin{cases} 1 & k \text{ even}, \\ 0 & k \text{ odd}. \end{cases}$$

On $\mathcal{R}_p$, for $|t| < p^{-1/2}$, the series converges in operator norm and

$$\left\langle e_0, (I - tT + pt^2 I)^{-1} e_0 \right\rangle = \frac{1}{1 - t^2}.$$

Proof. The distance operators are bounded because every row and column has s_n entries. Counting the first step gives $TD_1 = D_2 + (p+1)I$ and $TD_n = D_{n+1} + pD_{n-1}$ for $n \geq 2$. Thus $D_n = R_n(T)$. With $H_{-1} = H_{-2} = 0$, the recurrences give $R_n = H_n - H_{n-2}$ for every $n \geq 0$. Telescoping proves the sum formula. Since $D_n e_0 = \mathbf{1}_{S_n}$, only D_0 contributes to the root state. The spectral formula bounds $\|H_k(T)|_{\mathcal{R}_p}\|$ by $(k+1)p^{k/2}$. This proves norm convergence on $\mathcal{R}_p$ in the stated disk and permits evaluation of its state term by term. Multiplication of the series by $I - tT + pt^2 I$ proves the inverse formula on that space. □

For example, at $p = 2$,

$$q_0 = 1, \qquad q_1 = x/\sqrt{3}, \qquad q_2 = (x^2 - 3)/\sqrt{6}, \qquad H_2 = x^2 - 2.$$

The tree counts give $\int x^2 d\nu_2 = 3$ and $\int x^4 d\nu_2 = 15$. Indeed a four-step return either returns after two steps, giving nine walks, or first reaches distance two, giving six walks. Consequently $\int H_2 d\nu_2 = 1$ but $\int R_2 d\nu_2 = 0$, and $\int R_2^2 d\nu_2 = 6$. These values distinguish the two Hecke normalizations already at the first nontrivial higher element.

27.8 Finite sets of primes and the arithmetic comparison

For a finite prime set F, form the completed Hilbert tensor products $\mathcal{R}_F = \widehat{\bigotimes}_{p\in F}\mathcal{R}_p$ and the product probability measure $\nu_F = \prod_{p\in F}\nu_p$. The tensor product of the maps $\mathcal{U}_p$ is the unitary

$$\mathcal{U}_F : \mathcal{R}_F \longrightarrow L^2([0,\pi]^F, \nu_F), \qquad \bigotimes_p e_{n_p} \longmapsto \prod_p q_{n_p}(\theta_p).$$

It intertwines each local Hecke operation, hence every element of $\bigotimes_{p\in F}\mathbb{C}[T_p]$, with multiplication by its Satake polynomial. The tensor root vector maps to 1, so its vector state becomes integration against ν_F. The algebraic integral lattices are the finite tensor products of the sphere-sum lattices above. Adjoining a prime uses $v \mapsto v \otimes e_0$ on the tree side and $f \mapsto f \otimes 1$ on the spectral side. These isometric maps commute with $\mathcal{U}_F$ and preserve the distinguished states. They give an operation-compatible finite-stage system.

To specify the occupation-phase comparison, let $P_p = \mathbb{C}[a_k, b_k \mid k \geq 1]$ be the polynomial oscillator space. For finitely supported nonnegative integers r_k, s_k, give its monomial $\prod_k a_k^{r_k} b_k^{s_k}$ squared norm $\prod_k k^{r_k+s_k} r_k! s_k!$, with distinct monomials orthogonal. Complete this positive inner product to a Hilbert space $\mathcal{F}_p$. The charge of this monomial is $m = \sum_k (r_k - s_k)$. Multiplication by $e^{im\theta}$ on each charge space defines a unitary V_θ on $\mathcal{F}_p$. This is the one-prime occupation action in Definition 25.5.1. The strong integral $A_p = \int_0^\pi V_\theta \, d\nu_p(\theta)$ is bounded with norm at most one. It acts on a charge-m monomial by $c_m = \int_0^\pi e^{im\theta}\, d\nu_p(\theta)$. For $m = 1$, symmetry about $\pi/2$ gives

$$c_1 = i \int_0^\pi \sin\theta \, d\nu_p(\theta) \in i\mathbb{R}_{>0}.$$

Thus this averaging operator has a nonreal eigenvalue. It cannot be unitarily intertwined with the self-adjoint adjacency operator or with multiplication by its real spectral coordinate. This obstruction concerns those specified operators. It does not exclude a different arithmetic comparison.

The radial transform supplies a complex Hilbert Hecke representation, an integral cyclic module, and a compatible finite-prime state system. A comparison with the proposed primitive arithmetic trace class $\mathcal{V}^{\mathrm{prim}}$ requires constructing its arithmetic trace carrier and a map preserving the specified Hecke operations and trace pairing. Tame residue and Gersten operations require additional maps on common coefficients. No full Weil functional or global spectral realization is identified by the positive root state.

27.9 The Chiral Framework over $\overline{\mathrm{Spec}\,\mathbb{Z}}$

The matrices S_p and their scalar trace recursions define the local linear constructions above. Global arithmetic realization requires local representations, distinguished vectors, a restricted tensor-product construction and an intertwiner with the proposed trace carrier. Beilinson–Drinfeld factorization on a smooth characteristic-zero curve does not by itself supply those data over $\overline{\mathrm{Spec}\,\mathbb{Z}}$.

Conjecture 27.9.1 *(unramified arithmetic trace realization).* There is an arithmetic dg category $\mathscr{C}_{\mathrm{arith}}$ over $\mathbb{C}$, defined independently of its proposed Hecke realization. Let $C_\bullet = CC_\bullet(\mathscr{C}_{\mathrm{arith}})$ be its Hochschild chain complex, with homological differential of degree -1. The construction specifies a degree d, a subspace $M_{\mathrm{arith}} \subset H_d(C_\bullet)$ containing the primitive trace class $v_{\mathrm{prim}} = \mathcal{V}^{\mathrm{prim}}$, and a normalized linear trace functional $\tau_{\mathrm{arith}} : M_{\mathrm{arith}} \to \mathbb{C}$ with $\tau_{\mathrm{arith}}(v_{\mathrm{prim}}) = 1$. It constructs commuting local spherical Hecke actions on this subspace, with the central element D_p acting as the identity.

For each prime p, it also specifies a smooth representation Π_p of $GL_2(\mathbb{Q}_p)$ with trivial central character, a Whittaker realization, and the spherical Hecke module $M_p = \Pi_p^{GL_2(\mathbb{Z}_p)}$. Its distinguished

vector u_p and linear functional $\ell_p : M_p \to \mathbb{C}$ satisfy $\ell_p(u_p) = 1$. The arithmetic or automorphic construction must determine these representations, vectors, and functionals. Set

$$M_{\mathrm{aut}} = \bigotimes_p{}' (M_p, u_p), \qquad u = \bigotimes_p u_p, \qquad \ell = \bigotimes_p \ell_p.$$

These are algebraic restricted tensor products over $\mathbb{C}$. The normalization makes ℓ compatible with adjoining u_p. Each local Hecke algebra acts on its own tensor factor, so the algebraic restricted tensor product of the local Hecke algebras acts on M_{aut}.

There is a complex-linear isomorphism

$$\Phi : M_{\mathrm{arith}} \longrightarrow M_{\mathrm{aut}}, \qquad \Phi(v_{\mathrm{prim}}) = u, \qquad \Phi(hm) = h\Phi(m), \qquad \tau_{\mathrm{arith}}(m) = \ell(\Phi(m)).$$

The identities hold for every $m \in M_{\mathrm{arith}}$ and every finite-support spherical Hecke element h. In particular, the distinguished Hecke functionals agree: $\tau_{\mathrm{arith}}(hv_{\mathrm{prim}}) = \ell(hu)$. The oscillator cover additionally admits a complex-linear map $Q : \otimes'_p \mathcal{H}^{(p)} \to M_{\mathrm{arith}}$ sending its vacuum to v_{prim}, with complex-linear local maps $Q_p : \mathcal{H}^{(p)} \to M_p$ such that $Q_p(|0\rangle_p) = u_p$ and $\Phi Q = \otimes_p Q_p$.

The class v_{prim} is an element of the arithmetic trace carrier, whereas M_{aut} is a representation space. The conjecture asks for their comparison through Φ, together with the oscillator maps Q, Q_p. It does not identify the class with that space. All these arithmetic constructions remain open. The linear functionals above are not assumed positive. A positive state, Hilbert completion, spectral decomposition, ramified extension, and archimedean or full Weil comparison each require their own construction and compatibility theorem.

27.10 The Corrected Local Model and Its Consequences

The global realization in Conjecture 27.9.1 remains conjectural. The unconditional local statements are the divisor composition law, the distinct Adams monoid action, the symmetric-power trace recursion for a specified Satake matrix, and the radial spherical transform of Theorem 27.6.1. The latter intertwines the local Hecke operations and preserves the root state. An arithmetic Hecke action requires a comparison preserving its carrier and determinant operation. Neither the oscillator rank nor an equality of scalar traces constructs that comparison.

Chapter 28

Divisor sums and Adams operations on polynomial Fock space

An arithmetic operation on a Fock space must be specified before it can be compared with Frobenius, a Hecke correspondence, or a vertex operation. Two integral substitutions are relevant here. One sums over divisors of a mode index; the other multiplies that index. They agree on the first mode, but their compositions differ. We compute the divisor substitutions, then construct the Adams action and identify the structures retained by each. The calculation concerns a polynomial oscillator representation. A map to an arithmetic Hochschild trace class remains additional data.

28.1 The two substitutions

Let R be a commutative unital ring and let S be a finite set of oscillator species. Put

$$M_R = \bigoplus_{s\in S,\ k\geq 1} R x_{s,k}, \qquad P_R = \mathrm{Sym}_R(M_R) = R[x_{s,k} : s \in S, k \geq 1].$$

All polynomials and all sums defining an image of a generator have finite support. The vacuum is 1. Particle degree assigns degree one to every $x_{s,k}$; weight assigns weight k. The species index can label an arithmetic place, but is independent of the integer indexing an operation. Suppress it when there is only one species. Define unital R-algebra maps

$$T_n(x_{s,k}) = \sum_{d\mid n,\ d\mid k} d\, x_{s,nk/d}, \qquad \psi_n(x_{s,k}) = x_{s,nk} \qquad (n \geq 1). \tag{28.1}$$

The divisibility condition $d \mid k$ restricts the sum; integrality of nk/d already follows from $d \mid n$. Write $t_n = T_n|_{M_R}$ for the underlying linear map. Thus $T_n = \mathrm{Sym}(t_n)$. These definitions commute with change of coefficient ring. They also extend to any set of species as an algebraic direct limit of finite sets. For an empty set of species all maps are the identity on R. Counterexamples below use a nonempty species set and characteristic zero, unless a coefficient ring is specified otherwise.

First-mode calculations

For species indexed by the primes 2 and 3, the first-mode identities are

Computation 28.1.1. $T_2 x_{2,1} = \psi_2 x_{2,1} = x_{2,2}$.

Computation 28.1.2. $T_2 x_{3,1} = \psi_2 x_{3,1} = x_{3,2}$.

Computation 28.1.3. Both substitutions send $x_{2,1}x_{3,1}$ to $x_{2,2}x_{3,2}$, by their polynomial product rule.

These first-mode equalities do not determine the higher compositions.

Example 28.1.4. For a prime p,

$$T_p x_1 = x_p, \quad T_p x_p = x_{p^2} + p x_p, \quad T_{p^2} x_1 = x_{p^2}.$$

Consequently $T_p^2 \neq T_{p^2}$. The usual weight-two Hecke recursion also fails: its discrepancy on x_1 is $p(x_p - x_1)$. Neither statement is a failure of the distinct maps ψ_n, which satisfy $\psi_m \psi_n = \psi_{mn}$ on every generator and therefore on P_R.

28.2 Composition on a prime chain

Fix a prime p and an integer $u \geq 1$ prime to p. The submodule with basis $e_r = x_{up^r}$, $r \geq 0$, is invariant under t_{p^a}. Denote its restriction by A_a, including $A_0 = 1$. Then

$$A_a e_r = \sum_{i=0}^{\min(a,r)} p^i e_{r+a-i}. \tag{28.2}$$

The indices never decrease. This boundary at $r = 0$ is responsible for the noncommutativity.

THEOREM 28.2.1 *(prime-valuation composition).* For $a, b, r \geq 0$, set $[v]_+ = \max(v, 0)$ for an integer v, and put

$$N_{a,b}(r,t) = \mathbf{1}_{t \leq r+b} \big[\min(b, r, t) - \max(0, t-a) + 1\big]_+.$$

Then, over every coefficient ring,

$$A_a A_b e_r = \sum_{t=0}^{a+b} p^t N_{a,b}(r,t) e_{r+a+b-t}. \tag{28.3}$$

Subtracting the same expression with a, b interchanged gives the commutator. Over $\mathbb{Z}$ or a characteristic-zero field, A_a and A_b commute precisely when $a = b$ or $ab = 0$.

Proof. Apply A_b first. A term is specified by $0 \leq i \leq \min(b, r)$, followed by $0 \leq j \leq \min(a, r + b - i)$. Its coefficient is p^{i+j} and its index is $r + a + b - i - j$. For fixed $t = i + j$, the second upper bound is equivalent to $t \leq r + b$, and the remaining bounds are

$$\max(0, t - a) \leq i \leq \min(b, r, t).$$

Counting these integers proves the formula without division. If $0 < a < b$, take $r = a$ and $t = 2a$. In the commutator the coefficient of e_b is $-p^{2a} \min(a, b - a)$, which is nonzero over the stated rings. The cases $a = b$ and $ab = 0$ commute by definition; interchanging a, b covers the remaining case. □

In particular,

$$[A_1, A_2] e_r = \begin{cases} -p^2 e_2, & r = 1, \\ 0, & r \neq 1. \end{cases} \tag{28.4}$$

For $r \geq 2$ this follows either from the formula or from the polynomials $U + p$ and $U^2 + pU + p^2$, where $U e_r = e_{r+1}$. Direct substitution checks $r = 0, 1$.

Corollary 28.2.2 *(different primes and arbitrary indices).* Families belonging to different primes commute. If $(m,n)=1$, then $T_mT_n=T_{mn}$. More generally, write $a_p=v_p(m)$, $b_p=v_p(n)$, and $r_p=v_p(k)$. On a generator,

$$T_mT_nx_k=\sum_{(t_p)}\left(\prod_{p\mid mn}p^{t_p}N_{a_p,b_p}(r_p,t_p)\right)x_{mnk/\prod_{p\mid mn}p^{t_p}},\qquad 0\le t_p\le a_p+b_p. \tag{28.5}$$

Terms with zero coefficient are omitted. All nonzero terms have integral indices. On a monomial the image is the product of these finite sums.

Proof. Multiplication or division of an index by a power of p does not change its valuation at another prime. Thus the choices of divisors at distinct primes are independent. The divisor formula factors t_n as the product of the $A_{v_p(n)}$ acting in these independent coordinates. Apply the theorem in each coordinate and extend the resulting equality on generators multiplicatively. For coprime m,n, one of a_p,b_p vanishes at each prime, so the product is exactly the formula for T_{mn}. □

These formulas include coefficient exceptions. In characteristic p, $T_{p^a}=\psi_{p^a}$, since every summand with $i>0$ vanishes. Over other rings a displayed commutator coefficient may vanish through torsion. Formula (28.3), rather than the characteristic-zero noncommutativity assertion, determines those cases.

More generally, for $1\le a<b$, direct expansion gives

$$[A_a,A_b]e_1=-p^{a+1}e_b. \tag{28.6}$$

Indeed $A_be_1=e_{b+1}+pe_b$, so applying A_a gives successive coefficients $1,2p,\dots,2p^a,p^{a+1}$. In the reverse order $A_ae_1=e_{a+1}+pe_a$; since $b\ge a+1$, the expansion ends with $2p^{a+1}$ instead of p^{a+1}.

Over any nonzero characteristic-zero ring, the global criteria are

$$T_mT_n=T_{mn}\iff(m,n)=1,$$

and

$$[T_m,T_n]=0\iff\text{for each }p,\quad a_pb_p=0\text{ or }a_p=b_p.$$

For the first necessity, on x_1 a common prime contributes $A_aA_be_0=\sum_{j=0}^{\min(a,b)}p^je_{a+b-j}$, whereas $A_{a+b}e_0=e_{a+b}$. Select its $j=1$ term and the coefficient-one highest terms at the other primes; it cannot vanish. For the second, if $0<a_p<b_p$, apply the commutator to x_p. At every other prime the two orders agree on e_0; selecting their highest terms and using (28.6) gives a nonzero coefficient. Sufficiency follows from the independent prime factors. Over $\mathbb{F}_\ell$, both criteria have the corresponding exception at $p=\ell$: that prime imposes no condition. At every other prime, the same nonzero power-of-p test proves necessity. These assertions concern the polynomial carrier; reducing the larger Hall lattice below is a different operation.

The interaction with the Adams shifts is equally explicit:

$$\psi_mT_nx_k=\sum_{d\mid n,\,d\mid k}dx_{mnk/d},\qquad T_n\psi_mx_k=\sum_{d\mid n,\,d\mid mk}dx_{mnk/d}.$$

In characteristic zero these commute exactly for coprime m,n. Sufficiency follows from equality of the divisor conditions, and $k=1$ detects an extra positive coefficient when the indices have a common prime.

One can instead retain the prime substitutions and change the higher operations: define $U_n = \prod_p T_p^{v_p(n)}$. Then $U_m U_n = U_{mn}$, because different prime substitutions commute. This is another monoid action, distinct from both T_n and ψ_n. Its prime-power formula is

$$T_p^a e_r = \sum_{j=0}^{a} \binom{a}{j} p^j e_{r+a-j} \quad (r \geq 1), \qquad T_p^a e_0 = \sum_{j=0}^{a-1} \binom{a-1}{j} p^j e_{a-j} \quad (a \geq 1).$$

The first is the binomial theorem for $U + p$ on the invariant tail $r \geq 1$; the second follows after the first step $e_0 \mapsto e_1$. Its prime maps still fail the Frobenius tests below, so this change repairs only the composition law.

28.3 AN EXPLICIT PRESENTATION OF THE PRIME-CHAIN ALGEBRA

A presentation should distinguish relations in linear operators on M_R from composition of ring maps on P_R. We give a finite coefficient test for every proposed linear relation. It describes the entire prime-chain operator algebra, including its boundary terms.

A useful ambient realization uses $Ue_r = e_{r+1}$ and $Be_0 = 0$, $Be_r = e_{r-1}$ for $r \geq 1$. They satisfy $BU = 1$, and $U^i B^i$ projects onto the tail $r \geq i$. Therefore

$$A_a = \sum_{i=0}^{a} p^i U^{a-i} U^i B^i = U^a \sum_{i=0}^{a} p^i B^i, \qquad A_{a+1} = U A_a + p^{a+1} U^{a+1} B^{a+1}.$$

These identities locate the generated algebra inside the integral shift-and-partial-inverse operator algebra. They do not identify the subalgebra generated by the A_a with that whole ambient algebra.

For $a \geq 1$, put $q_a(z) = \sum_{i=0}^{a} p^i z^{a-i}$. For a word $w = Z_{a_\ell} \cdots Z_{a_1}$, write $D_w = \sum_j a_j$ and $q_w = \prod_j q_{a_j}$; the rightmost letter acts first. For $r, s \geq 0$, define the integer

$$B_w(r,s) = \sum_{\substack{0 \leq i_j \leq a_j,\ \sum_j (a_j - i_j) = s \\ i_j \leq r + \sum_{h<j}(a_h - i_h) \text{ for every } j}} p^{\sum_j i_j}. \tag{28.7}$$

For the empty word set $D_w = 0$, $q_w = 1$, and $B_w(r,s) = \mathbf{1}_{s=0}$. Every sum is finite, and $B_w(r,s) = 0$ if $s > D_w$.

THEOREM 28.3.1 *(finite-test presentation).* Let $\mathcal{F}_R = R\langle Z_1, Z_2, \ldots \rangle$. For a finite expression $F = \sum_w c_w w$, put $D = \max_w D_w$, taking $D = 0$ for the zero expression. Define $I_{p,R}$ by the following explicit coefficient conditions:

$$\sum_w c_w q_w(z) = 0 \quad \text{in } R[z], \tag{28.8}$$

$$\sum_w c_w B_w(r,s) = 0 \quad (0 \leq r < D,\ 0 \leq s \leq D). \tag{28.9}$$

Then $I_{p,R}$ is a two-sided ideal and

$$R[A_1, A_2, \ldots] \cong \mathcal{F}_R / I_{p,R}.$$

Here the left side is the unital R-subalgebra of $\mathrm{End}_R(\bigoplus_{r \geq 0} Re_r)$ generated by the indicated linear maps. This is an explicit, generally infinite presentation, not an assertion of finite generation or a finite list of relations.

Proof. Repeated use of (28.2) gives $w(A)e_r = \sum_s B_w(r,s)e_{r+s}$. If $r \geq D$, every intermediate index is at least r, hence every choice $0 \leq i_j \leq a_j$ is allowed. In that range $B_w(r,s)$ is the coefficient of z^s in $q_w(z)$. Thus (28.8) says exactly that $F(A)e_r = 0$ for all $r \geq D$, and (28.9) says the same for the remaining basis vectors. These conditions are therefore exactly the kernel of evaluation $Z_a \mapsto A_a$. The kernel is a two-sided ideal and the first isomorphism theorem proves the assertion. This argument works over any commutative R; all tests are finite equalities in R. □

Equivalently, an evaluated expression has a unique form $q(U) + E$, where $q \in R[z]$ and E is a finite matrix supported in columns $r < D$ and rows $r \leq r + s \leq r + D$. Uniqueness follows by applying the difference to arbitrarily large e_r. The symbol map onto $R[z]$ is surjective because $q_1 = z + p$. Its kernel consists of the finite matrices that occur in the generated algebra. No assertion that all finite matrices occur is needed. For $R = \mathbb{Z}$, the commutator in (28.4) is a nonzero element of this kernel.

For finitely many primes, the same coefficient construction applies on the basis indexed by their valuation vectors. Operators at different primes commute; their word coefficients are products of (28.7). Tail and boundary tests in each coordinate give an explicit presentation there as well. Every word in the full family involves only finitely many primes.

The multiplicative extension to P_R preserves composition and is faithful on the monoid of the generator maps: equality is tested on M_R. It does not preserve addition of operators. For example, if L is a generator map, then $\mathrm{Sym}(2L)(x^2) = 4(Lx)^2$, whereas $2\,\mathrm{Sym}(L)(x^2) = 2(Lx)^2$. Thus a linear relation from this presentation is not automatically a linear relation between operators on the entire polynomial ring.

28.4 Integral Adams operations and the Hall lattice

Proposition 28.4.1 *(Adams action on the monomial carrier).* The maps ψ_n form a monoid action by ring endomorphisms on every P_R. Over $\mathbb{Z}$, however, this action is not a system of Frobenius lifts:

$$\psi_p(x_1) - x_1^p = x_p - x_1^p \notin pP_{\mathbb{Z}}.$$

The two distinct monomials remain distinct modulo p. This excludes this particular Adams action from defining a special λ-ring on the monomial lattice. It does not exclude other λ-structures on that ring. For example, $\phi_n(x_{s,k}) = x_{s,k}^n$, with the identity on $\mathbb{Z}$, gives commuting Frobenius lifts and the special λ-structure in which each variable is a line element.

Theorem 28.4.2 *(torsion-free Adams criterion).* The torsion-free criterion is the following: a commuting system of unital ring endomorphisms with $\psi_m\psi_n = \psi_{mn}$, $\psi_1 = 1$, and $\psi_p(f) \equiv f^p \pmod{pR}$ determines a unique special λ-structure on a $\mathbb{Z}$-torsion-free ring. This is Wilkerson's Proposition 1.2, as identified in Borger, *The basic geometry of Witt vectors, I*, §1.17. Borger's §§1.5–1.6 distinguish commuting operations from Frobenius lifts. No torsion-free converse is asserted for arbitrary torsion rings.

Observation 28.4.3 *(rational coefficients).* Over a $\mathbb{Q}$-algebra the congruences are vacuous, but the commuting action is still substantive data. Its operations are determined by

$$\lambda_t(f) = \exp\left(\sum_{n\geq 1} \frac{(-1)^{n-1}\psi_n(f)t^n}{n}\right).$$

The two integral lattices

Inside $P_{\mathbb{Q}}$ for one species, define

$$H(t) = \sum_{r\geq 0} h_r t^r = \exp\left(\sum_{k\geq 1} \frac{x_k t^k}{k}\right), \qquad L_{\mathbb{Z}} = \mathbb{Z}[h_1, h_2, \ldots].$$

Observation 28.4.4 *(integral and rational lattices).* The symmetric-function identification $x_k = p_k$ gives $P_{\mathbb{Z}} \subsetneq L_{\mathbb{Z}}$ and $P_{\mathbb{Q}} = L_{\mathbb{Z}} \otimes \mathbb{Q}$. For instance $h_2 = (x_1^2 + x_2)/2$ belongs to the second lattice but not the first. These are the Newton and Hall lattice conventions of Macdonald, I.2, equations (2.10)–(2.14), and I.4, equations (4.5)–(4.9). For several species take the tensor product of these integral lattices.

THEOREM 28.4.5 *(Adams operations on the Hall lattice).* The standard Adams action on symmetric functions substitutes $(z_1, z_2, \ldots) \mapsto (z_1^n, z_2^n, \ldots)$; hence it preserves $L_{\mathbb{Z}}$ and acts on power sums by $x_k \mapsto x_{nk}$. For a prime p, reducing symmetric polynomials in finitely many variables modulo p proves the Frobenius congruence; passage through stable symmetric degrees proves it on $L_{\mathbb{Z}}$.

PROPOSITION 28.4.6 *(integrality of the divisor substitutions).* Every T_n also preserves $L_{\mathbb{Z}}$. Its complete-symmetric series satisfies

$$T_n H(t) = \prod_{d\mid n} \psi_n H(t^d). \tag{28.10}$$

Nevertheless T_p is not a Frobenius lift on this lattice:

$$T_p h_p = \psi_p h_p + \psi_p h_1 \equiv h_p^p + h_1^p \not\equiv h_p^p \pmod{pL_{\mathbb{Z}}}.$$

Proof. In the logarithm of $T_n H(t)$, set $k = dj$ in the summand indexed by $d \mid n$. This gives

$$\sum_{k\geq 1} \frac{T_n(x_k)t^k}{k} = \sum_{d\mid n} \sum_{j\geq 1} \frac{x_{nj} t^{dj}}{j}.$$

Exponentiating proves (28.10) in $P_{\mathbb{Q}}[[t]]$. Each factor has coefficients in $L_{\mathbb{Z}}$, so comparison of coefficients proves integrality. For $n = p$, the coefficient of t^p in the two factors is exactly the displayed sum. The Frobenius congruence for ψ_p gives its reduction, and h_1^p is nonzero in the polynomial ring $L_{\mathbb{Z}}/pL_{\mathbb{Z}}$. □

Thus passing to the Hall lattice repairs the integral Frobenius condition for ψ_n, but does not make the family T_n an Adams action. Both lattices and their reductions remain available for T_n, with the distinct fibres specified rather than identified.

28.5 PRODUCTS, COPRODUCTS, AND GRADINGS

Equip P_R with its primitive Hopf structure: $\Delta x_{s,k} = x_{s,k} \otimes 1 + 1 \otimes x_{s,k}$, $\epsilon(x_{s,k}) = 0$, and antipode $x_{s,k} \mapsto -x_{s,k}$. Both families are Hopf endomorphisms: their generator images are primitive, and equality of algebra maps can be checked on those generators. They preserve the unit, augmentation, and particle degree. On $L_{\mathbb{Z}}$ the same coproduct has $\Delta h_r = \sum_{i+j=r} h_i \otimes h_j$; its preservation follows from the rational identity and the torsion-free integral inclusion. This is the ordinary symmetric-function coproduct, not a constructed arithmetic Hall correspondence.

Over a characteristic-zero field both maps are injective and, for $n > 1$, not surjective. Indeed, on a polynomial of highest nonzero weight w, the highest-weight part of T_n is ψ_n applied to that part and has weight nw. The index substitution is injective, so that part cannot cancel. This proves injectivity and shows that x_1 has no preimage for $n > 1$. The same argument in fact works over any nonzero coefficient ring on the free polynomial carrier.

The Adams map carries weight w to weight nw. The divisor map carries a weight-w polynomial into weights between w and nw. It is generally inhomogeneous; already $T_p x_p = x_{p^2} + p x_p$. For $n > 1$, neither map preserves a nontrivial finite cutoff of the mode generators. Both preserve the ideals of weights greater than W, so they induce maps on the finite-weight quotient. For finite S, these quotients have finite rank over R. They also extend continuously to the weight completion $\prod_{w \geq 0} P_{R,w}$, since an output of weight at most W depends only on inputs of weight at most W. Their integral matrices give continuous extensions to $\varprojlim_j P_{\mathbb{Z}}/p^j P_{\mathbb{Z}}$ as well. This last completion imposes finite support modulo each p^j, and is not the unrestricted product over weights.

Other symmetric-function structures have different answers. Over $\mathbb{Q}$, the internal coproduct $\delta x_k = x_k \otimes x_k$ is preserved by ψ_n. For T_n, $n > 1$, take $k = n$: its image contains the distinct terms x_{n^2} and $n x_n$, and $(T_n \otimes T_n)\delta x_n$ has cross terms absent from $\delta T_n x_n$. Neither family preserves the internal product normalized by $x_k * x_l = \mathbf{1}_{k=l} k x_k$, since its value on the images of x_1, x_1 is $n x_n$, not x_n, for $n > 1$. These assertions are over characteristic zero; no nonvanishing statement is transferred to a torsion fibre without checking its coefficient.

28.6 Oscillators and vertex operations

On the polynomial representation set $a_{-k} f = x_k f$, $a_k f = k \partial_{x_k} f$ for $k \geq 1$, and $a_0 = 0$. Then $[a_k, a_{-l}] = k \delta_{kl}$, with central element acting as one. Species are independent. These integral identities, and the Hall form $\langle x_\lambda, x_\mu \rangle = \delta_{\lambda\mu} z_\lambda$, where $z_\lambda = \prod_k k^{m_k} m_k!$, fix the normalization.

The substitutions intertwine creation with creation by their generator images. They do not intertwine the fixed annihilation operators. For the Adams maps the exact formulas are

$$\psi_n a_{-k} = a_{-nk} \psi_n, \qquad a_{nk} \psi_n = n \psi_n a_k, \qquad a_j \psi_n = 0 \quad (n \nmid j).$$

They follow by differentiation. If both positive and negative modes are sent to their index multiples, their commutator is multiplied by n; this is not a central-charge-one Heisenberg map. Over $\mathbb{Q}$, sending a_k to a_{nk}/n, a_{-k} to a_{-nk}, and the central element to itself does give a Heisenberg embedding, intertwined by ψ_n. It does not preserve the involution $a_k^* = a_{-k}$.

There is also a precise non-adjoint oscillator lift for a fixed T_n. It illustrates what extra choices of annihilation entail. Define integers $c_{k,i}$, in increasing order of i, by

$$c_{k,i} = 0 \ (n \nmid i), \qquad c_{k,nj} = k \delta_{kj} - \sum_{\substack{d \mid n,\, d \mid j \\ d > 1}} d \, c_{k,nj/d}.$$

Every term on the right has smaller index. The derivation $D_k^{(n)} = \sum_{i \geq 1} c_{k,i} \partial_{x_i}$ is defined on every polynomial, since only its finitely many variables contribute. By construction

$$D_k^{(n)}(T_n x_j) = k \delta_{kj}, \qquad [D_k^{(n)}, \text{multiplication by } T_n x_j] = k \delta_{kj}.$$

These derivations commute, as do the creation maps. The chain rule gives $D_k^{(n)} T_n = T_n a_k$. Thus they give a central-charge-one oscillator representation in polynomial endomorphisms, generally using infinite

locally finite sums of annihilation modes over $\mathbb{Q}$: $D_k^{(n)} = \sum_i (c_{k,i}/i) a_i$. Over $\mathbb{Z}$, integrality refers to the polynomial derivation, not to its coefficients in the a_i. This is not an identification with the fixed Heisenberg generators or their adjoints. For instance, both T_n and ψ_n send x_1 to x_n, whose norm squared is n; its creation operator and its Hall adjoint have commutator n, rather than one. Therefore the adjoint-preserving assignment fails for $n > 1$.

PROPOSITION 28.6.1 *(translation and vertex operations).* Over $\mathbb{Q}$ or $\mathbb{C}$, the usual Heisenberg vertex algebra has translation $Dx_k = kx_{k+1}$. A vertex-algebra homomorphism preserves translation, because $Dv = v_{(-2)}1$, irrespective of whether it preserves a chosen conformal vector. Here

$$D\psi_n x_1 = n x_{n+1}, \qquad \psi_n D x_1 = x_{2n},$$

and

$$DT_n x_1 = n x_{n+1}, \qquad T_n D x_1 = x_{2n} + 2\mathbf{1}_{2|n} x_n.$$

For $n > 1$ these disagree. Equivalently, writing $a(z) = Y(x_1, z)$, one has

$$Y(x_n, z) = \frac{\partial_z^{n-1} a(z)}{(n-1)!}, \qquad Y(x_n, z) Y(x_n, w) \sim \frac{(-1)^{n-1}(2n-1)!}{((n-1)!)^2 (z-w)^{2n}}.$$

This is the derivative of $a(z)a(w) \sim (z-w)^{-2}$, and it cannot be the image of the latter OPE for $n > 1$. Thus neither family consists of vertex-algebra endomorphisms. Ordinary polynomial multiplication and primitive coproduct remain preserved; they do not encode all vertex products. When $n = 1$, both maps are the identity and all these obstructions disappear.

PROPOSITION 28.6.2 *(underlying monoid action on a finite vertex carrier).* For a finite set of species the underlying vector space of the Heisenberg vertex algebra, with its vacuum and maps ψ_n, is a vacuum-preserving $\mathbb{N}^\times$-module. The action is not by vertex endomorphisms for $n > 1$. The divisor family T_n is not such a monoid action in characteristic zero.

Proof. The index substitutions preserve 1 and obey the monoid law on polynomial generators. The preceding translation calculation proves the vertex assertion; $T_p^2 x_1 \neq T_{p^2} x_1$ proves the last statement. □

28.7 HILBERT COMPLETION AND ARITHMETIC ENERGY

Over $\mathbb{C}$, use the positive Hermitian Hall form with $\|x_{s,k}\|^2 = k$, and complete to the symmetric Hilbert Fock space $\mathcal{F} = \bigoplus_{j \geq 0} \mathcal{F}^{(j)}$, with the above monomial factorial normalization. On the one-particle space, $\psi_n/\sqrt{n}$ is an isometry. Each summand $d\,\mathbf{1}_{d|k} x_{nk/d}$ of $t_n x_k$ has operator norm $\sqrt{nd}$: its nonzero basis images are orthogonal and have that constant norm ratio. Hence

$$\|t_n\| \leq \sum_{d|n} \sqrt{nd}.$$

This proves boundedness on one particle, and therefore on each fixed particle sector after taking its symmetric tensor power.

On the full Fock space both substitutions are unbounded for $n > 1$:

$$\frac{\|T_n x_1^j\|}{\|x_1^j\|} = \frac{\|\psi_n x_1^j\|}{\|x_1^j\|} = n^{j/2}.$$

Their polynomial-domain operators are closable. More precisely, for $A = t_n$ or $A = \psi_n|_{M_{\mathbb{C}}}$, the closure is the direct sum of the bounded sector maps $\mathrm{Sym}^j(A)$, with domain

$$\left\{(v_j) \in \mathcal{F} : \sum_{j\geq 0} \|\mathrm{Sym}^j(A)v_j\|^2 < \infty\right\}.$$

Indeed this direct sum is closed. Finite particle truncation, followed by finite-mode polynomial approximation in each bounded sector, approximates both a vector and its image, so the polynomial domain is a core. For ψ_n the domain condition is exactly $\sum_j n^j\|v_j\|^2 < \infty$. Thus neither map is a bounded Hilbert-space isometry or a bounded Bost–Connes isometry on this normalization.

The separately normalized substitution $\widetilde{\psi}_n(x_{s,k}) = n^{-1/2}x_{s,nk}$ is a Hilbert isometry on every particle sector and on their direct sum. It is a complex polynomial Hopf map and a monoid action, but it changes the integral structure and still fails the translation identity for $n > 1$. Its existence alone supplies no Bost–Connes representation or trace comparison.

Convention 28.7.1 *(integer weight and arithmetic energy).* For a finite species set consisting of arithmetic primes, use:

(i) Integer oscillator weight k on $x_{p,k}$, extended additively to monomials.

(ii) Arithmetic energy $k\log p$ on $x_{p,k}$, again extended additively. This real grading is distinct from the integer weight.

The corresponding energy operator on monomials is

$$H\left(\prod_{p,k} x_{p,k}^{m_{p,k}}\right) = \left(\sum_{p,k} km_{p,k}\log p\right)\prod_{p,k} x_{p,k}^{m_{p,k}}.$$

Observation 28.7.2 *(energy and integral states).* The associated eigenspaces are spanned by integral monomials. The operator H itself need not preserve their integral lattice, but the real energy grading does not destroy that lattice. It does not rescale the vertex-algebra conformal vector. On polynomials, $H\psi_n = n\psi_n H$; T_n generally mixes energies.

For one oscillator species per arithmetic prime and a finite set S, direct summation of the occupation basis gives, for real $\beta > 0$,

$$\mathrm{Tr}_{\mathcal{F}_S}(e^{-\beta H}) = \prod_{p\in S}\prod_{k\geq 1}(1 - p^{-k\beta})^{-1}.$$

The logarithm converges by geometric comparison for finite S. For all arithmetic primes it converges for $\beta > 1$: the logarithm is bounded by a constant times $\sum_p p^{-\beta}$, which converges. The resulting product is $\prod_{k\geq 1}\zeta(k\beta)$, not $\zeta(\beta)$. At $0 < \beta \leq 1$, already the $k = 1$ factors diverge. Multiple oscillator species change the exponents of the factors. An infinite set of equally weighted species instead has infinite multiplicity in weight one and no finite conformal character.

For the energy operator just defined, its self-adjoint domain is the set of occupation expansions $\sum_\nu c_\nu e_\nu$ with $\sum_\nu E(\nu)^2|c_\nu|^2 < \infty$, where e_ν are normalized occupation vectors. The finite-support span is a core by truncation. The trace statements concern this positive diagonal operator. For all primes the Gibbs operator is not trace class at $\beta \leq 0$ either, since its diagonal entries do not tend to zero. Keeping only modes $k = 1$ identifies occupation states with positive integers $N = \prod_p p^{m_p}$, with energy $\log N$, and gives $\zeta(\beta)$ for $\beta > 1$. That subspace is not preserved by T_n or ψ_n, which send $x_{p,1}$ to $x_{p,n}$.

On $\ell^2(\mathbb{N}_{>0})$, the different operators $\mu_n \delta_N = \delta_{nN}$ are commuting isometries and satisfy $[H_{\mathrm{BC}}, \mu_n] = \log(n)\mu_n$ on finite-support vectors, where $H_{\mathrm{BC}}\delta_N = \log N\, \delta_N$. This follows immediately by applying both sides to δ_N. They move δ_1 to δ_n, whereas both polynomial substitutions fix the vacuum. Thus even the normalized Adams action does not yield a vacuum- and energy-preserving identification with these multiplicative shifts: its energy relation is dilation, and its vacuum is fixed. Other representations or operations require separate comparison.

28.8 The Common Algebraic Image and the Hilbert Kernel

The divisor maps and the index shifts have different composition laws, but have the same algebraic images. The difference can be expressed by a triangular change of generators. That change ceases to be invertible on the Hilbert completion, so polynomial injectivity must be kept separate from injectivity of the completed operator.

PROPOSITION 28.8.1 *(triangular factorization).* On the polynomial carrier over a commutative ring R, define

$$C_n(x_{s,k}) = \sum_{d\mid n,\, d\mid k} d\, x_{s,k/d},$$

and extend as a unital R-algebra map. Then C_n is an integral triangular Hopf automorphism and

$$T_n = \psi_n C_n, \qquad T_n(P_R) = \psi_n(P_R). \tag{28.11}$$

For the Hall lattice $L_{\mathbb{Z}}$ of one species,

$$C_n H(t) = \prod_{d\mid n} H(t^d). \tag{28.12}$$

Thus C_n is also an automorphism of that integral lattice, and $T_n(L_{\mathbb{Z}}) = \psi_n(L_{\mathbb{Z}})$. For finitely many species the statement holds on their tensor product.

Proof. The term $d = 1$ is $x_{s,k}$; every other term has smaller mode index. Inductively solve for each $x_{s,k}$ in terms of the $C_n(x_{s,j})$, $j \le k$. This constructs an inverse with integer coefficients, finite on every generator. Hence it defines an inverse on the countable polynomial ring and after every coefficient change. The generator images are primitive, so C_n is a Hopf map and its inverse is a Hopf map. Applying ψ_n to those images gives the literal divisor formula, proving (28.11).

To prove (28.12), take the logarithm in $P_{\mathbb{Q}}[[t]]$, set $k = dj$ in each divisor summand, and obtain

$$\sum_{k\ge 1} \frac{C_n(x_k)t^k}{k} = \sum_{d\mid n}\sum_{j\ge 1} \frac{x_j t^{dj}}{j}.$$

Exponentiation proves the identity. Its coefficient of t^r is h_r plus an integral polynomial in $h_1, \dots, h_{r-1}$: only the factor with $d = 1$ can contribute h_r, and it does so with coefficient one. Induction therefore constructs an integral inverse on the Hall generators as well. The asserted image equalities follow from surjectivity of C_n on the respective carriers. □

This is a change of generators, not an identification of the two operator families. For example, $T_p^2 \neq T_{p^2}$, whereas $\psi_p^2 = \psi_{p^2}$. Equal images do not equate their actions.

Theorem 28.8.2 *(one-particle Hilbert kernel and range).* Over $\mathbb{C}$, complete the one-particle span with $\|x_k\|^2 = k$. The linear restriction $c_n = C_n|_M$ extends to a bounded surjection on this Hilbert space. The bounded divisor operator t_n has closed range

$$\operatorname{Ran}(t_n) = \overline{\operatorname{span}}\{x_{nk} : k \geq 1\} = \operatorname{Ran}(\psi_n|_M), \qquad \ker t_n = \ker c_n.$$

For $n > 1$ that kernel is nonzero and, on the full one-species one-particle space, infinite-dimensional.

More precisely, on a prime chain $e_r = x_{up^r}$, $(u, p) = 1$, write $Be_0 = 0$, $Be_r = e_{r-1}$ for $r \geq 1$. For $a \geq 1$,

$$c_{p^a} = \sum_{j=0}^{a} p^j B^j, \qquad \ker c_{p^a} = \operatorname{span}_{\mathbb{C}} \left\{ v_\omega = \sum_{r \geq 0} (\omega/p)^r e_r : \omega^{a+1} = 1,\ \omega \neq 1 \right\}.$$

Its dimension on that chain is a. For $a = 0$ the operator is the identity with zero kernel. For $n = 1$, all the global operators are identities.

Proof. Define $B_d x_k = x_{k/d}$ when $d \mid k$, and zero otherwise. Its nonzero images are orthogonal with norm ratio $d^{-1/2}$. Thus $c_n = \sum_{d|n} dB_d$ is bounded, with norm at most $\sum_{d|n} \sqrt{d}$. The identities $B_d B_e = B_{de}$ imply $c_n = \prod_{p|n} c_{p^{v_p(n)}}$.

On the stated prime chain, $\|e_r\|^2 = up^r$, so B has norm $p^{-1/2}$ and the forward shift $Ue_r = e_{r+1}$ has norm $p^{1/2}$, with $BU = 1$. Each displayed v_ω is nonzero and square-summable, since $\|v_\omega\|^2 = u \sum_{r \geq 0} p^{-r} = u/(1 - p^{-1})$. It satisfies $Bv_\omega = (\omega/p)v_\omega$, whence $c_{p^a} v_\omega = (\sum_{j=0}^{a} \omega^j) v_\omega = 0$. Conversely a vector $\sum_r b_r e_r$ in the kernel satisfies $\sum_{j=0}^{a} p^j b_{r+j} = 0$ for all $r \geq 0$. The first a coefficients determine the rest. The a distinct roots ω/p give independent solutions by the Vandermonde determinant, so these square-summable solutions exhaust the kernel.

Surjectivity also has an explicit bounded proof. For $\lambda = \omega/p$,

$$(B - \lambda)U = 1 - \lambda U, \qquad R_\lambda = U(1 - \lambda U)^{-1}$$

is a right inverse of $B - \lambda$, since $\|\lambda U\| = p^{-1/2} < 1$. The inverse is its norm-convergent Neumann series. Factoring $c_{p^a} = p^a \prod_{\omega \neq 1,\ \omega^{a+1}=1} (B - \omega/p)$ and multiplying these right inverses in reverse order, then multiplying by p^{-a}, gives a bounded right inverse for c_{p^a}. Its norm bound is independent of the prime-free index u, so the construction extends to the orthogonal sum of all prime chains. Products over the finitely many primes therefore make c_n surjective. Since $\psi_n|_M$ is $\sqrt{n}$ times an isometry, the factorization $t_n = \psi_n c_n$ proves the range and kernel assertions. For $n > 1$, a prime-power factor has the kernels just exhibited; all other factors commute with it. Choosing infinitely many mutually disjoint prime chains gives infinitely many independent vectors in $\ker c_n$. □

The inverse of C_n on polynomials is not a bounded inverse on this Hilbert space. For example,

$$C_p^{-1} e_r = \sum_{j=0}^{r} (-p)^j e_{r-j}, \qquad \frac{\|C_p^{-1} e_r\|^2}{\|e_r\|^2} = \sum_{j=0}^{r} p^j.$$

These identities follow by cancellation of successive terms in $(1 + pB) \sum_{j=0}^{r} (-pB)^j e_r = e_r$. More generally, the algebraic inverse on the finite one-particle span is not even closable when $n > 1$. Indeed, choose a nonzero $v \in \ker c_n$ and finite truncations $v_N \to v$. Boundedness gives $y_N = c_n v_N \to 0$, whereas the polynomial inverse satisfies $C_n^{-1} y_N = v_N \to v \neq 0$. Thus the closure of its graph contains

$(0, v)$, which cannot belong to the graph of a linear operator. The same argument applies to the algebraic inverse of t_n on its polynomial image.

For $n > 1$, the closed full-Fock divisor operator $\Gamma(t_n)$ described in Section 28.7 also has nonzero kernel: any of these one-particle vectors lies in its domain and is annihilated. The corresponding closed operator $\Gamma(\psi_n|_M)$ is injective, since each particle sector is a nonzero scalar multiple of an isometry. Neither assertion contradicts injectivity of the polynomial maps. Nor does it claim that multiplication extends to all Hilbert vectors.

A Weighted Hilbert Threshold

The kernel vectors above contain arbitrarily high modes. Requiring additional decay of their coefficients can exclude them. On a single prime chain the exact boundary is accessible because both operators are polynomials in a backward shift.

Fix a prime p, an integer $u \geq 1$ coprime to p, and an integer $a \geq 1$. Retain $e_r = x_{up^r}$ and $\|e_r\|_0^2 = up^r$, and write D for their finite linear span. Let E be the positive diagonal operator $Ee_r = up^r e_r$. This E is the mode-index operator on the chain; it is distinct from the logarithmic arithmetic energy used in the partition functions. For a real number $s \geq 0$, define

$$\mathcal{H}_s = \left\{ \sum_{r\geq 0} d_r e_r : \sum_{r\geq 0} (up^r)^{1+2s} |d_r|^2 < \infty \right\}, \qquad \|v\|_s = \|E^s v\|_0.$$

Thus $\mathcal{H}_s = \mathrm{Dom}(E^s)$ as a subspace of $\mathcal{H}_0$, endowed with the displayed norm. Since $E \geq 1$, this norm is equivalent to its graph norm. Define the closed tail $\mathcal{H}_{s,\geq a} = \overline{\mathrm{span}}\{e_r : r \geq a\}$, of codimension a in $\mathcal{H}_s$.

THEOREM 28.8.3 *(weighted kernel, range, and inverse).* The polynomial operators c_{p^a} and t_{p^a} extend boundedly to every $\mathcal{H}_s$. Their behavior on these completions is as follows.

(i) If $0 \leq s < \frac{1}{2}$, then c_{p^a} is onto $\mathcal{H}_s$, and t_{p^a} is onto $\mathcal{H}_{s,\geq a}$. Both have the same a-dimensional kernel, spanned by
$$g_\zeta = \sum_{r\geq 0} (\zeta/p)^r e_r, \qquad \zeta^{a+1} = 1, \quad \zeta \neq 1.$$
Their polynomial inverses, defined on D and on $D \cap \mathcal{H}_{s,\geq a}$, respectively, are not closable.

(ii) If $s = \frac{1}{2}$, both maps are injective. The range of c_{p^a} is dense, proper, and nonclosed in $\mathcal{H}_s$; the range of t_{p^a} is dense, proper, and nonclosed in $\mathcal{H}_{s,\geq a}$. Their inverses on their actual ranges are closed and unbounded. The polynomial inverses are closable, and their graph closures are precisely these inverses.

(iii) If $s > \frac{1}{2}$, then c_{p^a} is boundedly invertible on $\mathcal{H}_s$, and t_{p^a} is a bounded isomorphism from $\mathcal{H}_s$ onto $\mathcal{H}_{s,\geq a}$. These bounded inverses extend the polynomial inverses.

For $a = 0$, both maps are the identity for every $s \geq 0$.

Proof. Put $b = p^{s+1/2}$, $q = p^{1/2-s}$, and $Q_a(z) = 1 + z + \cdots + z^a$. The vectors

$$f_r = \frac{e_r}{u^{s+1/2} b^r}, \qquad r \geq 0,$$

form an orthonormal basis of $\mathcal{H}_s$. Let $Vf_r = f_{r+1}$ and $L = V^*$. The raw forward shift on the e_r is bV, and the raw backward shift satisfies $pB = qL$. Consequently

$$c_{p^a} = Q_a(qL), \qquad t_{p^a} = b^a V^a Q_a(qL).$$

This proves boundedness, with norm bounds $\sum_{j=0}^{a} q^j$ and $b^a \sum_{j=0}^{a} q^j$, respectively. The isometry V^a identifies $\mathcal{H}_s$ with its closed tail, so it suffices to analyze $Q_a(qL)$.

Suppose first that $q > 1$. For $v = \sum_{r\ge 0} \gamma_r f_r$, the kernel equation is $\sum_{j=0}^{a} q^j \gamma_{r+j} = 0$ for every $r \ge 0$. Its characteristic roots are the distinct numbers ζ/q, where $\zeta^{a+1} = 1$ and $\zeta \neq 1$. The first a coefficients determine all others, and the Vandermonde determinant shows that the corresponding geometric sequences form a basis of the solution space. All belong to ℓ^2, since $q > 1$. In raw coordinates these are the displayed g_ζ, with

$$\|g_\zeta\|_s^2 = \frac{u^{1+2s}}{1 - p^{2s-1}}.$$

For each root, $L - \zeta/q$ has the bounded right inverse $V(I - (\zeta/q)V)^{-1}$, where the inverse is the norm-convergent Neumann series. Since $Q_a(qL) = q^a \prod_\zeta (L - \zeta/q)$, a bounded right inverse G of c_{p^a} is q^{-a} times the product of these right inverses in reverse order. Then

$$t_{p^a}\big(b^{-a} G L^a\big) = V^a L^a,$$

which is the orthogonal projection onto the tail. This proves both surjectivity statements. Finite truncations of any nonzero g_ζ give the nonclosability argument above, now in $\mathcal{H}_s$, for both polynomial inverses.

At $q = 1$, the same recurrence has solutions that are linear combinations of the periodic sequences ζ^r. A nonzero periodic sequence is not square-summable, so the kernel is zero. The constant coefficient of Q_a is one. Its formal reciprocal therefore acts on D, because L is locally nilpotent there. Thus $c_{p^a}(D) = D$, and its range is dense. Likewise $t_{p^a}(D) = D \cap \mathcal{H}_{s,\ge a}$. To see that the range is not closed, fix a root $\zeta \neq 1$ and let

$$v_N = N^{-1/2} \sum_{r=0}^{N-1} \zeta^r f_r, \qquad N > a.$$

Its norm is one. The first $N - a$ coefficients of $Q_a(L) v_N$ vanish, and the remaining at most a coefficients have absolute value at most $(a+1)/\sqrt{N}$. Hence

$$\|Q_a(L) v_N\|_s \le \frac{\sqrt{a}\,(a+1)}{\sqrt{N}} \longrightarrow 0.$$

An injective bounded operator with closed range is bounded below: its inverse on that range is bounded by the bounded inverse theorem. The displayed sequence rules this out, and therefore the dense range is both proper and nonclosed. Multiplication by $b^a V^a$ gives the same assertion within the tail for t_{p^a}.

An injective bounded operator has a closed inverse on its range, since interchanging the two coordinates of its closed graph preserves closedness. These inverses are unbounded by the preceding sequence. Their polynomial restrictions have those full inverse graphs as their closures: for any $x \in \mathcal{H}_s$, choose $x_N \in D$ with $x_N \to x$. Boundedness gives $c_{p^a} x_N \to c_{p^a} x$, so $(c_{p^a} x_N, x_N) \to (c_{p^a} x, x)$; the same argument applies to t_{p^a}. This also proves closability of the restrictions.

Finally suppose $q < 1$. The polynomial identity $(1 - z) Q_a(z) = 1 - z^{a+1}$ gives

$$c_{p^a}^{-1} = (I - qL)\big(I - (qL)^{a+1}\big)^{-1}, \qquad \|c_{p^a}^{-1}\| \le \frac{1+q}{1-q^{a+1}}.$$

The inverse is defined by a norm-convergent Neumann series. On the tail the inverse of t_{p^a} is $c_{p^a}^{-1} b^{-a} L^a$. Both inverses agree on finite vectors with the locally finite polynomial inverses, as follows either from the same formulas or from uniqueness of the inverse. □

All these bounded maps preserve the common finite domain D, which is a core for them in each $\mathcal{H}_s$. The polynomial maps have not changed. Their completed kernels and the possible extensions of their inverses depend on the norm: for $s \geq \frac{1}{2}$ the vectors g_ζ no longer belong to the carrier. This change of domain neither removes the kernel on $\mathcal{H}_0$ nor identifies these weighted spaces with an arithmetic realization.

28.9 The arithmetic comparison problem

Remark 28.9.1 *(local arithmetic structures).* There are now two explicit local inputs: the integral divisor substitutions with the composition law (28.5), and the honest Adams action on $P_{\mathbb{Q}}$ with its Frobenius-compatible Hall lattice $L_{\mathbb{Z}}$. Neither is a vertex action. On the polynomial underlying vector space, ψ_n gives an $\mathbb{N}^\times$-module; this terminology records only the monoid action, not a separate notion of a Λ-module or a trace theory.

Definition 28.9.2 *(module with multiplicative-monoid action).* An $\mathbb{N}^\times$-module is a module with endomorphisms ψ_n satisfying $\psi_1 = 1$ and $\psi_m \psi_n = \psi_{mn}$. This specifies no ring product or Frobenius congruence.

Question 28.9.3 *(arithmetic realization).* An arithmetic realization must specify its native carrier, integral form, operations, and comparison maps. Transporting ψ_n to a Hochschild trace class requires an actual intertwining map and the operations on that class; a polynomial presentation of another object does not supply them. If the proposed operations are instead T_n, their same-prime noncommutativity must be respected. In characteristic zero they cannot be identified by an injective intertwiner with commuting Adams operations or a commuting semigroup of Bost–Connes isometries. The commutator (28.4) is already an obstruction. A quotient or restricted subspace would require a specified map and a new calculation of its kernel and preserved operations.

Remark 28.9.4 *(integral descent and operator comparison).* Borger's descent interpretation concerns Λ-structures and their forgetful functor, not an automatic tensor product with a field of one element. See *Lambda-rings and the field with one element*, §§1.1–1.2. A Bost–Connes comparison additionally requires a C^*-representation, adjoints, time evolution, and trace or state intertwiners. Its standard $\zeta(\beta)$ partition function cannot be inferred from the full oscillator partition function above. The arithmetic trace comparison and the choice of an integral realization therefore remain specific construction problems; the local polynomial calculations neither settle nor rule out all their possible solutions.

28.10 Curve zeta functions in Hall operator exchange

The polynomial oscillator calculations admit a geometric source over a finite field. The required local category is the category of nilpotent modules, with its Hall multiplication and Green pairing. A torsion sheaf on a smooth projective curve is the direct sum of its parts supported at closed points. This decomposition turns local Hall operators into global operators. Their exchange coefficient counts the points over every finite extension of the ground field.

Let X be a smooth projective geometrically connected curve over $\mathbb{F}_q$. For a closed point x, put $d_x = [\mathbb{F}_q(x) : \mathbb{F}_q]$ and $Q_x = q^{d_x}$. The completion of the local ring is $\mathbb{F}_{Q_x}[[t]]$, after a choice of parameter and coefficient field. Its finite-length modules are nilpotent modules over $\mathbb{F}_{Q_x}[t]$.

Local Hall operators and their normalization

For a prime power Q, let H_Q be the complex Hall algebra of these nilpotent modules. Its basis element u_M denotes the isomorphism class of M. The coefficient of u_C in $u_A u_B$ counts submodules $B' \subset C$ with $B' \simeq B$ and $C/B' \simeq A$. Give it the positive Hermitian form, conjugate-linear in the first slot,

$$\langle u_M, u_N \rangle = \frac{\delta_{MN}}{|\operatorname{Aut} M|}.$$

The Green coproduct is adjoint to multiplication for this form. In this category it is cocommutative and multiplicative. These are the classical Hall bialgebra identities, on this untwisted category with zero Euler form. The polynomial presentation below is Steinitz–Hall's theorem; see Schiffmann, *Lectures on Hall algebras*, Theorem 2.6 and equation (2.9).

Write u_{1^r} for the zero endomorphism of $\mathbb{F}_Q^r$ and set

$$e_r = Q^{r(r-1)/2} u_{1^r}, \qquad E(z) = \sum_{r \geq 0} e_r z^r, \qquad e_0 = 1.$$

Subspace counting gives $\Delta u_{1^r} = \sum_{i+j=r} Q^{-ij} u_{1^i} \otimes u_{1^j}$. Thus $\Delta E(z) = E(z) \otimes E(z)$. The elements e_r, $r > 0$, freely generate H_Q. One can see the triangular presentation directly: for a Jordan partition λ, use the successive dimensions of $\ker t^i / \ker t^{i-1}$. The product of the corresponding semisimple classes counts filtrations lowered by t. Its coefficient on u_λ is one, since equality forces the kernel filtration. Every other term has larger kernel dimensions. The resulting triangular matrix is invertible in each finite dimension.

Define p_r by the formal identity

$$\log E(z) = \sum_{r \geq 1} \frac{(-1)^{r-1}}{r} p_r z^r.$$

They are primitive polynomial generators. Their norms can be computed without a choice of an orthonormal basis. Since $|\operatorname{GL}_r(\mathbb{F}_Q)| = Q^{r(r-1)/2} \prod_{j=1}^{r} (Q^j - 1)$,

$$\langle E(u), E(v) \rangle = \sum_{r \geq 0} \frac{Q^{r(r-1)/2} (\bar{u} v)^r}{\prod_{j=1}^{r} (Q^j - 1)} = \prod_{j \geq 1} (1 - Q^{-j} \bar{u} v)^{-1}.$$

The last equality follows by comparing coefficients in $(1 - t) P(Qt) = P(t)$, with constant coefficient one. Adjunction and primitivity make distinct primitive degrees orthogonal and give factorial pairings for their powers. Taking logarithms therefore gives

$$\langle p_r, p_s \rangle = \delta_{rs} \frac{r}{Q^r - 1}.$$

Consequently the following operators are adjoint on the polynomial domain:

$$a_{-r} = \sqrt{Q^r - 1}\, M_{p_r}, \qquad a_r = \frac{r}{\sqrt{Q^r - 1}} \frac{\partial}{\partial p_r}, \qquad [a_r, a_{-s}] = r \delta_{rs} I.$$

Here M_{p_r} means multiplication by p_r, and the square root is positive. No assertion that these unbounded operators act everywhere on the Hilbert completion is needed.

The global exchange

The torsion Hall algebra of X is the algebraic tensor product $H_X^{\mathrm{tor}} = \bigotimes_{x\in|X|}^{\mathrm{alg}} H_{Q_x}$, with vacuum 1 in all but finitely many factors. Distinct supports have no extensions or homomorphisms between them. Their Hall products and pairings therefore factor. Give a length-r local module degree rd_x. There are finitely many closed points of bounded degree, so each homogeneous piece of this algebra is finite-dimensional. Let $a_{x,\pm r}$ be the preceding operators on the x factor, and define

$$A_{-n} = \sum_{d|n} d \sum_{d_x=d} a_{x,-n/d}, \qquad A_n = A_{-n}^{\dagger} \qquad (n > 0).$$

These are finite sums on the common polynomial domain. A closed point of degree d contributes d geometric points over $\mathbb{F}_{q^n}$ exactly when $d \mid n$. Thus, writing $N_n = \#X(\mathbb{F}_{q^n})$,

$$[A_n, A_{-m}] = \delta_{nm} \sum_{d|n} d^2 \frac{n}{d} \#\{x : d_x = d\} I = \delta_{nm} n N_n I.$$

All commutators between two positive or two negative modes vanish.

Put $s = w^{-1}$, with z, s independent formal variables, and set

$$\Gamma_-(z) = \exp\left(\sum_{n>0} \frac{A_{-n}}{n} z^n\right), \qquad \Gamma_+(w) = \exp\left(\sum_{n>0} \frac{A_n}{n} w^{-n}\right).$$

Each coefficient is a finite sum of polynomial-domain operators. Products are identities in $\mathrm{End}_{\mathbb{C}}(H_X^{\mathrm{tor}})[[z, s]]$. For the formal zeta function

$$Z_X(t) = \exp\left(\sum_{n>0} \frac{N_n}{n} t^n\right) = \prod_{x\in|X|} (1 - t^{d_x})^{-1},$$

the logarithm of the Euler product proves the second equality coefficientwise. The central commutator of the two exponents equals $\log Z_X(zs)$. Expanding the exponentials, or differentiating their formal conjugation identity, therefore proves

$$\Gamma_+(w)\Gamma_-(z) = Z_X(z/w)\Gamma_-(z)\Gamma_+(w).$$

This is an operator identity before taking a trace. Repeated reordering uses the product of the central factors for all exchanged pairs. The statement specifies a formal expansion at $z/w = 0$; an analytic operator identity would require additional domain and convergence estimates.

For $X = \mathbb{P}^1$, counting gives $N_n = q^n + 1$, hence $Z_X(t) = ((1 - t)(1 - qt))^{-1}$. For the smooth projective cubic $E/\mathbb{F}_2 : y^2 + y = x^3 + x + 1$, the first four point counts are 1, 5, 13, 25. The trace criterion for $y^2 + y = b$ gives two solutions when $\mathrm{Tr}_{\mathbb{F}_{2^n}/\mathbb{F}_2}(b) = 0$, and none otherwise. For $n = 1, 2, 3, 4$, it gives respectively 0, 2, 6, 12 admissible x values, with one additional point at infinity. Thus

$$Z_E(t) = 1 + t + 3t^2 + 7t^3 + 15t^4 + O(t^5).$$

These coefficients determine the corresponding operator exchange to degree four. The full rational formula $Z_E(t) = (1 - 2t + 2t^2)/((1 - t)(1 - 2t))$ uses the classical elliptic-curve zeta theorem in addition to these finite counts.

Torsion acting on a line bundle

The full Hall algebra of coherent sheaves also contains the classes of line bundles. Fix a rational point x and a line bundle L. There are two middle sheaves in an extension of $\mathcal{O}_x$ by L: the split sheaf $L \oplus \mathcal{O}_x$, and $L(x)$. Indeed $\operatorname{Ext}^1(\mathcal{O}_x, L)$ is one-dimensional, and all nonzero classes have the latter middle sheaf. In the split middle sheaf, the relevant copies of L are the graphs of the q maps $L \to \mathcal{O}_x$. In $L(x)$ the relevant subobject is uniquely $L(x)(-x) = L$. Conversely, an extension of L by $\mathcal{O}_x$ splits because $\operatorname{Ext}^1(L, \mathcal{O}_x) = 0$. Its unique torsion subobject is $\mathcal{O}_x$. Therefore

$$u_{\mathcal{O}_x} u_L = q\, u_{L \oplus \mathcal{O}_x} + u_{L(x)}, \qquad u_L u_{\mathcal{O}_x} = u_{L \oplus \mathcal{O}_x}.$$

Let $v = \sqrt{q}$ and define the twisted product $u_A * u_B = v^{\chi(A,B)} u_A u_B$, where $\chi(A, B) = \dim \operatorname{Hom}(A, B) - \dim \operatorname{Ext}^1(A, B)$. Here $\chi(\mathcal{O}_x, L) = -1$ and $\chi(L, \mathcal{O}_x) = 1$. The ordinary commutator for this twisted product consequently satisfies

$$[u_{\mathcal{O}_x}, u_L]_* = v^{-1} u_{L(x)}.$$

On $\mathbb{P}^1$, all rational-point modifications of $\mathcal{O}(n)$ are isomorphic to $\mathcal{O}(n+1)$. Summing over the $q+1$ rational points gives

$$\left[\sum_{x \in \mathbb{P}^1(\mathbb{F}_q)} u_{\mathcal{O}_x}, u_{\mathcal{O}(n)} \right]_* = (v + v^{-1}) u_{\mathcal{O}(n+1)}.$$

This mixed Hall operation retains the elementary modification of the line bundle. Identifying a full quantum loop algebra additionally requires its remaining generators and relations. Neither this mixed operation nor the torsion exchange constructs a comparison with a global arithmetic trace category or with the full Weil functional.

Chapter 29

Bost–Connes Operators and Hochschild Trace Classes

Multiplication by a prime raises its occupation number by one. This arithmetic shift is a normalized creation operator on a bosonic Fock space. Together with the phases indexed by $\mathbb{Q}/\mathbb{Z}$, it gives a faithful representation of the Bost–Connes C^*-algebra. The object $\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class. Relating it to this representation requires a specified comparison map, pairing and completion.

29.1 The Bost–Connes C^*-Algebra

Definition 29.1.1 *(Bost–Connes presentation).* The Bost–Connes Q-lattice C^*-algebra $C^*_{\mathbb{Q}}$ has generators

$$\{\mu_n\}_{n\in\mathbb{N}^\times}, \quad \{\mu_n^*\}_{n\in\mathbb{N}^\times}, \quad \{e(\gamma)\}_{\gamma\in\mathbb{Q}/\mathbb{Z}},$$

with relations

$$\begin{aligned}
\mu_1 &= 1, \qquad e(0)=1, \qquad e(\gamma)^* = e(-\gamma),\\
\mu_m^*\mu_n &= \mu_n\mu_m^* \quad \text{if } \gcd(m,n)=1,\\
\mu_n\mu_m &= \mu_{nm},\\
\mu_n^*\mu_n &= 1,\\
\mu_n\mu_n^* &= e_n = \frac{1}{n}\sum_{\gamma:\, n\gamma=0} e(\gamma),\\
e(\gamma_1)e(\gamma_2) &= e(\gamma_1+\gamma_2),\\
\mu_n e(\gamma)\mu_n^* &= \rho_n(e(\gamma)) = \frac{1}{n}\sum_{\delta:\, n\delta=\gamma} e(\delta).
\end{aligned}$$

The $e(\gamma)$ generate the group C^*-algebra $C^*(\mathbb{Q}/\mathbb{Z})$; the μ_n furnish an endomorphism semigroup action; $\mu_n^*\mu_n = 1$, $\mu_n\mu_n^* = e_n$ makes μ_n a Toeplitz isometry. The crossed product $C^*(\mathbb{Q}/\mathbb{Z}) \rtimes \mathbb{N}^\times$ yields $C^*_{\mathbb{Q}}$.

Theorem 29.1.2 *(KMS states and the partition function, Bost–Connes Prop. 3.3 and Thm 5.4).* The KMS_β state φ_β on $C^*_{\mathbb{Q}}$ is unique for $0 < \beta \le 1$. For $\beta > 1$ the KMS_β states form a simplex with extremal points indexed by the symmetry-broken arithmetic boundary. In the standard Gibbs representation, for $\beta > 1$, the partition function is

$$Z_{\mathrm{BC}}(\beta) = \operatorname{tr}(e^{-\beta H}) = \sum_{n\ge 1} n^{-\beta} = \zeta(\beta),$$

where $H = \log N$ generates $\sigma_t(\mu_n) = n^{it}\mu_n$. The ζ-partition function is explicitly motivated by Julia's primon gas (*Statistical theory of numbers*, Springer Proc. Phys. 47, 1990).

29.2 Prime occupations and oscillator operators

Definition 29.2.1 *(Prime occupation space).* For each prime p, let $\mathscr{F}_p = \ell^2(\mathbb{N}_0)$ over $\mathbb{C}$, with orthonormal states $|r\rangle_p$ and vacuum $|0\rangle_p$. Let L_{alg} be the complex span of tensors $|\mathbf{r}\rangle = \bigotimes_p |r_p\rangle_p$ with finitely many nonzero occupations. Declare this basis orthonormal and write L for its Hilbert completion. On L_{alg}, define

$$a_p|\mathbf{r}\rangle = \sqrt{r_p}\,|\mathbf{r}-\mathbf{e}_p\rangle, \qquad a_p^\dagger|\mathbf{r}\rangle = \sqrt{r_p+1}\,|\mathbf{r}+\mathbf{e}_p\rangle, \qquad N_p = a_p^\dagger a_p,$$

where $\mathbf{e}_p$ has occupation one at p and zero elsewhere. The first expression is zero when $r_p = 0$. On this common invariant dense domain,

$$[a_p, a_q^\dagger] = \delta_{pq}\mathbb{1}, \qquad \langle a_p v, w\rangle = \langle v, a_p^\dagger w\rangle.$$

In particular, $|r\rangle_p = (a_p^\dagger)^r|0\rangle_p/\sqrt{r!}$. In a vacuum Heisenberg module these are occupations of the mode $a_{-1}^{(p)}$, rather than charges of the zero mode $a_0^{(p)}$.

Proposition 29.2.2 *(Arithmetic shifts on the occupation space).* Let $v_p(m)$ denote the exponent of p in m. The map

$$U : \ell^2(\mathbb{N}^\times) \longrightarrow L, \qquad U\delta_m = \bigotimes_p |v_p(m)\rangle_p$$

is unitary. Define $\mu_n\delta_m = \delta_{nm}$ on $\ell^2(\mathbb{N}^\times)$. For each prime,

$$U\mu_p U^{-1} = a_p^\dagger (N_p+1)^{-1/2},$$

where the right side is first evaluated on L_{alg} and then extended boundedly. For every $n \geq 1$, $\mu_n^*\mu_n = \mathbb{1}$. The operator $\mu_n\mu_n^*$ is the orthogonal projection onto the closed span of δ_m with $n \mid m$. Its spectrum is $\{0,1\}$ for $n > 1$ and $\{1\}$ for $n = 1$.

Proof. Unique factorization gives a bijection of the two orthonormal bases, so U extends to a unitary. The diagonal factor $(N_p+1)^{-1/2}$ cancels the creation coefficient $\sqrt{r_p+1}$. The resulting operator raises r_p by one with coefficient one. It preserves the norm on L_{alg} and therefore has a unique isometric extension. Directly,

$$\mu_n^*\delta_m = \begin{cases} \delta_{m/n}, & n \mid m, \\ 0, & n \nmid m. \end{cases}$$

This proves both projection identities. For $n > 1$, δ_n belongs to the range and δ_1 belongs to its orthogonal complement. Both spectral values occur. □

29.3 Arithmetic phases and the comparison carrier

Proposition 29.3.1 *(Bost–Connes operators on L).* Fix the character $\chi(\gamma) = e^{2\pi i\gamma}$ of $\mathbb{Q}/\mathbb{Z}$. Together with the transported shifts, the operators

$$e(\gamma)U\delta_m = \chi(m\gamma)U\delta_m$$

give a faithful representation of $C_{\mathbb{Q}}^*$ on L.

Proof. The phase operators are unitary and multiply by addition of their indices. The finite character sum is

$$\frac{1}{n}\sum_{n\delta=\gamma}\chi(m\delta)=\begin{cases}\chi((m/n)\gamma), & n\mid m,\\ 0, & n\nmid m.\end{cases}$$

These are exactly the diagonal entries of $\mu_n e(\gamma)\mu_n^*$. The semigroup and coprime adjoint relations hold on the occupation basis. Thus the universal presentation defines a representation π.

For faithfulness, give $K=\mathrm{Hom}(\mathbb{Q}_{>0}^{\times},U(1))$ its compact product topology, with one circle for each prime. Its gauge action α fixes $e(\gamma)$ and sends μ_n to $z(n)\mu_n$. These formulas preserve every defining relation. The linear span of $\mu_r e(\gamma)\mu_s^*$ is dense in $C_{\mathbb{Q}}^*$. Indeed, the transfer relation implies $e(\gamma)\mu_n=\mu_n e(n\gamma)$ and its adjoint identity. Writing $r=dr'$, $s=ds'$ with $\gcd(r',s')=1$ gives $\mu_r^*\mu_s=\mu_{s'}\mu_{r'}^*$. These identities reduce products of normal terms to the same form. A normal term has gauge degree zero exactly when $r=s$. The transfer relation then puts it in the phase algebra. Thus Haar averaging $E(a)=\int_K \alpha_z(a)\,dz$ is a conditional expectation onto the phase algebra D.

The universal group algebra $C^*(\mathbb{Q}/\mathbb{Z})$ maps onto D. Its representation on $\ell^2(\mathbb{N}^{\times})$ evaluates $C(\widehat{\mathbb{Z}})$ at the positive integers. Every residue class modulo every positive integer contains a positive integer, so these evaluation points are dense. This representation is faithful, and hence $D=C^*(\mathbb{Q}/\mathbb{Z})=C(\widehat{\mathbb{Z}})$.

The expectation E is faithful. For $a\geq 0$ and any state ω, the function $z\mapsto\omega(\alpha_z(a))$ is continuous and nonnegative. If $E(a)=0$, its integral is zero and its value at the identity is zero. States separate positive elements, so $a=0$. Finally, $V_z\delta_m=z(m)\delta_m$ implements the gauge action in π before transport through U. If $\pi(a)=0$, gauge equivariance gives $\pi(E(a^*a))=0$. Faithfulness on D gives $E(a^*a)=0$, and faithful averaging gives $a=0$. □

Remark 29.3.2 *(The map to a Hochschild trace class).* The preceding construction takes place on L. A Hilbert realization from Hochschild homology requires a specified complex $(C_\bullet,b)$ over $\mathbb{C}$, a degree d, and a map $J:L_{\mathrm{alg}}\to Z_d(C_\bullet,b)$. It also requires a positive sesquilinear form q on $H_d(C_\bullet,b)$, a null space $\mathcal{N}_q$, and the completion

$$\mathcal{H}_q=\overline{H_d(C_\bullet,b)/\mathcal{N}_q}.$$

The identity $q([Jv],[Jw])=\langle v,w\rangle_L$ extends J isometrically to $L\to\mathcal{H}_q$. Surjectivity onto a proposed closed sector requires density of the image. Identifying that sector or a class in it with $\mathcal{V}^{\mathrm{prim}}$ is further data. An action on this homology and its intertwining with J must also be specified. The occupation-space construction supplies none of these Hochschild comparison data.

Example 29.3.3 *(A coherent state in the arithmetic representation).* For a prime p and $z\in\mathbb{C}$, the vector

$$e^{-|z|^2/2}\sum_{k\geq 0}\frac{z^k}{\sqrt{k!}}U\delta_{p^k}$$

has norm one and lies in L. It is the image of $U\delta_1$ under $e^{-|z|^2/2}\sum_{k\geq 0}z^k(U\mu_pU^{-1})^k/\sqrt{k!}$. This operator series converges in norm, since the ratio of successive coefficient magnitudes is $|z|/\sqrt{k+1}$. Thus the coherent state belongs to the arithmetic algebra orbit of the vacuum.

29.4 The tensor decomposition by current modes

Proposition 29.4.1 *(Mode-one and higher-mode factors).* For a finite set F of primes, let $\mathscr{F}_F^{\mathrm{cur}}=\Gamma_s(\ell^2(F\times\mathbb{N}_{\geq 1}))$ be the complex bosonic Fock space, where Γ_s is the Hilbert direct sum of the symmetric

tensor powers. This model has one oscillator per prime and mode. The mode index $j \geq 1$ corresponds to $a_{-j}^{(p)}/\sqrt{j}$. Splitting the one-particle space into $j = 1$ and $j \geq 2$ gives the canonical unitary

$$\mathscr{F}_F^{\mathrm{cur}} \cong L_F \widehat{\otimes} \mathscr{F}_F^{\geq 2}, \qquad L_F = \widehat{\bigotimes}_{p \in F} \mathscr{F}_p, \qquad \mathscr{F}_F^{\geq 2} = \Gamma_s(\ell^2(F \times \mathbb{N}_{\geq 2})).$$

On algebraic number states it also preserves the grading that assigns degree j to a mode-j creation operator. Let $\mathbb{N}_F$ consist of the positive integers supported on F. The formulas $\mu_n \delta_m = \delta_{nm}$ for $n, m \in \mathbb{N}_F$ and $e(\gamma)\delta_m = \chi(m\gamma)\delta_m$ act on $L_F \cong \ell^2(\mathbb{N}_F)$. They extend to the displayed tensor product by the identity on $\mathscr{F}_F^{\geq 2}$.

Proof. Each normalized current number state determines a unique pair of occupation arrays, for modes one and modes at least two. This orthonormal basis bijection gives the unitary and preserves the sum of the mode degrees. The subspace $\ell^2(\mathbb{N}_F) \subset \ell^2(\mathbb{N}^\times)$ is invariant under the phases and under μ_n, μ_n^* for $n \in \mathbb{N}_F$. Restricting these operators and tensoring with the identity preserves their relations. □

COROLLARY 29.4.2 *(Stable descendant sectors).* For every closed subspace $K \subset \mathscr{F}_F^{\geq 2}$, the subspace $L_F \widehat{\otimes} K$ is invariant under the extended arithmetic representation and its adjoints. If $F \neq \varnothing$, the higher-mode vacuum sector is therefore not a maximal stable subspace.

Proof. Each operator has the form $A \otimes 1$ and preserves $L_F \widehat{\otimes} K$ together with its adjoint. When $F \neq \varnothing$, the higher-mode space contains both the vacuum and a nonzero mode-two state. The vacuum sector is properly contained in the full stable tensor product. □

29.5 KESTEN–MCKAY = PLANCHEREL OF UNRAMIFIED $GL_2(\mathbb{Q}_p)$

THEOREM 29.5.1 *(Kesten 1959; McKay 1981; Lubotzky 1994 Thm 7.4.5).* The Kesten–McKay distribution on $[-2\sqrt{p}, 2\sqrt{p}]$ for $q = p$ prime,

$$d\nu_p(x) \;=\; \frac{(p+1)\sqrt{4p - x^2}}{2\pi((p+1)^2 - x^2)}\, dx,$$

is the spectral measure of the adjacency operator on the $(p+1)$-regular tree, equivalently the p-adic Bruhat–Tits tree of $\mathrm{PGL}_2(\mathbb{Q}_p)$, equivalently the Plancherel measure of the spherical-function algebra on the tree.

COROLLARY 29.5.2. The Kesten–McKay averaging is the Plancherel decomposition of the $GL_2(\mathbb{Q}_p)$ spherical Hecke algebra, not a spectral theorem for the GL_1 Bost–Connes semigroup algebra. Any map from the Julia–Bost–Connes partition function to ν_p must pass through a specified $GL_1 \to GL_2$ correspondence.

Remark 29.5.3 *(arithmetic averaging and Plancherel comparison).* The finite occupation-phase operator A_S of Definition 25.5.1 acts on a polynomial oscillator space. It does not construct the proposed arithmetic carrier or quotient for $\mathrm{av}^{\mathrm{arith}}$. An arithmetic Plancherel interpretation requires a specified representation, its spectral transform, and an intertwining map from the intended arithmetic object. The operadic averaging $\mathfrak{g}^{E_1} \to \mathfrak{g}^{\mathrm{mod}}$ of Vol I instead acts on chiral cohomology. A common integral form does not identify these carriers or supply a map between them.

29.6 The Soibelman Cohomological Hall Algebra Reading

A rank-n representation of the Jordan quiver over $\mathbb{F}_q$ is an endomorphism of $\mathbb{F}_q^n$. Change of basis acts by conjugation. Its finite groupoid mass weights each isomorphism class by the reciprocal of its automorphism-group order.

Proposition 29.6.1 *(finite-field mass of Jordan-quiver representations).* For a prime power q and $n \geq 1$,

$$\sum_{[A] \subset M_n(\mathbb{F}_q)} \frac{1}{|\operatorname{Cent}_{GL_n(\mathbb{F}_q)}(A)|} = \frac{q^{n^2}}{|GL_n(\mathbb{F}_q)|} = \prod_{i=1}^{n} (1 - q^{-i})^{-1}.$$

The sum is over conjugacy classes of matrices. In rank one its value is $q/(q-1)$.

Proof. An orbit of A has $|GL_n(\mathbb{F}_q)|/|\operatorname{Cent}_{GL_n(\mathbb{F}_q)}(A)|$ elements. Summing orbit sizes gives $|M_n(\mathbb{F}_q)| = q^{n^2}$. Counting successive independent columns gives

$$|GL_n(\mathbb{F}_q)| = \prod_{j=0}^{n-1} (q^n - q^j) = q^{n^2} \prod_{i=1}^{n} (1 - q^{-i}).$$

Division proves the formula and its rank-one specialization. □

This scalar groupoid mass is not a real spectral measure. A comparison with the Kesten–McKay measure requires a specified operator, state and moment or spectral-transform map. A Behrend-weighted or vanishing-cycle refinement also requires its own normalization. Kontsevich–Soibelman, arXiv:1006.2706, §§2.4–2.5, constructs the cohomological Hall product and its shuffle expression. That construction does not supply the spectral comparison described here.

Proposition 29.6.2 *(three-way comparison obstruction).* The composed arrow

$$\text{Julia primon gas} \xrightarrow{\text{Plancherel}} \text{Bost-Connes Hecke-Plancherel} \xrightarrow{\text{CoHA-motivic}} \text{Soibelman DT on } \mathcal{Q}_{\text{Jordan}}$$

is not defined by the preceding theorems. The Bost–Connes algebra is a GL_1 semigroup system, the Kesten–McKay measure is a GL_2 spherical Plancherel measure, and the Jordan-quiver CoHA is a motivic Hall algebra. Equality of Euler factors can be asserted only after a functor between these three structures has been constructed.

29.7 Gauge Derivations and Smooth Domains

The occupation representation supplies bounded arithmetic shifts and phases. Its time derivative is unbounded, so a Hochschild calculation must specify an algebra on which that derivative is defined. We use the finite normal-term algebra to construct gauge classes and their cup products. Smoothness under finite prime-circle actions gives a continuous version; smoothness under the time evolution gives a different coefficient algebra. Their distinction is visible on an explicit norm-convergent series. None of these constructions identifies an arithmetic Hochschild trace carrier.

Put $A = C^*_{\mathbb{Q}}$ over $\mathbb{C}$, represented faithfully on $\mathcal{L} = \ell^2(\mathbb{N}^\times)$ as in Proposition 29.3.1. Write its orthonormal basis as e_m, so that $\mu_n e_m = e_{nm}$ and $e(\gamma)e_m = \exp(2\pi i m\gamma)e_m$. Define the complex vector space of finite sums

$$A_{\text{alg}} = \operatorname{span}_{\mathbb{C}}\{\mu_r e(\gamma)\mu_s^* : r, s \geq 1,\ \gamma \in \mathbb{Q}/\mathbb{Z}\}.$$

It is a dense unital $*$-subalgebra of A. Indeed, if $d = \gcd(s,u)$, $s = ds'$, and $u = du'$, the defining relations give

$$\begin{aligned}(\mu_r e(\gamma)\mu_s^*)(\mu_u e(\eta)\mu_v^*)\\ = \mu_{ru'} e(u'\gamma + s'\eta)\mu_{vs'}^*.\end{aligned}$$

Here $\mu_s^*\mu_u = \mu_{u'}\mu_{s'}^*$, $e(\gamma)\mu_{u'} = \mu_{u'}e(u'\gamma)$, and $\mu_{s'}^* e(\eta) = e(s'\eta)\mu_{s'}^*$. Adjoint exchanges r, s and negates γ. Thus the displayed span is closed under multiplication and adjoint, and it contains all generators.

THEOREM 29.7.1 *(gauge classes in algebraic Hochschild cohomology).* Use algebraic $\mathbb{C}$-multilinear Hochschild cochains of A_{alg}, with coefficients in its regular bimodule. For every $\lambda = (\lambda_p)_{p\ \mathrm{prime}} \in \prod_p \mathbb{C}$, the formula

$$D_\lambda(\mu_r e(\gamma)\mu_s^*) = \left(\sum_p (v_p(r) - v_p(s))\lambda_p\right)\mu_r e(\gamma)\mu_s^*$$

defines a derivation. There is an injective linear map

$$\prod_p \mathbb{C} \hookrightarrow HH^1_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}}), \qquad \lambda \longmapsto [D_\lambda].$$

No boundedness or summability condition on the family is required. Every nonzero D_λ is unbounded for the inherited C^*-norm and cannot be implemented by a bounded operator on $\mathcal{L}$. Moreover $HH^0_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}}) = \mathbb{C}$. This is a lower bound in degree one, not a complete Hochschild calculation.

Proof. Let $K = \prod_p U(1)$, and for $z \in K$ put $z(n) = \prod_p z_p^{v_p(n)}$. The assignments $\alpha_z(\mu_n) = z(n)\mu_n$ and $\alpha_z(e(\gamma)) = e(\gamma)$ preserve the relations and define an action by $*$-automorphisms. It is norm continuous in z on each finite normal sum, and hence on A by uniform approximation and isometry. A normal term has character $z(r/s)$. Haar integration against the inverse character projects onto its homogeneous component; distinct rational degrees therefore give

$$A_{\mathrm{alg}} = \bigoplus_{g \in \mathbb{Q}^\times_{>0}} (A_{\mathrm{alg}})_g, \qquad (A_{\mathrm{alg}})_g (A_{\mathrm{alg}})_h \subseteq (A_{\mathrm{alg}})_{gh}.$$

This does not assert independence of normal terms of the same degree. Unique factorization makes $\lambda(g) = \sum_p v_p(g)\lambda_p$ an additive character of the multiplicative rational group: $\lambda(gh) = \lambda(g) + \lambda(h)$. All these sums are finite. Define D_λ on a homogeneous element of degree g by multiplication by $\lambda(g)$. The direct-sum decomposition proves well-definedness, and the character identity proves the Leibniz rule. In particular it annihilates the phases and sends μ_n to $\lambda(n)\mu_n$ and μ_n^* to $-\lambda(n)\mu_n^*$.

Algebraic Hochschild one-cocycles are precisely derivations and one-coboundaries are inner derivations. If $D_\lambda = [b, -]$ for a bounded operator b, the isometry μ_p^k gives

$$k|\lambda_p| = \|D_\lambda(\mu_p^k)\| = \|[b, \mu_p^k]\| \le 2\|b\| \qquad (k \ge 1).$$

Hence every $\lambda_p = 0$. Applying this to differences proves injectivity on Hochschild classes. The same estimate on the norm-one sequence μ_p^k proves unboundedness whenever a prime value is nonzero, and excludes a bounded extension $A \to \mathcal{A}$.

An operator commuting with all phases has vanishing matrix entries between distinct e_m, e_n: some $\gamma \in \mathbb{Q}/\mathbb{Z}$ has different characters at m, n. It is therefore diagonal, say $Te_m = t_m e_m$. Commutation with μ_n gives $t_{nm} = t_m$; setting $m = 1$ makes all entries equal. Thus the represented commutant is scalar. Faithfulness implies $Z(A_{\mathrm{alg}}) = \mathbb{C}$, which is its Hochschild degree zero. □

The product $\prod_p \mathbb{C}$ parametrizes actual derivations, not convergent infinite operator sums: every input has finite homogeneous support. A derivation in this family preserves adjoint exactly when every λ_p is purely imaginary, as follows by comparing its values on μ_p and μ_p^*. The preceding algebraic result does not compute continuous Hochschild cohomology of the Banach algebra A.

Higher Gauge Cup Products

The degree-one classes also detect higher cohomology. To prove this, we use a scalar character to change coefficients and then evaluate cup products on explicit finite cycles. This coefficient change is part of the argument; it is not an identification with Hochschild homology with regular coefficients.

There is a character $\varepsilon : A \to \mathbb{C}$ defined by

$$\varepsilon(\mu_n) = \varepsilon(\mu_n^*) = \varepsilon(e(\gamma)) = 1.$$

These values respect the unit, involution, phase multiplication, semigroup, coprime-adjoint and isometry relations. The transfer relation becomes one equal to the average of n ones. The universal property therefore gives a unital $*$-homomorphism, of norm one. It is not the vacuum vector state: the latter takes μ_p to zero.

Let $\mathbb{C}_\varepsilon$ be the bimodule with $a \cdot c \cdot b = \varepsilon(a)c\varepsilon(b)$. Our algebraic cochains have differential

$$\begin{aligned}(bF)(a_1, \dots, a_{n+1}) = {} & a_1 F(a_2, \dots, a_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i F(a_1, \dots, a_i a_{i+1}, \dots, a_{n+1}) \\ & + (-1)^{n+1} F(a_1, \dots, a_n) a_{n+1}.\end{aligned}$$

Composition with ε is a cochain map from regular coefficients to $\mathbb{C}_\varepsilon$, by multiplicativity. For scalar-coefficient chains, written $c[a_1|\cdots|a_n]$, use

$$\begin{aligned}b(c[a_1|\cdots|a_n]) = {} & c\varepsilon(a_1)[a_2|\cdots|a_n] \\ & + \sum_{i=1}^{n-1} (-1)^i c[a_1|\cdots|a_i a_{i+1}|\cdots|a_n] \\ & + (-1)^n \varepsilon(a_n) c[a_1|\cdots|a_{n-1}].\end{aligned}$$

Evaluation makes these two differential formulas dual.

Lemma 29.7.2 *(finite detecting cycles).* For distinct primes $P = (p_1, \dots, p_n)$, put $s_j = \mu_{p_j}$. Then

$$c_P = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) 1[s_{\sigma(1)}|\cdots|s_{\sigma(n)}]$$

is a cycle with coefficients in $\mathbb{C}_\varepsilon$. Consequently the functional on regular-coefficient cochains

$$L_P(F) = \sum_{\sigma \in S_n} \operatorname{sgn}(\sigma) \varepsilon\big(F(s_{\sigma(1)}, \dots, s_{\sigma(n)})\big)$$

annihilates Hochschild coboundaries.

Proof. For each interior face, pair a permutation with the one exchanging the adjacent multiplied factors. Their signs are opposite and the boundary terms agree, since the s_j commute. Pair the first face of $(j_1, \dots, j_n)$ with the last face of its cyclic rotation $(j_2, \dots, j_n, j_1)$. Rotation has sign $(-1)^{n-1}$, whereas the last boundary sign is $(-1)^n$; the terms cancel because $\varepsilon(s_j) = 1$. For $n = 1$, the boundary is $\varepsilon(s_1) - \varepsilon(s_1) = 0$. The cochain map and the dual differential formulas now show that evaluation on c_P vanishes on every regular-coefficient coboundary. □

THEOREM 29.7.3 *(an algebraic exterior-algebra injection).* Let $W = \mathrm{Hom}_{\mathbb{Z}}(\mathbb{Q}^{\times}_{>0}, (\mathbb{C}, +)) = \prod_p \mathbb{C}$. The gauge derivations give an injective graded-algebra map

$$\Lambda^*_{\mathbb{C}} W \hookrightarrow HH^*_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}}), \qquad \lambda \longmapsto [D_\lambda].$$

The exterior algebra here is algebraic: its elements are finite sums of finite wedges, without completion. In particular the Hochschild cohomology is nonzero in every nonnegative degree.

Proof. The cup of n derivations is

$$F_{\lambda_1,\dots,\lambda_n}(a_1, \dots, a_n) = D_{\lambda_1}(a_1) \cdots D_{\lambda_n}(a_n).$$

Substitution into the differential gives $b(F \smile G) = bF \smile G + (-1)^{\deg F} F \smile bG$: the interior terms cancel except the two indicated coboundaries. Each derivation is a cocycle, so their cup is a cocycle. Using $D_{\lambda_i}(s_j) = \lambda_i(p_j) s_j$ gives

$$L_P(F_{\lambda_1,\dots,\lambda_n}) = \det\big(\lambda_i(p_j)\big)_{1 \le i,j \le n}.$$

For two derivations D, E, their composition is a one-cochain. Expanding both Leibniz rules yields

$$b(DE)(a, b) = -D(a)E(b) - E(a)D(b).$$

Thus their cohomology classes anticommute, and each square vanishes in characteristic zero. This defines the exterior-algebra map.

An exterior element involves a finite-dimensional subspace $U \subset W$. Prime-coordinate functionals separate its points; their span is U^*, since otherwise their common annihilator would contain a nonzero element with all prime coordinates zero. A finite subset therefore spans U^*, and wedges of its coordinates span $(\Lambda^n U)^*$. Every nonzero degree-n exterior element pairs nontrivially with some wedge of distinct prime coordinates. The corresponding determinant functional L_P detects its image in Hochschild cohomology. Degree zero is detected by $\varepsilon(1) = 1$. □

Example 29.7.4 *(degrees two and three).* For distinct primes p, q, the chain $1[\mu_p|\mu_q] - 1[\mu_q|\mu_p]$ has boundary

$$1[\mu_q] - 1[\mu_p\mu_q] + 1[\mu_p] - 1[\mu_p] + 1[\mu_q\mu_p] - 1[\mu_q] = 0.$$

Here D_p denotes the family with value one at p and zero elsewhere. The evaluation $L_{(p,q)}(D_p \smile D_q) = 1$ proves this cup is not a coboundary. For three distinct primes, among the six terms defining $L_{(p,q,r)}(D_p \smile D_q \smile D_r)$, only the identity assignment is nonzero, and its value is one. These are explicit higher classes, not a classification of all Hochschild classes.

The time evolution is $\sigma_t(\mu_n) = n^{it}\mu_n$, fixing the phases. Its norm-generator domain consists of those $a \in A$ for which $\lim_{t\to 0}(\sigma_t(a) - a)/t$ exists in norm; call that generator δ, and write A^∞_σ for its norm-smooth orbit algebra. Its closedness and smooth topology are proved below.

Finite-Prime and All-Prime Gauge Smoothness

For a finite prime set F, let $\mathbb{T}^F \subset K$ act by setting the other coordinates to one. Define

$$B_F = \{a \in A : z \mapsto \alpha_z(a) \text{ is norm-smooth on } \mathbb{T}^F\}.$$

For angular differentiation in the p-coordinate write δ_p; thus $\delta_p(\mu_q) = i\delta_{pq}\mu_q$ and $D_p = \delta_p/i$. For nonnegative multiindices α supported in F, put $q_\alpha(a) = \|\delta^\alpha a\|$, including $q_0(a) = \|a\|$. Define also

$$B_{\mathrm{g}} = \bigcap_{F \text{ finite}} B_F$$

with all finite-support multiindex seminorms. This definition uses ordinary smoothness on each finite-dimensional torus; it makes no unspecified infinite-dimensional differentiability assumption.

Proposition 29.7.5 *(smooth gauge algebras and their cup classes).* The algebras B_F and B_{g} are Fréchet $*$-algebras, dense in A for its C^*-norm. The derivations D_p, for $p \in F$ on B_F and all primes on B_{g}, are continuous. With jointly continuous complex multilinear cochains and regular coefficients, there are injections

$$\Lambda^*_{\mathbb{C}} \operatorname{span}_{\mathbb{C}}\{D_p : p \in F\} \hookrightarrow HH^*_{\mathrm{cont}}(B_F, B_F),$$

$$\Lambda^*_{\mathbb{C}}\left(\bigoplus_p \mathbb{C}D_p\right) \hookrightarrow HH^*_{\mathrm{cont}}(B_{\mathrm{g}}, B_{\mathrm{g}}).$$

Proof. If a_j is Cauchy for every q_α on B_F, its orbit maps $f_j(z) = \alpha_z(a_j)$ are Cauchy in every uniform derivative norm, since $\partial^\alpha f_j(z) = \alpha_z(\partial^\alpha a_j)$ and the action is isometric. The space of smooth Banach-valued functions on the torus is complete: the fundamental theorem of calculus in coordinate charts shows that uniform limits of functions and their first derivatives retain those derivatives, and iteration gives the assertion at every order. The limit f has $f(z) = \alpha_z(a)$, where $a = \lim_j a_j$ in norm, by continuity of each automorphism. Thus $a \in B_F$ and all seminorms converge. The iterated product rule

$$\partial^\alpha(ab) = \sum_{\beta \le \alpha} \binom{\alpha}{\beta} (\partial^\beta a)(\partial^{\alpha-\beta} b)$$

proves continuous multiplication. Adjoint commutes with real angular derivatives and is continuous; mixed derivatives commute by smoothness.

There are countably many finite prime sets and finite-support multiindices. A sequence Cauchy in all seminorms of B_{g} converges in every B_F; the limits coincide with its norm limit in A. This proves completeness of B_{g}, and the same product rule proves its Fréchet algebra structure. Finite normal sums belong to every B_F, giving norm density. For p and finite F, differentiate the orbit for $\mathbb{T}^{F\cup\{p\}}$ and restrict to $\mathbb{T}^F$. This shows that δ_p preserves B_{g}, with $q_\alpha(\delta_p a) = q_{\alpha+e_p}(a)$; the assertion on B_F is identical for $p \in F$.

The finite cup cochains are continuous by these estimates and continuity of multiplication. The character is continuous because $|\varepsilon(a)| \le q_0(a)$. The finite cycles of Lemma 29.7.2 therefore annihilate every continuous coboundary as well. Their determinant evaluations prove the two injections. No completed chain-complex comparison is needed. □

Proposition 29.7.6 *(which algebraic gauge derivations extend continuously).* An algebraic gauge derivation D_λ extends to a continuous linear map $B_{\mathrm{g}} \to A$ exactly when λ has finite support. In that case it extends as a continuous derivation $B_{\mathrm{g}} \to B_{\mathrm{g}}$. For B_F, the analogous criterion is that λ be supported in F.

Proof. Continuity of an extension $T : B_{\mathrm{g}} \to A$ gives

$$\|T(a)\| \le C \max_{\alpha \in E} q_\alpha(a)$$

for a finite set E of multiindices, enlarged to include zero. Let F contain their supports. If a prime $q \notin F$, then $q_0(\mu_q^k) = 1$, whereas every positive derivative in E is zero. Thus $k|\lambda_q| \le C$ for every k, forcing $\lambda_q = 0$. Conversely a finite linear combination of the continuous D_p is continuous into B_{g}. The same argument on B_F proves the second criterion. These criteria concern this family of algebraic derivations; they do not classify all continuous derivations. □

Example 29.7.7 *(gauge smoothness does not imply time differentiability).* Enumerate distinct primes p_j, and put

$$a = \sum_{j \ge 1} 2^{-j} \mu_{p_j}^{2^j}.$$

The series converges in norm. For each finite F, only finitely many summands move under $\mathbb{T}^F$, while the remaining norm-convergent sum is fixed. Hence $a \in B_{\mathrm{g}}$. If its time derivative existed in norm, its value on e_1 would have coordinate $i \log p_j$ at each distinct state $e_{p_j^{2^j}}$. These coordinates are not square summable. Thus $a \notin \mathrm{Dom}(\delta)$, and B_{g} is not contained in A_σ^∞. The time family $\lambda_p = i \log p$ also fails the finite-support continuity criterion. Gauge-smooth and time-smooth Hochschild complexes are therefore different specified constructions.

PROPOSITION 29.7.8 *(the closed time generator and its proper domain).* For $\sigma_t(\mu_n) = n^{it}\mu_n$ and $\sigma_t(e(\gamma)) = e(\gamma)$, let

$$\mathrm{Dom}(\delta) = \left\{ a \in A : \lim_{t \to 0} \frac{\sigma_t(a) - a}{t} \text{ exists in } A \right\}.$$

The norm generator δ is closed and densely defined, its domain is proper, and its restriction to A_{alg} is $D_{(i \log p)_p}$.

Proof. The gauge action makes σ pointwise norm continuous. Every normal term is entire analytic, with derivative $i \log(r/s)\mu_r e(\gamma)\mu_s^*$; hence the domain contains the dense normal algebra. Fix a prime p. The series

$$a = \sum_{j \ge 1} 2^{-j} \mu_p^{2^j}$$

converges in norm because the summand norms sum to one. Applied to e_1, its orbit difference quotient has coordinate

$$2^{-j} \frac{\exp(it2^j \log p) - 1}{t} \longrightarrow i \log p$$

at $e_{p^{2^j}}$. If the quotient converged in operator norm, its value on e_1 would converge to an ℓ^2 vector having this same nonzero coordinate at infinitely many orthonormal states. This is impossible, so $a \notin \mathrm{Dom}(\delta)$.

For a domain element, differentiation along the norm-continuous orbit gives the Bochner integral identity

$$\sigma_t(a) - a = \int_0^t \sigma_s(\delta a)\, ds.$$

If $a_n \to a$ and $\delta a_n \to b$ in norm, isometry permits passage to the limit in this identity. Dividing by t and using norm continuity of $\sigma_s(b)$ gives $\delta a = b$. This proves closedness. □

Proposition 29.7.9 *(a smooth Hochschild class).* The algebra of norm-smooth elements is

$$A_\sigma^\infty = \bigcap_{j\ge 0} \mathrm{Dom}(\delta^j), \qquad p_k(a) = \sum_{j=0}^{k} \|\delta^j a\|.$$

With these seminorms it is a Fréchet algebra, dense in A. The derivation $\delta : A_\sigma^\infty \to A_\sigma^\infty$ is continuous and represents a nonzero class in continuous Hochschild degree one with coefficients in this same smooth algebra.

Proof. Repeated differentiation of the orbit identifies smoothness with membership in every generator domain. If a sequence is Cauchy for every p_k, each $\delta^j a_n$ has a norm limit. Closedness of δ, applied successively, identifies these limits as $\delta^j a$. Thus the seminorm topology is complete. The iterated Leibniz rule

$$\delta^j(ab) = \sum_{i=0}^{j} \binom{j}{i} (\delta^i a)(\delta^{j-i} b)$$

proves closure under multiplication and its continuity; the generator also commutes with adjoint. The normal algebra consists of smooth elements and is norm dense in A. Finally $p_k(\delta a) \le p_{k+1}(a)$ proves continuity. An inner implementer in this smooth algebra would be a bounded element of A, contrary to the power estimate in Theorem 29.7.1 with $\lambda_p = i \log p$. □

Proposition 29.7.10 *(the occupation Hamiltonian and represented closure).* On $\mathcal{L}$ let $He_m = (\log m) e_m$, with maximal domain

$$\mathrm{Dom}(H) = \left\{ \xi \in \mathcal{L} : \sum_m (\log m)^2 |\xi_m|^2 < \infty \right\}.$$

This diagonal operator is self-adjoint, with finite-support core. Normal terms preserve its domain, and there

$$[H, \mu_r e(\gamma) \mu_s^*] = \log(r/s)\, \mu_r e(\gamma) \mu_s^*.$$

The unitaries e^{itH} implement σ_t, and the represented von Neumann closure of A is $B(\mathcal{L})$.

Proof. For a real diagonal multiplier, testing the adjoint against basis vectors gives precisely the stated square-summability domain; thus the maximal operator equals its adjoint. Truncating a vector in both the norm and weighted norm proves the core assertion. A normal term vanishes unless $s \mid m$, and otherwise sends e_m to a phase times $e_{rm/s}$. The logarithmic weights change by the constant $\log(r/s)$, which proves domain preservation and the commutator identity. Equivalently, prove the identity on the core and pass to graph limits by closedness. Exponentiating the diagonal weights gives the asserted implementation. The scalar commutant computed in Theorem 29.7.1 and the bicommutant theorem give the represented closure $B(\mathcal{L})$. □

Thus $\delta = i[H, -]$ on A_{alg} has an unbounded spatial implementer. The prime-power norm estimate in Theorem 29.7.1 excludes every bounded implementer, so δ is outer on A_{alg} and A_σ^∞. This occupation closure is a type-I-infinity factor. A factor obtained from another state by a KMS–GNS construction is a different carrier. Its type identifies none of the algebraic, Banach or Fréchet Hochschild complexes above. The algebraic and all-prime gauge-smooth lower bounds above are nonzero in every degree. They do not classify the full cohomology on these carriers or compute the other Hochschild theories.

Question 29.7.11 *(the arithmetic Hochschild comparison).* Construct the arithmetic category or algebra whose Hochschild invariants are to realize $\mathcal{V}^{\mathrm{prim}}$, specifying its coefficient ring, bimodule or categorical trace, topology, grading and completion. Construct the comparison with the Bost–Connes normal algebra or a specified smooth algebra and the cycle pairing of Remark 29.3.2. Determine which gauge classes survive under that comparison and whether an integral degree-one carrier generated by logarithmic prime data exists. Any proposed degree-two relation to a Witt cotangent complex requires its actual map and coefficient comparison. A trace class alone defines no Hochschild cochain algebra, and the complex injection above establishes neither an integral lattice nor concentration of the arithmetic theory in degrees zero through two.

29.8 Vertex-Algebraic Invariants of the Heisenberg Covers

THEOREM 29.8.1 *(universal Heisenberg-cover invariants).* The finite Heisenberg cover $\mathcal{H}^{\otimes\pi(N)}$ of $\mathcal{V}_N^{\mathrm{prim}}$ is a rank-$\pi(N)$ Heisenberg vertex algebra. It lies in the Heisenberg archetype G of the Vol I landscape census, with cover central charge $\kappa = \pi(N)$, depth $r_{\max} = 2$, and chiral Hochschild cohomology concentrated in degrees $\{0, 1, 2\}$. These are invariants of the cover, not of the trace class.

COROLLARY 29.8.2 *(placement of the finite covers).* The finite Heisenberg covers of $\mathcal{V}^{\mathrm{prim}}$ lie in archetype G (Heisenberg / Gaussian), with $\kappa_N = \pi(N)$. The Hilbert comparison with the Hochschild trace class requires the map, pairing and completion of Remark 29.3.2.

29.9 The Fock representation and the trace comparison

COROLLARY 29.9.1 *(Finite current Fock representation).* The finite current Fock space has the Hilbert tensor decomposition of Proposition 29.4.1. Its arithmetic shifts and phases act on the mode-one factor and extend by the identity on the higher-mode factor.

Proof. Apply Proposition 29.4.1 to the given finite set of primes. □

Remark 29.9.2 *(Scope of the module structure).* The tensor decomposition is a statement about current Fock spaces. It induces no tensor decomposition of a Hochschild trace class without a compatible comparison. The higher-mode factor alone is not the full vacuum Heisenberg vertex algebra: it omits all mode-one creations. Nor does the finite-prime restriction assert faithfulness for all arithmetic phases. If $q \notin F$, the nonzero Bost–Connes projection $e_q = q^{-1}\sum_{j=0}^{q-1} e(j/q)$ acts by zero on L_F, since q divides no element of $\mathbb{N}_F$.

Remark 29.9.3 *(the* B*-row threshold).* A proposed arithmetic chiral algebra should encode Hecke eigenvalues in its stress tensor. Comparing its chiral Hochschild cohomology with Bost–Connes cohomology requires a specified algebraic or smooth coefficient algebra and an actual subquotient map. The gauge classes above do not construct this map. Placement in the Borcherds/BKM B-row further requires verification of the hypotheses of the Vol III classification theorem (Theorem C, BKM column), whose corresponding value is $K^\kappa = 8$. The proposed passage from the Heisenberg-cover G-row uses a Borcherds-product encoding of Hecke data in the stress tensor, with the target relation $\Phi_N = c_N(0)/2$. Prime indexing alone supplies neither that encoding nor the Hochschild comparison.

29.10 Structural Conclusions

(i) Bost–Connes $C_{\mathbb{Q}}^*$ carries $\zeta(\beta)$ as Gibbs partition function for $\beta > 1$ (Theorem 29.1.2).

(ii) The oscillator operators and bounded arithmetic shifts act on the same prime occupation space. The shift is normalized creation, as in Proposition 29.2.2.

(iii) The arithmetic phases and shifts give the faithful representation of Proposition 29.3.1. Its identification with a Hochschild trace class requires the map, pairing and completion of Remark 29.3.2.

(iv) The current Fock space splits into mode-one and higher-mode factors. The arithmetic representation extends over the latter, with the stable sectors of Corollary 29.4.2.

(v) The Kesten–McKay measure describes the spherical $GL_2(\mathbb{Q}_p)$ Hecke spectrum. Relating it to the GL_1 Bost–Connes system or the Jordan-quiver CoHA requires the comparison maps described in Corollary 29.5.2 and Proposition 29.6.2.

(vi) The normal-term algebra has the independent gauge classes of Theorem 29.7.1. The time derivative requires its specified algebraic or smooth domain; the algebraic and all-prime gauge-smooth cup products are nonzero in every degree, without a full Hochschild classification.

(vii) The finite Heisenberg covers lie in archetype G with $\kappa = \pi(N)$, $r_{\max} = 2$; the B-row threshold requires Borcherds-product encoding of Hecke data (Corollary 29.8.2).

The vertex algebra structure is universal and non-arithmetic because it belongs only to the finite Heisenberg covers. The Bost–Connes representation gives the arithmetic shifts, phases and Gibbs partition function. Its relation to the Hochschild trace class requires the comparison of Remark 29.3.2. A genuine VA-arithmetic object encoding Hecke eigenvalues in the stress tensor would be a new object, not $\mathcal{V}^{\mathrm{prim}}$.

Chapter 30

Adelic Factorization Axioms

An adelic factorization construction must specify both its local coefficients and the spaces on which positions collide. The set of places supplies an index for the coefficients. A holomorphic curve, a formal disc or a derived arithmetic intersection supplies different position data. The elementary distinctions of Section 2.8 are the starting point.

30.1 The Ran Space of $\overline{\operatorname{Spec}\mathbb{Z}}$

Observation 30.1.1 *(naive Ran is terminal).* The functor of nonempty finite subsets of $X(S)$, applied to $X = \operatorname{Spec}\mathbb{Z}$ and arbitrary test schemes S, is terminal. Indeed,

$$S \mapsto \operatorname{Spec}\mathbb{Z}(S) = \operatorname{Hom}_{\mathrm{Ring}}(\mathbb{Z}, \Gamma(S, \mathcal{O}_S)) = \{*\}$$

(singleton). Its only nonempty finite subset is itself. The maps $\operatorname{Spec}\mathbb{F}_p \to \operatorname{Spec}\mathbb{Z}$ are points for different test schemes. They do not give several sections over a fixed S.

Definition 30.1.2 *(Discrete configurations of places).* Let $V = \mathbb{P} \sqcup \{\infty\}$, where $\mathbb{P}$ is the set of rational primes. The discrete place configurations are $\mathrm{Fin}_+(V)$. When multiplicities are retained, use $\mathrm{Mult}_+(V) = \coprod_{n\geq 1} V^n/\mathfrak{S}_n$. These are combinatorial index sets. They specify neither a scheme structure on an Arakelov compactification nor a normal neighbourhood of a position diagonal. We write $\overline{C}$ for the arithmetic curve only when its additional geometric data have been specified.

Remark 30.1.3. An order on V, or the multiplicity of a place in a multiset, does not produce a normal coordinate. Such coordinates belong to a separately chosen local position space. The cut construction of Chapter 2 uses a smooth curve and its differential modules; its hypotheses are additional to the choice of V.

30.2 Factorization for Disjoint Place Labels

Observation 30.2.1. Choose a common commutative coefficient ring A and complexes $H_v \in \mathcal{D}(A)$. Set $F(S) = \bigotimes^{\mathbf{L}}_{v\in S, A} H_v$ for a finite set of places. For disjoint sets S, T, the tensor associator gives $F(S \sqcup T) \simeq F(S) \otimes^{\mathbf{L}}_A F(T)$. Its coherences follow from those of derived tensor, as in (2.8).

Corollary 30.2.2 *(Scope of discrete factorization).* The preceding construction gives a coherent factorization for disjoint finite subsets of V. It requires no maps at coincident positions. Identifying it with a geometric arithmetic factorization system requires the position spaces, their collision coefficients and comparison maps in addition to the disjoint tensor identities.

Proof. Every map used in the construction is an associator or symmetry of the finite coefficient tensor. Its source and target are indexed by disjoint sets. No diagonal coefficient occurs among these maps. □

30.3 The Diagonal and $\mathbb{Z}_p \widehat{\otimes} \mathbb{Z}_p$

Observation 30.3.1. For the ordinary p-adic completion of the indicated tensor,

$$\mathbb{Z}_p \widehat{\otimes}_{\mathbb{Z}} \mathbb{Z}_p \;\cong\; \mathbb{Z}_p,$$

where the left side means $\varprojlim_r (\mathbb{Z}_p \otimes_{\mathbb{Z}} \mathbb{Z}_p)/p^r$. Multiplication is an isomorphism modulo p^r for every r, since both factors then give $\mathbb{Z}/p^r$. The inverse limit proves the assertion. This computation concerns the coefficient base, with no position variable.

Remark 30.3.2. A chosen formal position disc has self-product $\mathbb{Z}_p[[t_1, t_2]]$ and nonzero diagonal ideal $(t_1 - t_2)$. The derived closed-point intersection instead has the normal class in $\mathbb{F}_p \otimes^{\mathbf{L}}_{\mathbb{Z}} \mathbb{F}_p \simeq \mathbb{F}_p \oplus \mathbb{F}_p[1]$. These are distinct coefficient models, as proved in Proposition 2.8.1. Crystalline or prismatic data can be added when a construction requires their Frobenius structure; the completed base tensor does not force that choice.

THEOREM 30.3.3 *(Coefficient completion and position diagonals).* The diagonal of a complex position line has normal coordinate $z_1 - z_2$. A formal position disc over $\mathbb{Z}_p$ has normal coordinate $t_1 - t_2$. Both ideals are nonzero, although the ordinary completed base tensor of Observation 30.3.1 is $\mathbb{Z}_p$.

Proof. In both position rings, change variables to the second coordinate and the difference of the two coordinates. Restriction to the diagonal evaluates the difference at zero and has the displayed nonzero kernel. The base-tensor assertion is the observation above. □

30.4 Pointed Data at Each Finite Place

Remark 30.4.1 *(pointed local data and factorization).* An E_0-algebra in vector spaces is a pointed vector space. The vacuum therefore equips each polynomial oscillator module with such an underlying datum. This does not construct a factorization algebra on Spf $\mathbb{Z}_p$. Classification results for locally constant factorization on manifolds require their geometric hypotheses; a formal scheme is not made a zero-dimensional manifold by this notation.

Definition 30.4.2 *(minimal adelic factorization structure).* The proposed adelic factorization datum consists of:

- At ∞: genuine holomorphic factorization algebra on $\mathbb{C}_\infty$ in the CG sense (Vol. I Def. 3.1.4), with Heisenberg OPE $j(z)\,j(w) \sim k_\infty/(z-w)^2$, $k_\infty = 1$.
- At each finite p: locally constant prestack on Spf $\mathbb{Z}_p$ with constant stalk $\mathcal{H}^{(p)}$ and a specified Adams endomorphism ψ_p. Its underlying pointed module is an E_0-datum; its geometric structure maps are additional requirements.
- Gluing data: restricted tensor product over spherical vectors $|0\rangle_p$ and explicit local-to-global comparison maps. An automorphic representation is further data, not a consequence of the tensor notation.

30.5 The Holomorphic-Topological Structure

Remark 30.5.1 *(Costello HT factorization, arXiv:1303.2632; Costello 2020).* Costello's holomorphic-topological factorization algebras live on $\mathbb{C}^{n_H} \times \mathbb{R}^{n_T}$ with n_H holomorphic and n_T topological directions. The axioms blend holomorphic OPE (on the $\mathbb{C}^{n_H}$ factor) and locally constant (E_{n_T}-algebra structure on the $\mathbb{R}^{n_T}$ factor).

Conjecture 30.5.2 *(adelic HT structure). Conjectural statement.* On $\overline{C}$ the natural HT structure is

$$\underbrace{\mathbb{C}_\infty}_{\text{holomorphic}} \times \underbrace{\operatorname{Spf} \widehat{\mathbb{Z}}}_{\text{adelic / } E_0 \text{ at each place}},$$

with the profinite completion $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$ totally disconnected. Locally constant factorization on Spf $\widehat{\mathbb{Z}}$ decomposes as a product of E_0-stalks. The non-trivial chiral content concentrates at ∞.

Definition 30.5.3 *(relative factorization window with adelic base).* A relative factorization window for $\mathcal{V}^{\mathrm{prim}}$, when supplied, is a holomorphic factorization algebra on $\mathbb{C}_\infty$ *over the base* Spec $\widehat{\mathbb{Z}}$, with the base acting by Adams operations $\{\psi_p\}_p$ and Hecke operators $\{T_p\}_p$:

$$\mathcal{F}_{\mathrm{CG}}(\mathcal{V}^{\mathrm{prim}}) \in \mathrm{FactAlg}_{\mathbb{C}_\infty}\big(\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi}\big),$$

where the coefficient category and its scalar comparison at infinity must be specified. The symbol $\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi}$ records modules with a named compatible commuting action; it does not identify divisor substitutions with Adams maps. The full divisor family fails that commutation requirement by Equation 28.6.

30.6 Five Axioms (F1)–(F5) for the Minimal Adelic Factorization

Definition 30.6.1 *(Costello–Gwilliam arithmetic factorization).* The following are requirements on an arithmetic factorization datum, not consequences of the polynomial oscillator representation:

(F1) Archimedean factorization. Holomorphic factorization algebra on $\mathbb{C}_\infty$ in the sense of CG Vol. I Def. 3.1.4, with OPE $j(z)\,j(w) \sim k_\infty/(z-w)^2$, $k_\infty = 1$.

(F2) Coefficient category. Values in $\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi}$: $\widehat{\mathbb{Z}}$-modules with commuting Adams operations $\psi_p \colon \mathcal{M} \to \mathcal{M}$ satisfying $\psi_p\psi_q = \psi_q\psi_p$ and $\psi_p|_{\mathbb{Z}_p} = \mathrm{id}$.

(F3) Hecke-eigen decomposition. Global sections decompose as a restricted tensor product

$$\mathcal{V}^{\mathrm{prim}}(\mathbb{C}_\infty) = \bigotimes_p{}' \mathcal{H}^{(p)}$$

with specified reference vectors $|0\rangle_p$ and separately specified intertwiners for its Adams and Hecke operators.

(F4) Archimedean–finite compatibility. The archimedean Heisenberg level is $k_\infty = 1$, hence $v_p(k_\infty) = 0$ for every finite prime. The finite arithmetic datum is carried by the Satake eigenvalue a_p, not by a p-adic valuation of the archimedean level.

(F5) Regular p-adic product. At each finite place p, the local factor $\mathcal{H}^{(p)}$ carries regular (non-singular) commutative multiplication and Adams endomorphism ψ_p among its specified operations. The product $\mathcal{H}^{(p)} \otimes \mathcal{H}^{(p)} \to \mathcal{H}^{(p)}$ is the commutative multiplication in the Fock module: a commutative algebra structure, distinct from a BD factorization-algebra fusion.

Remark 30.6.2 *(scope of the five conditions).* Conditions (F1)–(F5) specify proposed local objects, coefficient actions and comparisons. The commutative product and index-shift action on the finite polynomial carrier satisfy the algebraic part of (F5). The geometric structure maps in (F1), the coefficient comparison in (F2), and the global tensor and operator identifications in (F3) require separate constructions. No arithmetic factorization existence theorem follows from this local polynomial calculation.

30.7 Classical Factorization at Finite Places: Absence of a BV Action Functional

Remark 30.7.1 *(BV quantization requires action functional).* CG Vol. I §4 constructs a factorization algebra of observables as a BV-quantization of a classical field theory $(\mathcal{E}, S)$. For the free boson on $C/\mathbb{C}$: $\mathcal{E} = \Gamma(C, \Omega^1_C)[-1]$, action $S[\phi] = \int_C \phi \wedge \bar{\partial}\phi$, the quantum factorization algebra is the Heisenberg factorization algebra (CG Vol. I Thm 4.6.1; as a translation-equivariant factorization algebra on $\mathbb{C}$, this recovers the Heisenberg vertex algebra, but the two structures are distinct: factorization algebra ≠ vertex algebra).

Observation 30.7.2 *(arithmetic differential forms and the free-field obstruction).* The sheaf of Kähler differentials $\Omega^1_{\overline{\mathbb{Z}}/\mathbb{Z}}$ on $\overline{\operatorname{Spec}\,\overline{\mathbb{Z}}}$ is zero in the ordinary algebraic sense; Arakelov geometry replaces it with a metrised line bundle at the archimedean place. A classical free-field action at a finite place p would require a section of $\Omega^1_{\overline{C}/\mathbb{F}_1}$ in a neighbourhood of p; the requisite $\mathbb{F}_1$-geometry remains unconstructed.

Remark 30.7.3. Borger's Frobenius-lift criterion has the torsion-free scope stated in Theorem 28.4.2. The monomial and Hall integral lattices carry different reductions. The shifts ψ_n preserve both, but are Frobenius lifts only on the latter. The divisor maps T_n also preserve both lattices and fail that condition even on the Hall lattice. These operations supply no action functional, BV bracket or geometric factorization map.

THEOREM 30.7.4 *(finite polynomial Adams datum).* For each finite arithmetic place p, let $P_{\mathbb{Z}_p} = \mathbb{Z}_p[x_k : k \geq 1]$. Its ordinary product, vacuum 1, and substitutions $\psi_n(x_k) = x_{nk}$ give a unital commutative algebra with an $\mathbb{N}^\times$-action. The prescribed ψ_p is not a Frobenius lift on this monomial lattice. An action functional or factorization algebra on $\operatorname{Spf}\,\mathbb{Z}_p$ is additional data.

Proof. The polynomial product and substitutions are defined over $\mathbb{Z}_p$, and $\psi_m\psi_n(x_k) = x_{mnk}$ proves the monoid law on generators. The two distinct monomials in $\psi_p(x_1) - x_1^p = x_p - x_1^p$ remain distinct modulo p. This proves the claimed failure of this particular Frobenius lift; it proves no impossibility of other integral structures or field theories. □

30.8 Factorization Boundary

(i) The finite-subset functor of $\operatorname{Spec}\,\mathbb{Z}(S)$ is terminal. Finite sets and multisets of places are separate discrete index sets (Observation 30.1.1, Definition 30.1.2).

(ii) Finite coefficient tensors give coherent factorization for disjoint place labels. Their geometric collision maps require additional data (Corollary 30.2.2).

(iii) The completed tensor product $\mathbb{Z}_p \mathbin{\widehat{\otimes}}_{\mathbb{Z}} \mathbb{Z}_p \cong \mathbb{Z}_p$ makes the completed base diagonal an isomorphism. Formal position discs and derived closed-point intersections retain normal data (Observation 30.3.1, Theorem 30.3.3).

(iv) At each finite place the vacuum gives a pointed module. A factorization structure on a formal scheme is additional geometry (Remark 30.4.1).

(v) The proposed relative datum includes a holomorphic factorization algebra on $\mathbb{C}_\infty$ with $\widehat{\mathbb{Z}}$-module coefficients and commuting Adams operations, as in (F1)–(F5) (Definition 30.5.3, Definition 30.6.1).

(vi) The monomial finite-place carrier has an Adams action whose prime shift fails the Frobenius congruence. BV quantization requires a separately supplied classical action functional (Theorem 30.7.4).

A Costello–Gwilliam window, if constructed with the stated data, is a holomorphic factorization algebra on $\mathbb{C}_\infty$ with an adelic local system decoration (axioms (F1)–(F5)); the full Hochschild trace class itself is not thereby made a vertex algebra.

Chapter 31

The Arithmetic Instanton Partition Function

Nekrasov's partition function has two equivariant parameters and a Coulomb modulus. The Hartnoll–Yang $L(s)$ sees only the degenerate ($\epsilon_2 \to \infty, b \to 0$) arithmetic limit; the full Ω-background is absent.

31.1 Nekrasov's Z_{inst} on $\mathbb{C}^2$

Theorem 31.1.1 *(Nekrasov, hep-th/0206161 Thm 2; Nekrasov–Okounkov hep-th/0306238 §3).* . For $U(N)$ gauge theory on $\mathbb{C}^2$ with equivariant torus action by (t_1, t_2) on $(z_1, z_2) \in \mathbb{C}^2$, $\epsilon_i = \log t_i$:

$$Z_{\text{inst}}^{U(N)}(\vec{a}, \epsilon_1, \epsilon_2; \Lambda) = \sum_{\vec{\lambda}} \Lambda^{N|\vec{\lambda}|} \prod_{\alpha,\beta=1}^{N} \prod_{s \in \lambda^{(\alpha)}} \frac{1}{E_{\alpha\beta}(s)(\epsilon_1 + \epsilon_2 - E_{\alpha\beta}(s))}$$

with $E_{\alpha\beta}(s) = a_\alpha - a_\beta - \epsilon_1 L_{\lambda^{(\beta)}}(s) + \epsilon_2(A_{\lambda^{(\alpha)}}(s) + 1)$, where $A_\lambda(s)$ (resp. $L_\lambda(s)$) denotes the arm length (number of boxes strictly to the right of s in λ) and leg length (number of boxes strictly below s in λ). This is the Nekrasov–Okounkov arm-on-α, leg-on-β convention.

31.2 The Arithmetic Curve as a One-Dimensional Object: No Instanton Sector

Observation 31.2.1. $\mathbb{C}^2$ is real 4-dimensional with a T^2 torus action. The Arakelov-compactified arithmetic curve $\overline{C} = \overline{\operatorname{Spec} \mathbb{Z}}$ has arithmetic Krull dimension 1; arithmetic Chow groups $\widehat{\mathrm{CH}}^*(\overline{C})$ live only in degrees 0, 1. There is no $\widehat{\mathrm{CH}}^2$; no instanton class.

Corollary 31.2.2. . A $U(N)$-gauge theory on the arithmetic 1-dimensional $\overline{C}$ is 2d Yang–Mills in character with no instanton sector. The primon partition function $L(s)$ is the degenerate Nekrasov limit on the self-product $\overline{C} \times_{\mathbb{F}_1} \overline{C}$, not a direct $Z_{\text{inst}}^{U(2)}$ on $\overline{C}$.

31.3 The Self-Product $\overline{C} \times_{\mathbb{F}_1} \overline{C}$ as Arithmetic Surface

Principle 31.3.1 *(Deligne).* Arakelov-theoretic constructions on Spec $\mathbb{Z}$ become two-dimensional on the self-product. Durov's arXiv:0704.2030 and Connes–Consani arXiv:1405.4527 and arXiv:1502.05580 supply the $\mathbb{F}_1$ base over which $\overline{C} \times_{\mathbb{F}_1} \overline{C}$ is a surface.

Definition 31.3.2 *(arithmetic surface setup).* On the self-product $\overline{C} \times_{\mathbb{F}_1} \overline{C}$:

- Torus action: $\mathbb{G}_m(\mathbb{F}_1)^2 = \{1\}^2$ literally, or $(\mathbb{Z}_{>0}, \times)^2$ in Connes–Consani semigroup form.
- Fixed points: pairs (p, q) of primes; or single primes p on the diagonal.
- Equivariant weights: $\epsilon_p = \log p$ per prime.

31.4 RANK ANALYSIS: $U(1)^\infty$ PER PRIME

Observation 31.4.1. The primon construction $\mathcal{V}^{\mathrm{prim}}$ carries Coulomb-branch moduli $\{a_p\}_p$ indexed by primes. The gauge rank is $|\mathbb{P}| = \aleph_0$, and $L(s)$ is the arithmetic Nekrasov partition function of a $U(1)^{\mathbb{P}}$ (abelian, rank-$\aleph_0$) theory with one Coulomb factor per prime.

Definition 31.4.2 *(abelian arithmetic Nekrasov per prime).*

$$Z^{U(1)}_{\mathrm{inst},p}(a_p, \epsilon_1^{(p)}, \epsilon_2^{(p)}; \Lambda_p) \;=\; \sum_{\lambda} \Lambda_p^{|\lambda|} \prod_{s\in\lambda} \frac{1}{E_{\mathrm{II}}(s)\big(\epsilon_1^{(p)} + \epsilon_2^{(p)} - E_{\mathrm{II}}(s)\big)},$$

the $N = 1$ specialisation of Chapter 31.1.1 with $E_{\mathrm{II}}(s) = -\epsilon_1^{(p)} L_\lambda(s) + \epsilon_2^{(p)}(A_\lambda(s) + 1)$. On the CY / Nekrasov–Okounkov slice $\epsilon_1 + \epsilon_2 = 0$, $\epsilon_1 = -\epsilon_2 = \hbar$:

$$Z^{U(1),\mathrm{CY}}_{\mathrm{inst}} \;=\; \sum_{\lambda} \frac{\Lambda^{|\lambda|}}{\prod_{s\in\lambda} h_\lambda(s)^2} \;=\; \exp(\Lambda),$$

after absorbing the $\epsilon_1\epsilon_2$-normalisation into Λ. The equality is the hook-length identity $\sum_{\lambda\vdash n} \prod_{s\in\lambda} h_\lambda(s)^{-2} = 1/n!$.

COMPUTATION 31.4.3. At $\Lambda_p = p^{-s}$:

$$Z^{U(1),\mathrm{CY}}_{\mathrm{inst},p}(s) \;=\; \exp(p^{-s}).$$

The product over primes gives

$$\prod_p Z^{U(1),\mathrm{CY}}_{\mathrm{inst},p}(s) \;=\; \exp\!\left(\sum_p p^{-s}\right).$$

This is the first plethystic logarithmic term of the Euler product, not the Euler factor itself. The factor $(1 - p^{-s})^{-1}$ belongs to the arithmetic Fock degeneration below.

31.5 THE $\epsilon_2 \to \infty$ DEGENERATION

Definition 31.5.1 *(degenerate per-prime limit).* Set per prime p:

$$\epsilon_1^{(p)} = \log p, \qquad \epsilon_2^{(p)} = +\infty.$$

In this limit $1/\epsilon_2^{(p)} \to 0$ and every Young diagram with $|\lambda| \geq 2$ contributes 0. The sum collapses to

$$Z^{U(1)}_{\mathrm{inst},p}\big|_{\mathrm{arith}} \;=\; 1 + p^{-s}.$$

THEOREM 31.5.2 *(primon partition as degenerate Nekrasov).* . The Hartnoll–Yang primon partition function $\zeta(s)$ is obtained from a per-prime theory only if the charge-k contribution survives with weight p^{-ks} for every $k \geq 0$:

$$\boxed{\zeta(s) \;=\; \prod_p \sum_{k\geq 0} p^{-ks} \;=\; \prod_p (1 - p^{-s})^{-1}.}$$

For a rank-N local system ρ, the analogous Euler factor is $\det(1 - p^{-s}\rho_p(\mathrm{Frob}_p))^{-1}$; that is a separate rank-N extension, not the primon rank statement. The two-term $\epsilon_2 \to \infty$ degeneration gives $\prod_p(1 + p^{-s})$, not the Euler product. The Euler factor therefore belongs to the all-charge Fock specialization, not to the vanishing of all Young diagrams of size at least 2.

31.6 Arakelov Coulomb Modulus

Definition 31.6.1 *(arithmetic Coulomb modulus).* The complex parameter $s = \sigma + i\tau \in \mathbb{C}$ (as in p^{-s}) decomposes via the Arakelov degree map: its real part $\sigma = \mathrm{Re}(s)$ is the arithmetic first Chern class

$$\sigma \;=\; \widehat{c}_1\big(\mathcal{O}(\sigma\cdot[\infty])\big) \;\in\; \widehat{\mathrm{CH}}^1(\overline{C})\otimes\mathbb{R} \;\cong\; \mathbb{R},$$

under the canonical identification of $\widehat{\mathrm{CH}}^1(\overline{C})\otimes\mathbb{R}$ with $\mathbb{R}$ by the archimedean degree map; the imaginary part $\tau = \mathrm{Im}(s)$ parameterises the unitary direction (Hecke-character / spectral angle). The Nekrasov Coulomb modulus $\vec{a}$ is replaced by this single arithmetic modulus s. The Hecke-character tuple $\{\theta_p\}$ is the arithmetic analogue of the non-trivial Coulomb splitting $a_\alpha - a_\beta$ for $U(N)$.

Remark 31.6.2 *(Gillet–Soulé Arakelov pairing).* On $\overline{C}\times\overline{C}$ the height pairing at $\infty\times\infty$ is $s\cdot s'$ up to finite contributions (Gillet–Soulé *Arithmetic intersection theory*, Publ. IHES 1992).

31.7 Nekrasov–Shatashvili Limit: $\log\zeta(s) = \sum_p \mathcal{W}_p^{\mathrm{NS}}(s)$

Theorem 31.7.1 *(arithmetic NS identity).* . The regulated per-prime NS superpotential $\mathcal{W}_p^{\mathrm{NS}}(s) = \log(1-p^{-s})^{-1} = \sum_{k\ge1} p^{-ks}/k$ sums over primes to

$$\boxed{\log\zeta(s) \;=\; \sum_p \mathcal{W}_p^{\mathrm{NS}}(s).}$$

The Dedekind zeta logarithm is the sum over primes of the arithmetic Nekrasov–Shatashvili superpotential, evaluated at arithmetic Coulomb modulus s.

31.8 AGT: Semiclassical Liouville Degenerates to Free Boson

Remark 31.8.1 *(AGT obstruction).* AGT (Alday–Gaiotto–Tachikawa arXiv:0906.3219): $Z^{U(2)}_{\mathrm{inst}}(\vec{a},\epsilon_1,\epsilon_2;\Lambda) = \mathcal{B}^{\mathrm{Liouville}}_{c,\Delta_i}(\vec{q})$ with $c = 1+6(b+b^{-1})^2$, $b^2 = \epsilon_1/\epsilon_2$. In the arithmetic limit $\epsilon_2\to\infty$, $b\to 0$: $c\to\infty$. The AGT correspondence at finite b requires Liouville theory at finite central charge; its $b\to 0$ limit yields the semiclassical Liouville theory, which degenerates further to a free boson (Theorem 31.8.2).

Theorem 31.8.2 *(semiclassical-Liouville → free boson).* (Teschner arXiv:hep-th/0104158; Harlow–Maltz–Witten arXiv:1108.4417). In the $b\to 0$ limit, Virasoro degenerates to Heisenberg: the Liouville primary $V_\alpha = e^{2\alpha\varphi}$ with $\alpha = \alpha_0 + \alpha_1 b$ becomes a free-boson vertex operator of charge α_0; Virasoro conformal blocks become free-boson correlators.

Corollary 31.8.3 *(arithmetic AGT at $b\to 0$).* . Per prime,

$$Z^{U(1)}_{\mathrm{inst},p}\big|_{b^{(p)}\to 0}(\Lambda_p) \;=\; \mathrm{Tr}_{\mathrm{Sym}(\mathbb{C}a_{-1})}(\Lambda_p^{N_p}) \;=\; (1-\Lambda_p)^{-1}.$$

At $\Lambda_p = p^{-s}$ this gives the primon Heisenberg trace $(1-p^{-s})^{-1}$ per prime.

Theorem 31.8.4 *(Hartnoll–Yang primon trace = $b\to 0$ AGT).* .

$$L(s) \;=\; \prod_p Z^{U(1)}_{\mathrm{inst},p}\big|_{\mathrm{AGT},\,b\to 0}(s) \;=\; \prod_p \langle \mathcal{H}^{(p)}_{k=1}\rangle_{\mathrm{partition}}.$$

The rank-1 Heisenberg per prime is the semiclassical-Liouville degeneration of Virasoro at prime p, and the AGT map reduces to a free-boson partition at each place.

31.9 MAULIK–OKOUNKOV AND THE BETHE-HECKE SHADOW

THEOREM 31.9.1 *(Maulik–Okounkov arXiv:1211.1287, Thm 1.5.1).* . The R-matrix on equivariant cohomology of the instanton moduli space $\mathcal{M}_{N,k}$ generates the Yangian $Y(\widehat{\mathfrak{gl}}_N)$. $Z^{U(N)}_{\text{inst}}$ is the trace of the holonomy of the MO R-matrix.

Definition 31.9.2 *(primon Bethe-Hecke shadow).* The *primon Bethe-Hecke shadow* is the commutative Bethe/Hecke algebra acting on the arithmetic instanton model. Fixed-point data are indexed by N-tuples of Young diagrams per prime; the arithmetic action surviving the $\epsilon_2 \to \infty$ degeneration is through Hecke transfer operators, not an RTT R-matrix or Yangian Hopf structure.

THEOREM 31.9.3 *(L-function as MO trace).* . $L(s, \rho)$ is the Bethe/Hecke transfer trace in the arithmetic instanton shadow. The Maulik–Okounkov Yangian $Y(\widehat{\mathfrak{gl}}_N)$ governs the complex-geometric instanton count; its arithmetic avatar, in the degenerate limit, is the commutative Hecke algebra acting at each prime.

31.10 THE TOPOLOGICAL-SECTOR READING (COMPATIBLE WITH NEKRASOV)

Remark 31.10.1 *(Kurokawa/Deninger).* The identity $L(s) = \sum_{n\geq 1} n^{-s}$ expresses $\zeta(s)$ as a sum over arithmetic topological classes with p-adic valuation $v_p(n)$; the term n^{-s} carries the arithmetic class indexed by the prime factorization of n. From the $\mathbb{F}_1$-zeta perspective of Kurokawa (Proc. Japan Acad. 2005) and Deninger (1994), $\zeta(s) = \det(s - \Theta)^{-1}_{\text{reg}}$ for a hypothetical cohomological operator Θ.

THEOREM 31.10.2 *(motivic-topological compatibility).* . The motivic instanton partition function (Nekrasov–Okounkov §4; Behrend motivic DT arXiv:math/0507523) on the arithmetic surface localises in the $\epsilon_2 \to \infty$ limit to the $\mathbb{F}_1$-cohomological partition sum. Young diagrams collapse to their size $|\lambda|$, which labels the instanton number c_2^{Ar}, and the c_2^{Ar}-sum becomes the v_p-sum:

$$Z^{U(N),\text{arith}}_{\text{inst},p}(s, \rho_p) \;=\; \det(1 - p^{-s}\rho_p(\text{Frob}_p))^{-1}.$$

31.11 THE ($\epsilon_2 \to \infty$, $b \to 0$) DEGENERATE LIMIT: STRUCTURE OF $L(s)$

(i) The arithmetic curve $\overline{C}$ has arithmetic Krull dimension 1; Nekrasov's $\mathbb{C}^2$ is real dimension 4. The self-product $\overline{C} \times_{\mathbb{F}_1} \overline{C}$ is the arithmetic surface carrying the instanton data (Chapter 31.3.1).

(ii) The gauge group is $U(1)^{\mathbb{P}}$, abelian, rank $\aleph_0$ (Chapter 31.4.1).

(iii) The Ω-background per prime is $(\epsilon_1^{(p)}, \epsilon_2^{(p)}) = (\log p, +\infty)$ (Chapter 31.5.1).

(iv) The primon partition function $L(s)$ is the ($\epsilon_2 \to \infty$, $b \to 0$) degenerate Nekrasov limit (Chapter 31.5.2).

(v) The Coulomb modulus is the arithmetic first Chern class $s = \widehat{\deg}\, O(\sigma)$ (Chapter 31.6.1).

(vi) $\log \zeta(s) = \sum_p \mathcal{W}_p^{\text{NS}}(s)$: the zeta logarithm is the sum of arithmetic Nekrasov–Shatashvili superpotentials (Chapter 31.7.1).

(vii) In the $b \to 0$ AGT limit, the Liouville conformal block at prime p degenerates to the free-boson partition function $(1 - p^{-s})^{-1}$ (Chapter 31.8.3).

(viii) The Maulik–Okounkov R-matrix reduces, in the arithmetic degeneration, to the Hecke transfer algebra; $L(s, \rho)$ is the Hecke transfer trace (Chapter 31.9.3).

$L(s)$ is the ($\epsilon_2 \to \infty$, $b \to 0$) degenerate limit of the Nekrasov partition function: the Euler-factor data of the Ω-background survives; the full instanton moduli geometry contracts to fixed-point contributions labeled by $\epsilon_1^{(p)} = \log p$ per prime.

Chapter 32

The Arithmetic Modular Functor

Segal's modular functor assigns conformal blocks to marked Riemann surfaces and uses sewing along circles. The arithmetic curve has no such sewing category. Tate theory supplies the object occupying the same formal position.

32.1 Axioms and Their Translation

Each Segal axiom for a Riemann surface $\Sigma_{g,n}$ – finiteness of conformal blocks, sewing along circles, modular invariance, and the partition-function trace – has an arithmetic analogue on the Arakelov curve $(\overline{\operatorname{Spec} \mathcal{O}_K}, S)$. The entries below are a dictionary of roles. They are not literal identifications of the two categories.

Convention 32.1.1 *(arithmetic Segal dictionary).*

Geometric Segal	Arithmetic Segal
Riemann surface $\Sigma_{g,n}$	Arakelov curve $(\overline{\operatorname{Spec} \mathcal{O}_K}, S)$
Orientation	Trivialization of $\det R\Gamma$ (Deligne)
Genus contribution	Arakelov discriminant volume $\frac{1}{2}\log\lvert d_K\rvert$
Marked point	Place (finite or archimedean)
Sewing circle	Punctured formal disk $\operatorname{Spec} K_{\mathfrak{p}}$
Intermediate rep	Weil–Deligne parameter (ρ, N)
Sewing law	Euler-product factorization of $L(s,\chi)$
Monodromy $U(1)$	Frobenius $\alpha_p = \chi_p(p)$
$\mathrm{MCG}(\Sigma)$	arithmetic symmetry group acting on labels and Hecke lines
Modular S-matrix	Γ-factor + functional equation
Verlinde scalar	Class-number residue at $s = 1$
Conformal block at $\{V_i\}$	Tate integral $\prod_v \int \lvert\cdot\rvert^s \Phi_v$
$Z(\Sigma) = \operatorname{tr} q^{L_0 - c/24}$	finite Euler product $\prod_{\mathfrak{p}} (1 - N\mathfrak{p}^{-s})^{-1}$, completed by the archimedean Tate factors

32.2 Arakelov Discriminant as Lattice Volume

Observation 32.2.1 *(the discriminant term is not a genus).* The geometric genus satisfies $g = \frac{1}{2}\dim_{\mathbb{R}} H^1(\Sigma;\mathbb{R})$; equivalently, the Jacobian $J(\Sigma) = H^0(\Sigma,\Omega^1)^*/H_1(\Sigma,\mathbb{Z})$ is a g-dimensional torus whose Weil height is $\frac{1}{2}\log\det(\operatorname{Im}\tau)$ for the period matrix τ. The arithmetic analogue is $\frac{1}{2}\log\lvert d_K\rvert = \frac{1}{2}\log(\operatorname{covol}(\mathcal{O}_K \subset K \otimes_{\mathbb{Q}} \mathbb{R}))$. Both are half-logarithms of lattice covolumes; the functional is the same, the lattices differ. The number $\frac{1}{2}\log\lvert d_K\rvert$ is not an integer genus and is not a Betti number.

Definition 32.2.2 *(arithmetic Euler characteristic).*

$$\chi^{\mathrm{arith}}(\overline{X}) \;:=\; -\widehat{\deg}\,\omega_{\overline{X}} + \sum_{v\mid\infty} \log \|\cdot\|_v .$$

On $\operatorname{Spec} O_K$ with signature (r_1, r_2), $\chi^{\mathrm{arith}} = \log|d_K| - r_1\log(\pi/4) - r_2\log(\pi/2)$ by Minkowski–Odlyzko. Additive on disjoint unions of Arakelov surfaces.

32.3 Weil–Deligne Sewing

THEOREM 32.3.1 *(sewing law).* .

Here $\mathcal{F}^{\mathrm{arith}}$ denotes the arithmetic modular functor defined in Definition 32.8.1 (an adelically factorized assignment of meromorphic lines to Arakelov surfaces with marked places); and $\mathcal{V}^{\mathrm{prim}}$ denotes the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2 (a class in K-theory, not a vertex algebra). The ℓ-adic coefficient system at a non-archimedean prime $\mathfrak{p}$ is the étale cohomology local system attached to $\mathcal{V}^{\mathrm{prim}}$ via the comparison isomorphism $H^*_{\text{ét}}(-, \mathbb{Q}_\ell)$ for any prime $\ell \neq p$; this is the coefficient ring of the Weil–Deligne representation, not an enrichment of $\mathcal{V}^{\mathrm{prim}}$ with vertex-algebra structure.

$$\mathcal{F}^{\mathrm{arith}}(\overline{X}_1 \cup_p \overline{X}_2) \;=\; \bigoplus_{(\rho,N)} \mathcal{F}^{\mathrm{arith}}(\overline{X}_1; \rho, N) \otimes_{\mathrm{End}(\rho)} \mathcal{F}^{\mathrm{arith}}(\overline{X}_2; \rho, N)^*$$

where (ρ, N) runs over isomorphism classes of Weil–Deligne representations of $W_{\mathbb{Q}_p}$ whose coefficients are ℓ-adic ($\ell \neq p$), ρ continuous, N the monodromy operator.

Remark 32.3.2 *(labels are Langlands parameters).* Segal's intermediate representation labels are local Galois representations. At archimedean places, sewing is along Hodge structures (Weil-group representations of $W_{\mathbb{R}}$ or $W_{\mathbb{C}}$). The correspondence between WZW representation labels and automorphic representations under local Langlands is:

$$\{\text{irr. admissible } G(\mathbb{Q}_p)\text{-reps}\} \;\leftrightarrow\; \{\text{Weil–Deligne } L\text{-parameters}\}.$$

The arithmetic functor uses local Langlands parameters in the Segal sewing position.

32.4 Arithmetic Symmetries

Observation 32.4.1. The arithmetic symmetry group has two complementary actions. The Galois group $\mathrm{Gal}(\overline{K}/K)$ controls label permutations: it acts on Weil–Deligne parameters at marked places, the arithmetic counterpart of the deck transformations on the geometric surface. The adelic quotient $\mathrm{GL}_n(\mathbb{A}_K)/\mathrm{GL}_n(K)$ acts through Hecke correspondences on automorphic lines. This pair is the arithmetic replacement for the geometric mapping-class action; it is not a mapping class group of a surface.

THEOREM 32.4.2 *(arithmetic symmetry action).* . There is an arithmetic symmetry action in which $\mathrm{Gal}(\overline{K}/K)$ acts on local Langlands labels and $\mathrm{GL}_n(\mathbb{A}_K)$ acts by Hecke correspondences. At an unramified prime p, Frobenius generates the quotient $\mathrm{Gal}(\bar{k}_p/k_p) \cong \widehat{\mathbb{Z}}$. This is only the unramified quotient of local monodromy; the inertia and wild inertia are not Dehn twists and are not discarded in ramified sewing.

32.5 Verlinde Scalar and the Class Number Formula

Theorem 32.5.1 *(arithmetic Verlinde).* (Tate's thesis, class number formula). The arithmetic Verlinde scalar attached to the empty-marking sector is the residue of the Dedekind zeta at $s = 1$:

$$\boxed{\mathsf{Ver}^{\mathrm{arith}}(K) \;:=\; \mathrm{Res}_{s=1}\zeta_K(s) \;=\; \frac{2^{r_1}(2\pi)^{r_2}h_K R_K}{w_K\sqrt{|d_K|}}.}$$

This scalar is generally not an integer dimension of conformal blocks; it is the class-number residue in the Verlinde position of the arithmetic analogy.

32.6 Explicit Computation: Conformal Blocks via Tate Integrals

Computation 32.6.1 *(conformal block at* $(\mathbb{Z}, \{p, \infty\}, \mathrm{triv})$*).* $\mathcal{F}^{\mathrm{arith}}(\mathrm{Spec}\,\mathbb{Z}, \{p, \infty\}, V_{\mathrm{vac}} \otimes \lambda_\infty)$ is spanned by the Tate integral

$$\Phi_p(s) \;=\; \Lambda_\zeta(s) \cdot (1 - p^{-s}),$$

where $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$ is the completed Riemann zeta (Tate's thesis, §3.4). Removing the p-th Euler factor from $\zeta(s)$ gives $\zeta(s)(1 - p^{-s})$; multiplication by $\pi^{-s/2}\Gamma(s/2)$ completes to $\Lambda_\zeta(s)(1 - p^{-s})$. Dimension: 1.

Observation 32.6.2. The vacuum conformal block at prime p is the completed zeta function with the p-th Euler factor removed. The sewing axiom at p reinserts it.

Computation 32.6.3 *(sewing at* $\{2, 3\}$*).* The vacuum conformal block at marked places $\{2, 3, \infty\}$ is $\Lambda_\zeta(s)(1 - 2^{-s})(1 - 3^{-s})$ (the completed zeta with the Euler factors at 2, 3 removed; Chapter 32.6.2). Sewing at the two finite places with unramified Satake parameters $\alpha_p = \chi_p(p) \in \{\pm 1\}$ reinserts the twisted Euler factors:

$$\Phi(s) \;=\; \Lambda_\zeta(s)\,\frac{(1 - 2^{-s})(1 - 3^{-s})}{(1 - \alpha_2 \cdot 2^{-s})(1 - \alpha_3 \cdot 3^{-s})},$$

where $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$. For trivial Satake $(\alpha_2, \alpha_3) = (1, 1)$ one recovers $\Phi(s) = \Lambda_\zeta(s)$; for a character with local data specified only at 2 and 3, this is only a two-prime partial twist. The full completed L-function $\Lambda(s, \chi)$ is obtained only after replacing the Euler factor at every finite prime by $(1 - \chi(p)\,p^{-s})^{-1}$, together with the correct archimedean factor and conductor.

32.7 Functional Equation as Sewing Axiom

Theorem 32.7.1 *(Tate's global functional equation).* .

Let $\Lambda(s, \chi)$ denote the completed Dirichlet L-function with its conductor and parity-dependent archimedean factor. Then

$$\Lambda(s, \chi) \;=\; \varepsilon(\chi) \cdot \Lambda(1 - s, \chi^{-1}),$$

where $\varepsilon(\chi)$ is the root number, proved by adelic Poisson summation (Tate's thesis, §4.4). The arithmetic analogue of Segal sewing is the functional equation.

Remark 32.7.2 *(finiteness reading).* The content of sewing is not dimension 1 per se; it is the $s \leftrightarrow 1 - s$ involution on the one-dimensional line whose invariants are the values of the completed L-function.

32.8 FIVE-AXIOM ARITHMETIC MODULAR FUNCTOR

Definition 32.8.1. An *arithmetic modular functor* is a functor

$$\mathcal{F}\colon \mathcal{C}^{\mathrm{Arak}} \to \mathrm{Hom}(\mathbb{C}_s, \mathrm{Line})$$

(from Arakelov surfaces to lines depending meromorphically on a parameter s) satisfying:

(A1) Finiteness. $\mathcal{F}(\overline{X}, S, \{\chi_{\mathfrak{p}}\})$ is a 1-dimensional meromorphic line, with pole divisor prescribed by the completed L-function represented by the line.

(A2) Factorization. For independent places, $\mathcal{F}(\overline{X}, S, \{\chi_{\mathfrak{p}}\}) = \bigotimes_{\mathfrak{p}\in S} \mathcal{F}_{\mathfrak{p}}(\chi_{\mathfrak{p}})$.

(A3) Weil–Deligne sewing. For $S = S_1 \sqcup S_2$ along a parameter (ρ, N) at an extra prime $\mathfrak{q}$,

$$\mathcal{F}(\overline{X}, S \cup \{\mathfrak{q}\}) \;=\; \sum_{(\rho,N)} \mathcal{F}(\overline{X}_1, S_1 \cup (\rho, N)) \cdot \mathcal{F}(\overline{X}_2, S_2 \cup (\rho, N))^{-1},$$

summed over unramified (ρ, N).

(A4) Modular invariance. the Galois action on local labels and the Hecke action of $GL_n(\mathbb{A}_K)$ act on the functor.

(A5) Functional equation.

$$\mathcal{F}(\overline{X}, S, \chi)(s) \;=\; \varepsilon(\chi) \cdot \mathcal{F}(\overline{X}, S, \chi^{-1})(1 - s).$$

This is the arithmetic modular invariance: $\mathrm{SL}_2(\mathbb{Z})$ becomes the $\mathbb{Z}/2$ flip $s \leftrightarrow 1 - s$.

THEOREM 32.8.2 *(Tate line in the arithmetic Segal position).* (Tate's thesis). Tate's adelic construction gives a meromorphic L-line satisfying (A1)–(A5) in the zeta and Dirichlet sectors. No uniqueness is asserted before the source category and the local test-line normalizations are fixed.

The geometric and arithmetic Segal functors are different functors. The conjecture says that Tate's L-functor satisfies the arithmetic axioms occupying the Segal positions.

Chapter 33

Arithmetic bar constructions and residue comparisons

Continuous Galois cochains give an integral arithmetic input to the coefficient bar. Their relative products and coefficient limits are constructed in Chapter 10. A comparison with chiral collision operations requires residue complexes on the geometric carrier. It also requires compatible operations and maps identifying them with the coefficient model. The elementary residue and bar constructions below specify what is available before making that comparison.

33.1 Incidence of finite places

Observation 33.1.1. The ordered n-tuples of distinct finite places of Spec $\mathbb{Z}$ form a countable set. Giving this set the discrete topology produces a combinatorial configuration model. It is not an identification with the scheme configuration functor, and its distinct-place tuples contain no collision locus. A topology describing collisions must be supplied separately.

Definition 33.1.2 *(incidence poset of arithmetic places).* Let $\mathcal{I}_K$ be the poset of finite subsets of the finite places of K, ordered by inclusion. Its order complex has a simplex for every finite strict chain of such subsets. The simplicial cochains of this order complex are a combinatorial coefficient complex. They do not by definition carry the differential forms or residues of a geometric configuration space.

A motivic fundamental group is another construction with a specified base and category of motives. Relating its operations, or those of a Grothendieck–Teichmüller Lie algebra, to this incidence complex requires an actual map. Neither a common set of prime labels nor a formal resemblance between relations provides that map.

33.2 Steinberg symbols and reciprocity

Observation 33.2.1 *(constant differences).* For two distinct rational primes p, q, the difference $p - q$ is a constant in $\mathbb{Q}^\times$. Its relative differential in $\Omega^1_{\mathbb{Q}/\mathbb{Q}}$ is zero. Thus it does not supply the nonzero logarithmic form associated with moving insertion coordinates on a complex curve.

Theorem 33.2.2 *(Steinberg relation and the rational tame symbols).* In Milnor K-theory, $\{a, 1 - a\} = 0$ for $a \neq 0, 1$. In particular $\{p, 1 - p\} = 0$ in $K_2^M(\mathbb{Q})$. Tate's theorem identifies

$$K_2^M(\mathbb{Q}) \cong \{\pm 1\} \oplus \bigoplus_p \mathbb{F}_p^\times$$

by the real sign symbol together with the finite tame symbols. The finite symbols alone have an order-two kernel.

Proof. The first assertion is a defining relation of K_2^M. The isomorphism is the external theorem stated in Theorem 10.9.2. The class $\{-1,-1\}$ has trivial finite tame symbols and real sign -1, and that theorem identifies it as the kernel generator. □

This theorem does not identify the Steinberg relation with an Arnold relation on configuration-space forms. Such an identification would need a map on the complexes carrying those relations and a comparison of their induced operations.

THEOREM 33.2.3 *(dimension-one residues and their range).* For each finite place v of K, the normalized tame symbol is a homomorphism

$$\partial_v : K_2^M(K) \longrightarrow k_v^\times, \qquad \partial_v\{\pi_v, u\} = \bar{u}.$$

There is no codimension-two term on $\operatorname{Spec} O_K$. On $\mathbb{P}^1_F$, the normed tame symbols have common recipient $F^\times$ and obey (10.8).

Proof. Proposition 10.9.1 constructs the local homomorphisms and checks their Steinberg relations. The ring O_K has dimension one, proving the second assertion. The last assertion is the tame-symbol reciprocity theorem for the projective line with its norm maps, cited in §10.9. □

For a general degree n, the dimension-one residue diagram has terms $K_n^M(K)$ and $\bigoplus_v K_{n-1}^M(k_v)$. No additional codimension-two points are produced by writing a further arrow. A surface construction instead starts from a regular arithmetic surface X, a curve $C \subset X$, and a point $x \in C$. Its successive symbols require these flags and appropriate recipients and norm maps. A sum or product of symbols in different fields is undefined until those maps are specified. Exactness and a motivic comparison are additional statements with their own coefficient hypotheses.

33.3 THE COEFFICIENT TENSOR COALGEBRA

Fix a procyclic group $\Gamma \cong \mathbb{Z}_\ell$, with chosen generator, and put $\Lambda = \mathbb{Z}_\ell[[\Gamma]]$. Proposition 10.10.1 identifies it with $\mathbb{Z}_\ell[[T]]$. If the full cyclotomic group has a finite factor, that factor must either be retained in the group ring or removed by a stated choice. It is not part of the displayed procyclic identification.

Definition 33.3.1 *(coefficient bar over Λ).* Let A be an augmented associative dg Λ-algebra, with augmentation ideal I. In cohomological grading put $sI = I[1]$. Its coefficient bar is

$$B_\Lambda A = \bigoplus_{n \geq 0} (sI)^{\otimes_\Lambda n},$$

with deconcatenation coproduct and differential $b = b_1 + b_2$, where

$$b_1(sa) = -s(da), \qquad b_2(sa \otimes sb) = (-1)^{|a|} s(ab).$$

Extend these maps as coderivations with the Koszul tensor convention. The empty word is the coaugmentation. Completion, when needed, is specified as in (10.5).

The identities $d^2 = 0$, Leibniz's rule, and associativity imply $b^2 = 0$, by Proposition 3.2.1. This is an associative coefficient construction. The primitive arithmetic $\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class and is not thereby an augmented algebra A. Its identification with such an input requires a separately constructed object, product, and augmentation.

A proposed additional residue differential must act on a common complex with the bar differential. If a residue complex is tensored with $B_\Lambda A$, the tensor is a complex. A coalgebra structure on it also requires a compatible diagonal on that residue complex. Names such as an Iwasawa differential or a tame-symbol weight do not specify degree-one endomorphisms of this tensor.

Question 33.3.2 *(a mixed arithmetic differential).* Construct a common trigraded coalgebra and coderivations d_{Iw}, d_{res}, d_{loc} of the three coordinate degrees, realizing respectively the intended Iwasawa, residue, and local bar operations. Do they satisfy

$$d_i^2 = 0, \qquad d_i d_j + d_j d_i = 0 \quad (i \neq j)?$$

With these tridegrees, the equations are equivalent to $(d_{\mathrm{Iw}} + d_{\mathrm{res}} + d_{\mathrm{loc}})^2 = 0$, since its six homogeneous components have distinct tridegrees. The first requirement is construction of the displayed maps on the same carrier. Nilpotence is the subsequent equation.

Question 33.3.3 *(archimedean comparison).* Choose an archimedean realization of the arithmetic coefficient object and a chiral algebra on a specified complex curve. Construct and test a map from the realized arithmetic bar to that chiral bar, including its operations, scalar extension, and unit.

The elementary equality $\Omega^j_{\mathbb{R}/\mathbb{R}} = 0$ for $j > 0$ supplies no such comparison: the point $\operatorname{Spec}\mathbb{R}$ is not the complex curve on which chiral collisions take place. Real Galois cochains also differ from a trivial complex at $\ell = 2$, by Proposition 10.8.1.

33.4 Graded Koszulness and arithmetic purity

Let $A = \bigoplus_{j \geq 0} A_j$ be a connected graded algebra over a field k, so $A_0 = k$, with augmentation onto degree zero. The internal weight j is distinct from resolution degree i. By definition, A is Koszul when $\operatorname{Tor}_i^A(k,k)_j = 0$ for $i \neq j$. The coefficient bar resolves this Tor group under the hypotheses of Proposition 3.3.1.

Theorem 33.4.1 *(a conditional weight criterion).* Suppose k has characteristic zero and each A_j is finite-dimensional. Assume the total groups $\operatorname{Tor}_i^A(k,k)$ are finite-dimensional, and a bar-compatible operator F preserves internal weights. Fix an embedding of its eigenvalue field into $\mathbb{C}$ and a real number $q > 1$. Assume that every eigenvalue on a nonzero internal-weight-j bar term has absolute value $q^{j/2}$. Then A is Koszul if and only if every nonzero $\operatorname{Tor}_i^A(k,k)$ is pure of weight i, meaning that its eigenvalues have absolute value $q^{i/2}$.

Proof. The differential preserves internal weight and commutes with F. Every eigenvalue on its weight-j cohomology therefore still has absolute value $q^{j/2}$, since eigenvalues on a subquotient come from the original operator. If the Tor groups are diagonal, their purity follows. Conversely, $q^{j/2} \neq q^{i/2}$ when $i \neq j$. Purity in weight i thus forces every off-diagonal summand to vanish, which is the Koszul condition. □

An arithmetic application requires the graded algebra, its realization, and the operator. It must also identify internal grading with the stated arithmetic weights. Frobenius weights, Hodge filtrations, and Sen weights are attached to different objects. An equivalence between their purity conditions is not supplied by this graded argument. The proposed criterion for a p-adic Simpson realization of $\mathcal{V}^{\mathrm{prim}}$ therefore remains a comparison problem, including existence of that realization.

Remark 33.4.2 *(comparison of realizations).* A de Rham–étale comparison theorem has a specified geometric input and coefficient range. It does not identify arbitrary mixed Hodge modules over $\mathbb{C}$ with Frobenius modules over finite fields. Any purity argument here must carry those realization hypotheses before invoking a comparison.

33.5 The primary Mellin character

The positive integers under multiplication form the free commutative monoid on the primes. Let V have a basis e_m indexed by $m \geq 1$, with energy $He_m = (\log m)e_m$. Its Mellin character is the absolutely convergent sum $\chi_V(s) = \sum_{m\geq 1} m^{-s}$ for $\operatorname{Re} s > 1$. This grading records multiplicative labels, not homological degree.

THEOREM 33.5.1 *(the multiplicative-label character).* For the displayed graded space,

$$\chi_V(s) = \prod_p (1 - p^{-s})^{-1} = \zeta(s), \qquad \operatorname{Re} s > 1.$$

If a specified primary zero-mode quotient of an arithmetic bar is isomorphic to V with these energies, it has the same Mellin character. The existence of that quotient and isomorphism is an additional hypothesis.

Proof. For finitely many primes, expansion of the geometric series and unique factorization give the sum over integers supported on those primes. Absolute convergence of $\sum_m m^{-s}$ for $\operatorname{Re} s > 1$ permits the increasing-prime limit. This proves the Euler product. A grading-preserving isomorphism preserves the summands and their energies, proving the last assertion. □

Question 33.5.2 *(the Bost–Connes comparison).* Construct an augmented arithmetic Heisenberg coefficient algebra and its Koszul dual. Is there a comparison with the Bost–Connes system that preserves the intended multiplication, module category, and time evolution? A Mellin character equal to $\zeta(s)$ is one scalar condition on such a comparison. It does not determine these objects or imply their equivalence.

33.6 Complementarity and the functional equation

Put $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$, using the meromorphic continuation of the zeta function. The classical functional equation is $\xi(s) = \xi(1-s)$. To derive it from an arithmetic duality one needs an evaluation map that turns the duality into reflection of the Mellin parameter.

Question 33.6.1 *(arithmetic complementarity).* Construct arithmetic Heisenberg and dual coefficient objects with defined central parameters $\kappa_{\mathsf{G}}^{\mathrm{Ar}}$ and $(\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}}$, together with an evaluation to completed Mellin data. Can that evaluation identify

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \quad \text{with} \quad \xi(s) = \xi(1-s)?$$

It must include the archimedean gamma factor and the polar terms, and it must identify the two functions rather than merely their uncompleted Dirichlet coefficients.

The numerical equation on central parameters has no Mellin variable. Without the requested map it proves neither meromorphic continuation nor a functional equation. An arithmetic comparison preserving the full evaluation would explain these analytic operations. An equality of characters in the half-plane of convergence leaves it open.

33.7 Coalgebra duality with Iwasawa coefficients

The coderived category of comodules and the contraderived category of contramodules use different acyclicity conventions and different infinite operations. A contramodule over a coalgebra C has a contraaction from $\mathrm{Hom}(C, P)$ to P, obeying contraassociativity and a counit identity. It is not a comodule with the arrow reversed. A co–contra comparison requires a specified coefficient category and the corresponding derived constructions.

Question 33.7.1 *(an arithmetic co–contra comparison).* For a specified dg coalgebra C over Λ, construct the comodules, contramodules, and derived categories appropriate to its topology. Under what projectivity, conilpotence, and completeness hypotheses does the comparison give an equivalence

$$D^{\mathrm{co}}(C\text{-comod}) \simeq D^{\mathrm{ctr}}(C\text{-contramod})?$$

Determine separately when the coalgebra unit $C \to B_\Lambda \Omega_\Lambda C$ and algebra counit $\Omega_\Lambda B_\Lambda A \to A$ are equivalences in the chosen categories.

The bar takes an augmented algebra as input and the cobar takes a coaugmented coalgebra. Thus the expression $\Omega_\Lambda B_\Lambda C$, with only a coalgebra C supplied, is not the coalgebra unit. The coefficient adjunction and its algebra resolution are constructed in Chapter 3. Their extension to the intended arithmetic categories remains separate. Theorem 46.1.5 gives a lifting criterion once the required adjunction is constructed.

Remark 33.7.2 *(the module μ-invariant).* For a finitely generated torsion Λ-module M, the Iwasawa invariant is $\mu(M) = \mathrm{length}_{\Lambda_{(\ell)}} M_{(\ell)}$. An arbitrary coalgebra has no such invariant without choosing a module to which the definition applies. Proposition 10.10.2 gives a conilpotent coalgebra with quotient $\mu = 1$, and a nonconilpotent one with quotient $\mu = 0$. Thus this module invariant cannot replace the coalgebra hypotheses in the displayed question.

33.8 A concrete arithmetic coefficient bar

Definition 33.8.1 *(relative Galois coefficient bar).* For the strict Galois cochain cospan with specified multiplicative local conditions over R_r, let P_r be the complex (10.3), with either endpoint product. Its arithmetic coefficient bar is

$$\mathcal{B}_r = B_{R_r}(R_r \oplus P_r).$$

The augmentation is the external scalar projection. Its coefficient completion is $\varprojlim_r \mathcal{B}_r$, with tensor target (10.5), when the local conditions and maps form a compatible coefficient tower.

Theorem 33.8.2 *(properties of the coefficient construction).* The finite-stage bars have square-zero differential and coassociative counital coproduct. They are conilpotent, and the two endpoint choices are isomorphic by the integral all-arity comparison of Chapter 11. For a compatible tower that comparison extends to the specified coefficient completion. An interpretation as a derived tensor retains the resolution hypotheses of Proposition 3.3.1.

Proof. The dg identities for the endpoint products are Proposition 11.1.1. The coefficient-bar identities then apply. Finite words admit only finitely many reduced cuts. The all-arity maps and their coefficient continuity are the constructions of Chapter 11. □

33.9 The arithmetic comparison to be constructed

The continuous-cochain bar and the local tame symbols are defined on their displayed carriers. The first has a multiplication, augmentation, and ordered bar coproduct. The second changes coefficient fields along valuations. A chiral arithmetic comparison must relate these operations, not just their prime labels.

The common residue carrier and mixed maps are asked for in Question 33.3.2. Archimedean realization requires Question 33.3.3. The arithmetic weight realization is the hypothesis needed for Theorem 33.4.1.

The Mellin model has its stated character. Its identification with a primary bar quotient, its Bost–Connes duality, and its completed functional equation comparison remain separate.

Likewise, the proposed numerical complementarity values 0, 8, 13, 250/3, 25/3 require actual arithmetic objects and computed central parameters before they classify any examples. In particular, a proposed K3–Mukai Borcherds realization of the value eight is its own construction. Neither those numerical candidates nor the Iwasawa module invariant settle the coefficient, geometric, and co–contra comparisons above.

Chapter 34

The Automorphic Vertex of the Langlands–TQFT Triangle

Kapustin–Witten realizes geometric Langlands as S-duality in $\mathcal{N} = 4$ gauge theory on $\Sigma \times C$. The arithmetic trace class has a different problem: whether the Hartnoll–Yang BKL–primon correspondence supplies a bulk theory at all.

$\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class whose graded character is $\zeta(s)$. Three TQFT frameworks (Kapustin–Witten, Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees (BLLPRvR), and Chern–Simons/WZW) offer candidate TQFT-bulk structures for the Langlands triangle. Each fails at a specific structural obstruction, placing $\mathcal{V}^{\mathrm{prim}}$ on the automorphic vertex rather than the TQFT vertex.

34.1 The Kapustin–Witten Obstruction: Absence of Complex Structure

Theorem 34.1.1 *(Kapustin–Witten setup).* . Geometric Langlands for $C/\mathbb{C}$ arises as S-duality of 4D $\mathcal{N} = 4$ super Yang–Mills (SYM) on $\Sigma \times C$ with Σ topologically twisted and C holomorphically twisted. Categories $D(\mathrm{Bun}_G)$ and $\mathrm{QCoh}(\mathrm{Loc}_{^L G})$ appear as boundary conditions; S-duality $\tau \mapsto -1/\tau$ exchanges them.

Observation 34.1.2 *(arithmetic obstruction).* $\overline{C} = \overline{\mathrm{Spec}\,\mathbb{Z}}$ is an arithmetic 1-scheme with closed-point residue fields $\mathbb{F}_p$ at each prime p, plus the archimedean place. The holomorphic twist of $\mathcal{N} = 4$ super Yang–Mills requires a complex structure on the compactified direction; $\overline{\mathrm{Spec}\,\mathbb{Z}}$ carries no such structure, its closed fibres being spectra of finite fields rather than complex-analytic curves.

Corollary 34.1.3 *(Kapustin–Witten is undefined over $\mathbb{Z}$).* . The expression "$\mathcal{N} = 4$ SYM on $\Sigma \times \overline{\mathrm{Spec}\,\mathbb{Z}}$" names no defined theory in 2026's mathematics. The Kapustin–Witten holomorphic twist requires a complex structure on the compactified direction; the topological Σ-coupling and the S-duality $\tau \mapsto -1/\tau$ are consequences. The arithmetic compactification $\overline{\mathrm{Spec}\,\mathbb{Z}}$ admits no such structure.

34.2 The BLLPRvR Obstruction: Infinite Flavour Rank

Theorem 34.2.1 *(BLLPRvR, arXiv:1312.5344).* . The Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees (BLLPRvR) correspondence assigns a vertex algebra (VA) $\chi(\mathcal{T})$ to any 4D $\mathcal{N} = 2$ superconformal field theory (SCFT) $\mathcal{T}$, with central charges satisfying $c_{2d} = -12c_{4d}$ and $k_{2d} = -\frac{1}{2}k_{4d}$.

Observation 34.2.2. The finite Heisenberg covers of the primon construction are generated by the modes $\{a_{p,n}\}_{p\in S, n\in\mathbb{Z}}$ for a finite set of primes S. The formal cover over all primes would have flavour group $\prod_{p\in\mathbb{P}} U(1)_p$, hence flavour rank $\aleph_0$. The Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ itself is not a vertex algebra, and the scalar $r_\zeta = 2$ of Chapter 35 is a determinant-rank residue rather than a two-dimensional central charge. No 4D $\mathcal{N} = 2$ SCFT has flavour symmetry of rank $\aleph_0$: the flavour rank is bounded by the gauge rank plus hypermultiplet content, both finite for any theory with a Lagrangian description.

COROLLARY 34.2.3. . The VA $\chi(\mathcal{T})$ assigned by BLLPRvR to any 4D $\mathcal{N} = 2$ SCFT $\mathcal{T}$ has finite flavour rank. The all-prime Heisenberg cover has countable flavour rank, while $\mathcal{V}^{\mathrm{prim}}$ is only its Hochschild trace class. Hence no BLLPRvR vertex algebra of a 4D $\mathcal{N} = 2$ SCFT is $\mathcal{V}^{\mathrm{prim}}$. The class-$\mathcal{S}$ construction on an infinite-genus or infinite-puncture arithmetic curve would require $\overline{\mathrm{Spec}\,\mathbb{Z}}$ to carry the complex structure of a Riemann surface, obstructed by Chapter 34.1.2.

34.3 The Chern–Simons Obstruction: Irrational Levels

Observation 34.3.1 *(non-integer level).* Witten's Chern–Simons/WZW correspondence gives $CS_k(G)$ on $\Sigma \times \mathbb{R}$ with boundary vertex operator algebra (VOA) $V_k(\mathfrak{g})$ at integer level $k \in \mathbb{Z}$. A boundary theory whose finite Heisenberg covers reproduce all prime Euler factors would require gauge group $\prod_{p\in\mathbb{P}} U(1)_p$ with effective levels $k_p = 1/\log p$. These levels are irrational; the Chern–Simons path integral on non-trivial 3-manifolds requires $k \in \mathbb{Z}$ for well-definedness.

COROLLARY 34.3.2. . No finite-level abelian Chern–Simons theory has a boundary vertex algebra whose all-prime Hochschild trace is $\mathcal{V}^{\mathrm{prim}}$.

34.4 The Belinski–Khalatnikov–Lifshitz Billiard: Thermodynamic Coarse-Graining

Observation 34.4.1 *(Selberg scattering versus primon partition).* The Selberg trace formula on $\mathrm{SL}(2,\mathbb{Z})\backslash\mathbb{H}^2$ expresses the spectral density of the Laplacian as a sum over Maass cusp forms plus a continuous Eisenstein series contribution. The Eisenstein scattering phase is $\zeta(2it)/\zeta(2it+1)$ on the critical line, a scattering-matrix entry; the primon partition function is $\prod_p (1-p^{-s})^{-1} = \zeta(s)$, with pole at $s = 1$. The two occurrences of ζ are structurally distinct: scattering amplitude versus thermodynamic partition function.

THEOREM 34.4.2 *(Hartnoll–Yang: thermodynamic coarse-graining).* (Hartnoll–Yang arXiv:2502.02661, §3). The primon–Belinski–Khalatnikov–Lifshitz (BKL) correspondence is a thermodynamic coarse-graining: at high temperature, the Selberg continuous spectrum above eigenvalue $1/4$ is replaced by the primon oscillator count. The spectral match is asymptotic, not exact.

34.5 The Automorphic Vertex

THEOREM 34.5.1 *($\mathcal{V}^{\mathrm{prim}}$ on the automorphic vertex).* . $\mathcal{V}^{\mathrm{prim}}$ occupies the automorphic vertex through the GL_2 Iwahori Hecke category. The abelian GL_1 class-field-theory row is only its determinant shadow:

$$\underbrace{\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})}_{\mathcal{V}^{\mathrm{prim}}} \longrightarrow \underbrace{\{\text{automorphic characters of } GL_1(\mathbb{A}_{\mathbb{Q}})\}}_{\det\text{-shadow}} \longleftrightarrow \underbrace{\{1\text{-dimensional Galois representations}\}}_{\text{Artin reciprocity}}.$$

The Euler product $\prod_p (1-p^{-s})^{-1}$ is the abelian determinant trace. It is not an identification of $\mathcal{V}^{\mathrm{prim}}$ with the category of GL_1 automorphic representations.

34.6 Asymptotic Symmetries at the BKL End-of-Time Boundary

PROPOSITION 34.6.1 *(Damour–Henneaux–Nicolai hep-th/0207267).* . BKL dynamics for 4D pure gravity on T^3 reduces to null billiards on the Weyl chamber of AE_3, a rank-3 hyperbolic Kac–Moody algebra; the fundamental domain is a modification of $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}^2$.

Observation 34.6.2 *(rank obstruction for AE_3).* A soft-mode algebra at the BKL end-of-time boundary decomposes into Weyl-group representations of $W(AE_3)$, where AE_3 has root lattice of rank 3. The primon Heisenberg algebra is generated by $\{a_{p,n}\}_{p\in\mathbb{P},n\in\mathbb{Z}}$, with generator index set of cardinality $\aleph_0$. The two index sets are incommensurable; $\mathcal{V}^{\text{prim}}$ is the bosonic Fock quantisation of the Eisenstein continuous sector of the gravitational superspace, not the full $W(AE_3)$ soft-mode algebra. The Hartnoll–Yang thermodynamic match (Chapter 34.4.2) is a coarse-graining of the Eisenstein density of states, not a spectral identification.

34.7 The Vol III Φ_d Functor: Arithmetic Domain Boundary

Observation 34.7.1. Vol III's functor $\Phi_d = \mathrm{Sp}^{\mathrm{ch}}_{\Sigma_{d-1},C} \circ \Phi^{\mathrm{FA}}_d$ takes a Calabi–Yau d-fold over $\mathbb{C}$ as input. $\overline{\mathrm{Spec}\,\mathbb{Z}}$ is an arithmetic 1-scheme over $\mathbb{Z}$; it admits no Calabi–Yau structure. The functor Φ_d is therefore defined on the $\mathbb{C}$-analytic locus of the programme, with $\overline{\mathrm{Spec}\,\mathbb{Z}}$ outside its domain.

Remark 34.7.2. When a Calabi–Yau 3-fold carries an $\mathrm{SL}_2(\mathbb{Z})$ action on its elliptic-fibration moduli (for example, K3×E), the modular-form output of Φ_3 carries arithmetic data. The Borcherds product Φ_N ($N \in \{1, 2, 3, 4, 6\}$) lives on $\mathrm{Sp}_4(\mathbb{Z})$-moduli space; it is an automorphic object, occupying the automorphic vertex together with $\mathcal{V}^{\text{prim}}$.

34.8 Automorphic Placement

Theorem 34.8.1 *(automorphic placement of $\mathcal{V}^{\text{prim}}$).* . Each candidate TQFT-bulk framework for $\mathcal{V}^{\text{prim}}$ (Kapustin–Witten, BLLPRvR, holomorphic Chern–Simons, the Costello–Gaiotto holomorphically-twisted theory, and Vol III Φ_d) is obstructed by a specific structural obstruction listed in §§34.1–34.7. $\mathcal{V}^{\text{prim}}$ occupies the automorphic vertex of the Langlands–TQFT triangle (Chapter 34.5.1).

Remark 34.8.2 *(the Deninger programme).* A rigorous construction of $\overline{\mathrm{Spec}\,\mathbb{Z}}$ as a "curve over $\mathbb{F}_1$" with a Frobenius-type $\mathbb{R}_{>0}$-action, Deninger's $\mathbb{F}_1$-geometric programme, would supply the missing TQFT-bulk vertex. The arithmetic site of Connes–Consani (arXiv:1405.4527) provides one candidate foundation.

34.9 The Automorphic Vertex: Structural Consolidation

Each obstruction in §§34.1–34.7 is structural: the complex-structure requirement of Kapustin–Witten (Chapter 34.1.3), the finite flavour-rank bound of BLLPRvR (Chapter 34.2.3), the integrality requirement of Chern–Simons levels (Chapter 34.3.2), the thermodynamic rather than spectral character of the Hartnoll–Yang match (Chapter 34.4.2), and the $\mathbb{C}$-analytic domain of Φ_d (Chapter 34.7.1). The automorphic vertex placement (Chapter 34.5.1) is the consequence: $\mathcal{V}^{\text{prim}}$ is identified by Artin reciprocity with the automorphic side of the Langlands triangle, with the TQFT-bulk vertex remaining Deninger's open programme.

Chapter 35

Local central charge and global residue

A local central charge is a coefficient in a stress-tensor operator product. A pole order of a global scalar determinant is a different invariant. Both can equal two in a rank-two Heisenberg example, but their equality does not construct a global Virasoro action.

35.1 Rescaling and the conformal vector

Observation 35.1.1 *(Rescaling and Virasoro normalization).* Let T be a nonzero stress tensor on the Heisenberg algebra. For $T' = \lambda T$, its singular product is

$$T'(z)T'(w) \sim \lambda^2\left(\frac{c/2}{(z-w)^4} + \frac{2T(w)}{(z-w)^2} + \frac{\partial T(w)}{z-w}\right).$$

The standard conformal identities for the original translation operator force $\lambda = 1$.

The second pole requires $\lambda^2 = \lambda$. If $\lambda = 0$, the zero state cannot implement the nonzero translation operator. Thus the fourth-pole coefficient $\lambda^2 c$ cannot be interpreted as a new central charge while the other conformal identities are left unsatisfied.

Remark 35.1.2. At a prime p, take the standard rank-two Sugawara state. Its oscillator grading is $L_0^{(p)}$, while the chosen arithmetic energy is

$$H_p = (\log p) L_0^{(p)}.$$

The real number $\log p$ weights this operator. It does not rescale the conformal state.

Theorem 35.1.3 *(The local central charge).* Each rank-two level-one Heisenberg factor has central charge two. The operator H_p has energy $m \log p$ on a mode-m creator. It is not the zero mode of a scalar-rescaled stress tensor satisfying the same conformal identities.

Proof. For two orthogonal currents, the stress tensor is $T = \frac{1}{2}(:a^2: + :b^2:)$. Its two independent double contractions give coefficient one at the fourth pole, so $c/2 = 1$. The single contractions give the required second and first poles, as in Proposition 6.4.6. The energy formula follows from the oscillator grading. The rescaling observation proves the final assertion. □

35.2 The sum over primes

Write $\mathcal{H}_{\mathbb{P}} = \bigotimes'_p \mathcal{H}^{(p)}$ for the algebraic restricted tensor using the vacua. A vector has nonvacuum factors at only finitely many primes. This is the explicit current cover of Chapter 6. It is separate from any proposed arithmetic trace class.

Observation 35.2.1. The formal sum $\sum_p \omega_p$ is not a vector of $\mathcal{H}_{\mathbb{P}}$. In the Hilbert completion its finite partial sums have squared norm equal to the number of primes included, so they do not converge there either.

The norm assertion follows because each ω_p has squared norm one and different prime sectors are orthogonal. It rules out the indicated sum, with its indicated normalization. The stronger absence of a conformal state implementing the whole Hilbert oscillator grading is proved in Proposition 6.4.6.

COROLLARY 35.2.2. The sums of local modes $\sum_p L_m^{(p)}$, for $m \geq -1$, act on $\mathcal{H}_{\mathbb{P}}$. For $m \leq -2$, these same sums do not define operators on its vacuum. Consequently the prescribed sums do not give a full Virasoro representation on this carrier.

Proof. The modes with $m \geq -1$ annihilate each local vacuum. Only the finitely many occupied prime factors contribute. For $m \leq -2$, each local vacuum receives a nonzero creation state. The infinite sum is not in the algebraic restricted tensor and has divergent Hilbert norm. □

35.3 THE PRIME ZETA FUNCTION AND ANALYTIC CONTINUATION

The prime zeta function is

$$P(s) = \sum_p p^{-s}, \qquad \operatorname{Re} s > 1.$$

Taking logarithms of the Euler product and applying Möbius inversion gives

$$\log \zeta(s) = \sum_{r \geq 1} \frac{P(rs)}{r}, \qquad P(s) = \sum_{r \geq 1} \frac{\mu(r)}{r} \log \zeta(rs). \tag{35.1}$$

Here μ is the Möbius function. The sums first converge absolutely in the stated half-plane. Local branches of the logarithms give the continuation where they are defined.

THEOREM 35.3.1 *(Natural boundary of prime zeta).* The line $\operatorname{Re} s = 0$ is a natural boundary for the analytic continuation of P. In particular P has no holomorphic continuation to a neighborhood of the origin.[1]

The real singularities at $s = 1/r$ occur when r is squarefree. The coefficient $\mu(r)$ matters: (35.1) does not assert a branch point for every integer denominator or every putative zero contribution. The natural-boundary theorem concerns the surviving singularities.

COROLLARY 35.3.2. Ordinary analytic continuation does not assign $P(0)$ a finite value. Hence it does not define a global central charge by $c = 2P(0)$.

Proof. Such an evaluation would require a holomorphic germ at zero. The natural-boundary theorem excludes that germ. Other regularization prescriptions require their own definitions and do not construct the missing stress-tensor modes. □

Remark 35.3.3. The value $\zeta(0) = -1/2$ belongs to the zeta function of all positive integers. Replacing P by ζ changes the indexing set of the regularized sum. It does not evaluate the sum of the local prime charges.

[1] C.-E. Fröberg, *On the prime zeta function*, BIT **8** (1968), 187–202. See also P. L. Krapivsky and J. M. Luck, *Zeta-regularization and natural boundaries*, §2.2, equations (2.11)–(2.12), arXiv:2606.24536.

35.4 Pole order and logarithmic residue

A specified scalar determinant can have a finite pole order. The meromorphic function itself, its leading Laurent coefficient, and the residue of its logarithmic derivative must be distinguished.

Theorem 35.4.1. Suppose a scalar determinant is identified near $s = 1$ with $D(s) = \zeta(s)^2 h(s)$, where h is holomorphic and $h(1) \neq 0$. Then its pole order is two, and

$$-\operatorname{Res}_{s=1} \frac{D'(s)}{D(s)} = 2, \qquad \lim_{s \to 1} (s-1)^2 D(s) = h(1).$$

The separately defined scalar $r_\zeta = 2 \operatorname{Res}_{s=1} \zeta(s)$ also equals two. None of these scalar calculations defines a Virasoro action.

Proof. Write $\zeta(s) = (s-1)^{-1} u(s)$, where u is holomorphic and $u(1) = 1$. Then

$$D(s) = (s-1)^{-2} u(s)^2 h(s), \qquad \frac{D'}{D} = -\frac{2}{s-1} + 2\frac{u'}{u} + \frac{h'}{h}.$$

The last two terms are regular near one. This proves the pole, limit and logarithmic-residue formulas. The residue of ζ is one, giving the stated value of r_ζ. □

To apply the theorem to an arithmetic trace, one must construct its determinant and prove the local factorization with $h(1) \neq 0$. The equality $r_\zeta = 2$ alone proves neither premise.

35.5 The surviving Witt modes

Theorem 35.5.1. For $m, n \geq -1$ with $m + n \geq -1$, the prescribed sums satisfy

$$[L_m, L_n] = (m-n) L_{m+n}, \qquad L_m = \sum_p L_m^{(p)}.$$

The bracket is zero when $m = n = -1$. The negative sums with index at most -2 remain undefined on the restricted vacuum.

Proof. On any vector, the contributing prime set is finite. Different prime factors commute, so their Witt brackets add. A Virasoro central term would require $m + n = 0$. In this index range the possible values of m are -1, 0, 1, and $m(m^2 - 1) = 0$. Thus the central term vanishes on these modes. The vacuum calculation above excludes the remaining prescribed sums. □

Remark 35.5.2. For a finite prime set S, the full local sum has central charge $2|S|$. When $|m| \geq 2$, its central commutator coefficient grows with $|S|$. There is no finite limit for this unrenormalized coefficient. This is a statement about the specified sums, not an obstruction to every other representation.

35.6 Mellin reflection and a modular comparison

Set

$$\Lambda(s) = \pi^{-s/2} \Gamma(s/2) \zeta(s), \qquad \xi(s) = \tfrac{1}{2} s(s-1) \Lambda(s).$$

The first function retains the poles at zero and one. The second removes them.

THEOREM 35.6.1. The completed zeta functions satisfy $\Lambda(s) = \Lambda(1-s)$ and $\xi(s) = \xi(1-s)$. If an independently specified scalar trace is identified with one of these functions, it inherits that reflection with the same normalization. Such an identification does not by itself construct a genus-one state space or its modular action.

Proof. Let $\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}$. Poisson summation for the Gaussian gives $\theta(t) = t^{-1/2}\theta(1/t)$. Its Mellin integral initially converges for $\operatorname{Re} s > 1$:

$$\Lambda(s) = \frac{1}{2}\int_0^\infty (\theta(t)-1)t^{s/2}\frac{dt}{t}.$$

Split at one and use the theta identity on $(0,1)$. The result is

$$\Lambda(s) = -\frac{1}{s} - \frac{1}{1-s} + \frac{1}{2}\int_1^\infty (\theta(t)-1)\big(t^{s/2} + t^{(1-s)/2}\big)\frac{dt}{t}.$$

The integral is entire by exponential decay and is invariant under $s \mapsto 1-s$. The two rational terms exchange. Multiplication by $s(s-1)/2$ proves the assertion for ξ. Transport through a specified scalar identification gives the conditional trace consequence. □

A vertex-algebra genus-one trace instead has the form $\operatorname{Tr} q^{L_0 - c/24}$, on a specified graded state space and convergence domain. Relating its modular substitution to Mellin reflection requires a map between those constructions. A shared functional equation does not supply that map.

35.7 ARITHMETIC DEGREE AND A POSSIBLE ANOMALY COMPARISON

For a finite divisor $D = \sum_p n_p[p]$ on $\operatorname{Spec}\mathbb{Z}$, define its arithmetic degree by $\widehat{\deg} D = \sum_p n_p \log p$. Archimedean metric contributions are separate data for a metrized line bundle.

PROPOSITION 35.7.1. The finite divisor $[p]$ has degree $\log p$. For $\operatorname{Re} s > 1$, these degree weights satisfy

$$-\frac{\zeta'(s)}{\zeta(s)} = \sum_p \sum_{r\ge 1} (\log p)\, p^{-rs}.$$

Proof. The first equality is the definition of arithmetic degree. Differentiate the absolutely convergent logarithmic Euler product $\log\zeta(s) = \sum_{p,r} p^{-rs}/r$. Normal convergence on smaller half-planes justifies the derivative. □

A conformal state ω_p is a vector, not a metrized line bundle. A Deligne pairing requires geometric line bundles.

For example, let $\pi : Y \to S$ be a smooth projective curve family of integral complex schemes, with line bundles L, M. Its Deligne pairing is the following determinant line.[2]

$$\langle L, M\rangle = \det R\pi_*(L\otimes M) \otimes (\det R\pi_* L)^{-1} \otimes (\det R\pi_* M)^{-1} \otimes \det R\pi_* \mathcal{O}_Y.$$

A metric refinement must additionally specify metrics and norms. The scalar $\log p$ does not identify this line with a quadratic expression in the conformal state.

[2] I. Biswas, G. Schumacher and L. Weng, *Deligne pairing and determinant bundle*. Theorem 1, arXiv:1106.0255.

Remark 35.7.2. In the convention $\langle T^{\mu}_{\mu} \rangle = -cR/(24\pi)$, the two-dimensional Weyl anomaly describes metric variation of a quantum field theory.[3] An arithmetic comparison would assign metrized determinant lines to the relevant field data and compare their variation with this functional. Arithmetic degree alone does not prove such a variation formula.

35.8 The comparison data

The local current factors have central charge two. Their restricted product has the prescribed Witt modes with indices at least -1, and its unchanged negative sums fail on the vacuum. A scalar determinant with the specified zeta factor has pole order two, with the logarithmic residue computed above.

The arithmetic questions concern maps relating these objects. A trace identification must preserve its Mellin normalization and polar factors. A conformal or anomaly comparison must additionally construct the state space, modes or metrized lines whose operations are being compared.

[3] For the Euclidean effective action, see T. Bautista, A. Benevides and A. Dabholkar, *Nonlocal quantum effective actions in Weyl-flat spacetimes*. Equations (2.26) and (3.2), arXiv:1711.00135.

Chapter 36

Integral Relative Galois Cochains and Their Bar Coalgebras

36.1 The relative arithmetic problem

A global Galois cochain can become a coboundary at every specified local field. The local primitives belong to the data of its relative class. For a restriction map of cochain algebras $f : A \to B$, a relative cocycle is therefore a pair

$$(a, y), \qquad da = 0, \qquad f(a) = dy.$$

Products of such pairs must retain a local primitive. If a has degree n, the expression $(-1)^n f(a)\, y'$ is a primitive for $f(aa')$. This observation determines the associative product used below.

Fix a number field K, a rational prime ℓ, and a finite set S of places containing the archimedean places and all places above ℓ. Write S_f for its finite places. Let $G_{K,S}$ be the Galois group of the maximal extension unramified outside S, and let G_{K_v} be the absolute Galois group of the completion at v. Fix the embeddings of algebraic closures that define homomorphisms

$$j_v : G_{K_v} \longrightarrow G_{K,S} \qquad (v \in S_f).$$

They need not be injective. All strict functoriality statements refer to these fixed homomorphisms. Conjugate choices require the corresponding cochain homotopies.

Put $R_r = \mathbb{Z}/\ell^r\mathbb{Z}$ for $r \geq 1$, with trivial Galois action and discrete topology. The continuous cochain model is classical.[1] The cochains below are continuous normalized inhomogeneous cochains. They compute continuous group cohomology by definition. Only finite local places enter the relative complex. An identification with a compact-support theory requires its own archimedean conventions.

Complexes are cohomologically graded. The differential has degree 1. For homogeneous maps and elements, the tensor convention is

$$(u \otimes v)(x \otimes y) = (-1)^{|v||x|} u(x) \otimes v(y).$$

We write $sM = M[1]$ and $|sa| = |a| - 1$. Tensor products are algebraic over the displayed coefficient ring until a completion is explicitly introduced.

[1] J. S. Milne, *Class Field Theory*, version 4.03 (2020), Chapter II, §4, pp. 86–89.

36.2 CONTINUOUS COCHAINS AND THE PATH FIBER

For a profinite group G and a discrete commutative ring R, let $C^n(G, R)$ consist of continuous functions $G^n \to R$ that vanish when any argument is the identity. Set $C^0(G, R) = R$ and $C^n = 0$ for $n < 0$. The trivial action gives

$$\begin{aligned}(dc)(g_1, \dots, g_{n+1}) = {} & c(g_2, \dots, g_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i c(g_1, \dots, g_i g_{i+1}, \dots, g_{n+1}) \\ & + (-1)^{n+1} c(g_1, \dots, g_n).\end{aligned}$$

The product of degrees n, m is

$$(cc')(g_1, \dots, g_{n+m}) = c(g_1, \dots, g_n) c'(g_{n+1}, \dots, g_{n+m}).$$

LEMMA 36.2.1. These formulas define a unital differential graded R-algebra. Precomposition with a continuous homomorphism of profinite groups is a morphism of such algebras.

Proof. The terms in d^2 cancel in pairs. Deleting or multiplying the ith entry and then the jth entry agrees with the operation in reverse order with the shifted index. The two alternating signs differ by -1. Associativity handles the pair of adjacent multiplications. If an argument is the identity, its two adjacent terms cancel, so normalization is preserved. In $d(cc')$, the terms before the cut at n are $(dc)c'$. The terms after that cut are $(-1)^n c(dc')$. The two extra terms at the cut cancel. This proves the Leibniz rule. Both bracketings of a triple product evaluate the same three consecutive argument blocks. The constant 1 in degree zero is the unit. Precomposition respects each formula term by term. □

Apply this lemma to

$$A_r = C^\bullet(G_{K,S}, R_r), \qquad B_r = \prod_{v \in S_f} C^\bullet(G_{K_v}, R_r), \qquad f_r = (j_v^*)_v : A_r \longrightarrow B_r.$$

The finite product in B_r uses componentwise multiplication.

THEOREM 36.2.2. Let $f : A \to B$ be a morphism of differential graded algebras over a commutative ring R. The formulas

$$P(f)^n = A^n \oplus B^{n-1}, \qquad D(a, y) = (da, f(a) - dy), \tag{36.1}$$

$$(a, y)(a', y') = (aa', (-1)^n f(a) y') \qquad (|(a, y)| = n) \tag{36.2}$$

define an associative nonunital differential graded algebra. Its underlying complex is the relative complex $\mathrm{Cone}(f)[-1]$ with the sign convention in (36.1).

Proof. The square of D has second component $f(da) - df(a) = 0$. For three inputs of degrees n, m, k, either bracketing has second component $(-1)^{n+m} f(a) f(a') y''$. The first components agree by associativity in A. The second component of $D((a, y)(a', y'))$ is

$$f(a)f(a') - (-1)^n f(da) y' - f(a) dy'.$$

The expression $D(a, y)(a', y') + (-1)^n (a, y) D(a', y')$ gives the same formula. The first components agree by the Leibniz rule in A. The cone statement follows from the displayed differential. □

The product is asymmetric on chains. An interval algebra explains both this asymmetry and the sign. Define I_R by

$$I_R^0 = Re_0 \oplus Re_1, \quad I_R^1 = Rh, \quad de_0 = -h, \quad de_1 = h, \quad dh = 0,$$

with products

$$e_i e_j = \delta_{ij} e_i, \qquad e_0 h = h = h e_1, \qquad e_1 h = h e_0 = h^2 = 0.$$

Its unit is $e_0 + e_1$. The evaluations ev_i send e_i to 1, the other idempotent to 0, and h to 0.

Proposition 36.2.3. The algebra I_R is a differential graded algebra. There is a strict isomorphism of nonunital differential graded algebras

$$P(f) \longrightarrow \{(a, \beta) \in A \times (B \otimes I_R) : (\mathrm{id} \otimes \mathrm{ev}_0)\beta = f(a),\ (\mathrm{id} \otimes \mathrm{ev}_1)\beta = 0\},$$

given in degree n by

$$(a, y) \longmapsto (a, f(a)e_0 + (-1)^n y h).$$

Here be_i denotes $b \otimes e_i$.

Proof. The relations identify the graded algebra with the path algebra of the single directed edge $0 \to 1$, where that edge has degree one. Thus multiplication is associative. Checking the four idempotent products and the products with h verifies the Leibniz rule. Every element on the right has the unique indicated form. The coefficient of h in its differential is $(-1)^{n+1} f(a) + (-1)^n dy$, which equals $(-1)^{n+1}(f(a) - dy)$. In a product of two such elements, only $e_0 h = h$ contributes an edge term. That coefficient is $(-1)^m f(a) y'$. This equals $(-1)^{n+m}$ times the second component in (36.2). □

The constant inclusion $R \to I_R$ is a quasi-isomorphism: its quotient has differential an isomorphism between two rank-one modules. Thus the interval description is an integral path-fiber construction. It requires no polynomial integration or division by integers.

The opposite choice of endpoint gives a second relative product. Its relation to the first can be computed without changing the underlying cochain complex.

Proposition 36.2.4. On $P(f)$ the formula

$$\mu_R((a, y), (a', y')) = (aa', yf(a'))$$

also defines an associative differential graded product. Let μ_L denote (36.2). The degree-minus-one bilinear map

$$K((a, y), (a', y')) = (0, (-1)^{n+1} y y'), \qquad |(a, y)| = n,$$

satisfies

$$DK + K(D \otimes 1 + 1 \otimes D) = \mu_L - \mu_R.$$

Consequently both products induce the same product on relative cohomology.

Proof. For μ_R, both triple products have second component $yf(a')f(a'')$. Its Leibniz rule follows by expanding $d(yf(a'))$ with $|y| = n - 1$. For the homotopy identity, the three second components on the left are

$$\begin{aligned} &(-1)^n dy\, y' - y\, dy', \\ &(-1)^n (f(a) - dy) y', \\ &-y(f(a') - dy'). \end{aligned}$$

Their sum is $(-1)^n f(a)\,y' - y f(a')$, as required. On cocycles the difference of products is a boundary. $\square$

The right product is the specialization with vanishing second local term of the gluing-cone product

$$(u,a,b)(u',a',b') = (uu',\,aa',\,b\,r(u') + (-1)^{|u|}s(a)b').$$

Here r and s are differential graded algebra maps to the same target, and the cone differential is $(du, da, r(u) - s(a) - db)$. Proposition 36.2.4 compares the induced relative cohomology products. Theorem 36.4.2 extends this binary comparison to an isomorphism of the full bar coalgebras.

COROLLARY 36.2.5. Put $P_r = P(f_r)$. Its cohomology is the relative global-to-finite-local continuous Galois cohomology, with the exact sequence

$$\cdots \to H^{n-1}(B_r) \to H^n(P_r) \to H^n(A_r) \xrightarrow{H^n(f_r)} H^n(B_r) \to \cdots .$$

For $S_f \neq \varnothing$, $H^0(P_r) = 0$, and

$$0 \longrightarrow R_r^{S_f}/R_r \longrightarrow H^1(P_r) \longrightarrow \ker(H^1(A_r) \to H^1(B_r)) \longrightarrow 0,$$

where $R_r \to R_r^{S_f}$ is the diagonal inclusion.

Proof. The short exact sequence $B_r[-1] \to P_r \to A_r$ gives the long exact sequence. Both global and local degree-zero cohomology consist of constants, and their restriction is the diagonal inclusion. $\square$

36.3 The bar coalgebra and its universal map

The relative product supplies the multiplication needed for a bar differential. The tensor bar and its twisting-cochain description are classical.[2] For any nonunital differential graded R-algebra P, its unitization is

$$U = R \oplus P, \qquad (r,p)(t,q) = (rt,\, rq + tp + pq), \qquad \epsilon(r,p) = r.$$

The differential is zero on R and equals D on P. In particular $P = \ker\epsilon$. Define the tensor coalgebra

$$\mathcal{B}(U) = \bigoplus_{j\geq 0} (sP)^{\otimes j}, \qquad \Delta[v_1|\cdots|v_j] = \sum_{i=0}^{j} [v_1|\cdots|v_i] \otimes [v_{i+1}|\cdots|v_j].$$

The empty word is 1, the counit projects onto its coefficient, and the coaugmentation includes it. The reduced coproduct $\bar\Delta$ omits its two end terms. Repeated reduced coproducts vanish on each word, which is the conilpotence convention used here.

THEOREM 36.3.1. There is a unique coderivation b on $\mathcal{B}(U)$ with $b(1) = 0$ whose projections to sP are

$$b_1(sa) = -s(Da), \qquad b_2(sa \otimes sb) = (-1)^{|a|}s(ab), \qquad b_j = 0 \quad (j > 2).$$

It has degree one and satisfies $b^2 = 0$ over every commutative ring. Consequently $\mathcal{B}(U)$ is a conilpotent differential graded coalgebra.

[2] J.-L. Loday and B. Vallette, *Algebraic Operads* (2012), §2.2. The proof below fixes the cohomological signs and works over the displayed commutative ring.

Proof. On a word, insert b_1 in every one-letter position and b_2 in every adjacent two-letter position. An insertion after $v_1, \dots, v_i$ has sign $(-1)^{|v_1|+\cdots+|v_i|}$. Cutting a word before or after the inserted block proves the coderivation identity. Conversely that identity and projection to one-letter words determine the formula.

In the square, two insertions with disjoint supports cancel: reversing their order crosses two degree-one operations. The overlapping insertions have supports of lengths one, two, or three. On one letter the result is $sD^2a = 0$. On two letters, the three terms are

$$(-1)^{|a|+1}sD(ab) + (-1)^{|a|}s((Da)b) + s(aDb) = 0.$$

On three letters, the two terms are

$$(-1)^{|b|}s((ab)c) - (-1)^{|b|}s(a(bc)) = 0.$$

They vanish by the Leibniz rule and associativity. Every term in the square is of one of these types, so the proof covers every word length. It uses cancellation of opposite signs, including in characteristic two, and never divides by two. □

A twisting cochain packages the compatibility between a differential and a multiplication. For a coaugmented conilpotent differential graded coalgebra C and an augmented differential graded algebra U, it is a degree-one map $t : C \to U$ with $t(1) = 0$, $\epsilon t = 0$, and

$$d_U t + t d_C + \mu(t \otimes t)\bar{\Delta} = 0. \tag{36.3}$$

The tensor sign in this formula is part of the stated convention.

Theorem 36.3.2. The map $\tau : \mathcal{B}(U) \to U$ sending sa to a and all other lengths to zero is a twisting cochain. Composition with τ gives a bijection between differential graded coalgebra maps $C \to \mathcal{B}(U)$ preserving coaugmentation and twisting cochains $C \to U$.

Proof. On length one, (36.3) reads $Da - Da = 0$. On length two, its last two terms are $(-1)^{|a|}ab$ and $(-1)^{|a|-1}ab$. Other lengths contribute zero. For a twisting cochain t, define

$$F_t(c) = \epsilon_C(c)1 + \sum_{j \geq 1} (st)^{\otimes j}\bar{\Delta}^{(j-1)}(\bar{c}), \qquad \bar{c} = c - \epsilon_C(c)1.$$

Conilpotence makes the sum finite for each c. Coassociativity gives $\Delta F_t = (F_t \otimes F_t)\Delta$, and its one-letter projection is st. Those properties also prove uniqueness by applying repeated reduced coproducts and then projecting every output to length one. The difference $bF_t - F_t d_C$ satisfies the coderivation identity relative to F_t. Its one-letter projection is zero precisely when (36.3) holds. Repeated reduced coproducts show that a relative coderivation with zero one-letter projection is zero. This proves that F_t commutes with differentials and proves both directions. □

36.4 Changing the endpoint in every arity

A binary homotopy compares two products, but a bar map must also compare their compositions on longer words. Ordered products of the local primitives supply all the required components. For the identity map $f : R \to R$, put $u = s(1, 0)$ and $v = s(0, 1)$. Their degrees are -1 and 0. The bar conventions above give

$$b_1 u = -v, \qquad b_1 v = 0, \qquad b_{2,L}(u, v) = v, \qquad b_{2,R}(v, u) = -v.$$

Both binary operations send (u, u) to u; their other values on these generators vanish. The comparison below sends

$$[v|v] \longmapsto [v|v] + [v], \qquad [v|v|v] \longmapsto [v|v|v] + 2[v|v] + [v].$$

Each term contracts consecutive blocks of local primitives. This ordered contraction makes sense without commutativity of the algebras.

Let R be any commutative ring. Consider a cospan of associative differential graded R-algebras

$$A \xrightarrow{f} B \xleftarrow{g} C.$$

Put

$$P^n = A^n \oplus C^n \oplus B^{n-1}, \qquad D(a, c, y) = (d_A a, d_C c, f(a) - g(c) - d_B y). \tag{36.4}$$

For $x = (a, c, y)$ of degree p define

$$\mu_L(x, x') = (aa', cc', (-1)^p f(a)\, y' + y\, g(c')), \tag{36.5}$$

$$\mu_R(x, x') = (aa', cc', y f(a') + (-1)^p g(c)\, y'). \tag{36.6}$$

The relative case is obtained by taking $C = 0$ in the category of nonunital algebras. If f, g are unital, $(1_A, 1_C, 0)$ is a unit for both gluing products.

LEMMA 36.4.1. The two formulas (36.5) and (36.6) define differential graded associative algebras on (36.4).

Proof. The square of D vanishes because f and g commute with differentials. Write the degrees of three inputs as p, q, r. The third component of either parenthesization of μ_L is

$$(-1)^{p+q} f(a) f(a')\, y'' + (-1)^p f(a)\, y'\, g(c'') + y\, g(c')\, g(c'').$$

For μ_R the corresponding common component is

$$y f(a') f(a'') + (-1)^p g(c)\, y' f(a'') + (-1)^{p+q} g(c)\, g(c')\, y''.$$

The first two components are associative by assumption.

For the Leibniz identity of μ_L, the third component of $D\mu_L(x, x')$ is

$$\begin{aligned} f(a) f(a') - g(c) g(c') - (-1)^p f(d_A a)\, y' - f(a) d_B y' \\ - d_B y\, g(c') + (-1)^p y\, g(d_C c'). \end{aligned}$$

Expanding $\mu_L(Dx, x') + (-1)^p \mu_L(x, Dx')$ gives this expression; the terms $f(a)\, g(c')$ cancel. For μ_R, the third component of $D\mu_R(x, x')$ is

$$\begin{aligned} f(a) f(a') - g(c) g(c') - d_B y\, f(a') + (-1)^p y f(d_A a') \\ - (-1)^p g(d_C c)\, y' - g(c) d_B y'. \end{aligned}$$

The same expansion on the Leibniz side gives these terms, with the two occurrences of $g(c) f(a')$ cancelling. The first two components obey the original Leibniz identities. This proves the assertion over R without division. □

The endpoint isomorphism

For either product, first regard P as a nonunital algebra and use its augmented unitization $U = R \oplus P$. This fixes the meaning of the normalized bar even when the gluing algebra already has a unit. The normalized bar is

$$\mathcal{B}_L = T^c_R(sP) = \bigoplus_{n\geq 0} (sP)^{\otimes_R n}, \qquad \mathcal{B}_R = T^c_R(sP),$$

where $s : P \to P[1]$ has degree -1. Its coproduct is deconcatenation; the summand R is the empty word, counit target, and coaugmentation source. Its coderivation is determined by

$$b_1(sx) = -sDx, \qquad b_{2,L/R}(sx, sx') = (-1)^{|x|} s\mu_{L/R}(x, x'). \tag{36.7}$$

Higher Taylor coefficients of these differentials vanish. Lemma 36.4.1 implies $b^2_L = b^2_R = 0$ by the one-, two-, and three-input checks.

We identify the suspended module with

$$W = sP = sA \oplus sC \oplus B, \qquad s(a, c, y) \longleftrightarrow (sa, sc, y).$$

Thus, if $w_i = s(a_i, c_i, y_i)$ has degree q_i, then $|y_i| = q_i$. Define degree-zero maps $F_n : W^{\otimes n} \to W$ by

$$F_1 = \mathrm{id}_W, \qquad F_n(w_1, \dots, w_n) = s(0, 0, y_1 y_2 \cdots y_n) \quad (n \geq 2). \tag{36.8}$$

The multiplication in the last expression is the ordered multiplication of B. In particular, it introduces no reordering sign. Equation (36.8) uses the suspended convention (36.7); signs in an unsuspended convention must be obtained by the tensor rule, not copied without change.

Theorem 36.4.2 *(Integral endpoint change).* For every cospan of differential graded associative algebras over R, the maps (36.8) are the corestrictions of a coaugmentation- and counit-preserving isomorphism

$$\mathcal{F} : (\mathcal{B}_L, b_L, \Delta_{\mathrm{dec}}) \xrightarrow{\cong} (\mathcal{B}_R, b_R, \Delta_{\mathrm{dec}})$$

of differential graded coalgebras. Its inverse $\mathcal{G}$ has corestrictions

$$G_1 = \mathrm{id}_W, \qquad G_n(w_1, \dots, w_n) = (-1)^{n-1} s(0, 0, y_1 \cdots y_n) \quad (n \geq 2).$$

Both maps preserve the increasing filtration by word length. They are defined over the integers and require no division. In particular they are valid in characteristics two and three and over $\mathbb{Z}/\ell^r$.

Proof. The full coalgebra maps. For a word of length $N > 0$, partition its inputs into consecutive nonempty blocks. Explicitly,

$$\mathcal{F}[w_1|\cdots|w_N] = \sum_{N=n_1+\cdots+n_k} [F_{n_1}(w_1, \dots, w_{n_1})|\cdots|F_{n_k}(w_{N-n_k+1}, \dots, w_N)]. \tag{36.9}$$

Here $k \geq 1$, all $n_i \geq 1$, and $\mathcal{F}(1) = 1$. There are 2^{N-1} terms before any vanish. Cutting the output between two blocks is equivalent to first cutting the input there and independently partitioning the two resulting words. This proves

$$\Delta_{\mathrm{dec}}\mathcal{F} = (\mathcal{F} \otimes \mathcal{F})\Delta_{\mathrm{dec}}.$$

It also proves that (36.9) is the coalgebra map with the indicated corestrictions. The same construction gives $\mathcal{G}$. Since only finitely many partitions occur, algebraic tensor products and direct sums suffice.

The chain equation in every arity. Let $\pi_1 : T^c(W) \to W$ be projection to length one. Both $b_R\mathcal{F}$ and $\mathcal{F}b_L$ are coderivations relative to $\mathcal{F}$. Equality of their corestrictions therefore implies equality of the full maps. In this tensor coalgebra the implication can also be proved by induction on input length: all reduced coproduct terms of a difference are determined by shorter input words, leaving only a primitive difference; a primitive element of $T^c(W)$ with zero length-one component is zero.

Set

$$Q_j = q_1 + \cdots + q_j, \qquad Q_0 = 0.$$

In the coordinates above, the unary differential is

$$b_1(sa, sc, y) = (-sd_A a, -sd_C c, d_B y - f(a) + g(c)).$$

Here b_1^{tens} inserts b_1 at position j with sign $(-1)^{Q_{j-1}}$. For $n \geq 2$, write $U_n = b_1F_n - F_n b_1^{\mathrm{tens}}$. Its first two components vanish, and its third component is

$$\sum_{j=1}^{n} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} \big(f(a_j) - g(c_j)\big) y_{j+1} \cdots y_n. \tag{36.10}$$

Indeed, the terms containing $d_B y_j$ cancel by the graded Leibniz rule in B. This cancellation is the source of the higher comparison.

For $n = 1$ the chain equation holds because F_1 is the identity and the unary differentials agree. For $n = 2$, the third components of the binary bar operations are

$$\begin{aligned} b_{2,L}(w_1, w_2)_B &= f(a_1)\, y_2 - (-1)^{q_1} y_1 g(c_2), \\ b_{2,R}(w_1, w_2)_B &= -(-1)^{q_1} y_1 f(a_2) + g(c_1)\, y_2. \end{aligned}$$

Their first two components agree. Hence, as maps $W^{\otimes 2} \to W$,

$$b_{2,L} - b_{2,R} = U_2.$$

Thus

$$b_1F_2 + b_{2,R} = F_2 b_1^{\mathrm{tens}} + b_{2,L}.$$

Now let $n \geq 3$. The third component of the target binary contribution $\sum_{i=1}^{n-1} b_{2,R}(F_i, F_{n-i})$ is

$$g(c_1)\, y_2 \cdots y_n - (-1)^{Q_{n-1}} y_1 \cdots y_{n-1} f(a_n). \tag{36.11}$$

All interior splits vanish: both outputs then have only a B component, whose binary product in the gluing cone is zero. The third component of the source binary contribution is

$$\begin{aligned} &\sum_{j=1}^{n-1} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} f(a_j)\, y_{j+1} \cdots y_n \\ &\qquad - \sum_{j=2}^{n} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} g(c_j)\, y_{j+1} \cdots y_n. \end{aligned} \tag{36.12}$$

To see the second sum, move the sign of the inserted degree-one b_2 past its preceding suspended inputs, and then use the second term of $b_{2,L}$. No input factors are permuted.

Adding (36.11) to (36.10) gives exactly (36.12). The f term with $j = n$ and the g term with $j = 1$ are cancelled by the two endpoints. For $n \geq 3$ all first and second components of the remaining terms vanish. This proves the corestriction equation in every arity, and hence

$$b_R \mathcal{F} = \mathcal{F} b_L.$$

The inverse. The length-one component of either composite is the identity. For length $n \geq 2$, every contribution to its corestriction is an ordered product $y_1 \cdots y_n$ in the third component. An input with a vanishing local component gives zero in all such contributions. For $\mathcal{F}\mathcal{G}$, a partition into k blocks contributes sign $(-1)^{n-k}$, and there are $\binom{n-1}{k-1}$ such partitions. The total coefficient is

$$\sum_{k=1}^{n} \binom{n-1}{k-1} (-1)^{n-k} = (1-1)^{n-1} = 0.$$

For $\mathcal{G}\mathcal{F}$, the outer coefficient instead gives $(-1)^{k-1}$ and the same binomial cancellation applies. Thus both composites have exactly the identity corestrictions. Formula (36.9) proves that the full composites are identities. Since $\mathcal{F}$ is a chain map and $\mathcal{G}$ is its inverse, $\mathcal{G}$ is a chain map as well. □

Corollary 36.4.3. The two relative algebras of Proposition 36.2.4 are A_∞-isomorphic with identity first component, and their normalized bar coalgebras are isomorphic over R. If the gluing maps are unital, all higher components vanish when any input is the native gluing unit $(1_A, 1_C, 0)$.

Proof. The relative case is the specialization $C = 0$. A coalgebra map satisfying the bar chain equation is exactly an A_∞ map in the convention (36.7). The explicit inverse makes it an isomorphism in that sense. The higher coefficients depend on every local component; the local component of the native unit is zero. □

The isomorphism $\mathcal{F}$ preserves differential, deconcatenation, coaugmentation, counit, and the increasing word filtration. It does *not* say that the identity of P is a strict multiplicative map. Nor does it preserve the two original universal twisting cochains by an identity: if τ_R extracts a single suspended letter, then $\tau_R \mathcal{F}$ has higher components $(0, 0, y_1 \cdots y_n)$. Those components are part of the comparison, not terms to discard.

Strict naturality

A strict map of cospans consists of maps $\alpha : A \to A'$, $\gamma : C \to C'$, and $\beta : B \to B'$ with

$$\beta f = f' \alpha, \qquad \beta g = g' \gamma.$$

It induces $(a, c, y) \mapsto (\alpha a, \gamma c, \beta y)$ on the gluing cones. Because $\beta(y_1 \cdots y_n) = \beta(y_1) \cdots \beta(y_n)$, it commutes with every F_n and G_n, and therefore with both full coalgebra maps. If H_L and H_R denote the induced tensorwise bar maps, then

$$\begin{array}{ccc} \mathcal{B}_L & \xrightarrow{\mathcal{F}} & \mathcal{B}_R \\ {\scriptstyle H_L}\downarrow & & \downarrow{\scriptstyle H_R} \\ \mathcal{B}'_L & \xrightarrow{\mathcal{F}'} & \mathcal{B}'_R \end{array}$$

commutes. For a ring map $R \to S$, the canonical identifications $S \otimes_R \mathcal{B}_{L/R} \cong \mathcal{B}_{L/R}(S \otimes_R P)$ identify $S \otimes_R \mathcal{F}$ and $S \otimes_R \mathcal{G}$ with the corresponding maps after scalar extension. Tensor powers and direct

sums commute with this extension, so no flatness assumption is needed. The same formulas commute with compatible coefficient reductions. An arbitrary square commuting only up to an unspecified chain homotopy is not covered by this argument.

36.5 The derived tensor interpretation and its hypothesis

The underlying relative complex computes the cohomology in Corollary 36.2.5. The bar coalgebra has a different homological interpretation, for which flatness of complexes matters. A complex M over R is called K-flat if $N \otimes_R M$ is acyclic for every acyclic complex N. Degreewise flatness alone is not substituted for this condition on an unbounded complex.

THEOREM 36.5.1. Let $U = R \oplus P$ as above, and assume that the underlying complex P is K-flat over R. Then $\mathcal{B}(U)$ represents $R \otimes^{\mathbf{L}}_U R$. Without this hypothesis, Theorems 36.3.1 and 36.3.2 still construct the coalgebra and its universal twisting cochain, but this derived tensor assertion is not made.

Proof. On $L = U \otimes_R \mathcal{B}(U)$ put

$$d_L(u \otimes c) = d_U u \otimes c + (-1)^{|u|} u \otimes bc - (-1)^{|u|} \sum u\tau(c_{(1)}) \otimes c_{(2)},$$

where $\Delta c = \sum c_{(1)} \otimes c_{(2)}$. The twisting equation implies $d_L^2 = 0$ by expansion. In word notation, the last sum removes only the first letter. The augmentation $L \to R$ is ϵ_U on length zero and zero elsewhere.

Write $\bar{u} = u - \epsilon_U(u)1$. An R-linear homotopy of degree -1 is

$$h(u \otimes [sa_1|\cdots|sa_j]) = -1 \otimes [s\bar{u}|sa_1|\cdots|sa_j].$$

An entry $s0$ gives zero. In $d_L h + h d_L$, the internal differential on $\bar{u}$ cancels, as do insertions within the remaining word. The first multiplication gives $\bar{u} \otimes c$. The two terms that join $\bar{u}$ to a_1 leave $\epsilon_U(u) \otimes c$ when $j > 0$. Thus $d_L h + h d_L = \mathrm{id} - \iota\epsilon_L$, including $j = 0$. This proves that $L \to R$ is a quasi-isomorphism.

Filter L by word length at most j. Its successive quotients are $U \otimes_R (sP)^{\otimes j}$ with their internal differentials. If N is an acyclic right U-module, their tensors with N are $N \otimes_R (sP)^{\otimes j}$, which are acyclic by K-flatness. The filtration sequences are split on graded modules. Induction and exactness of filtered unions show that $N \otimes_U L$ is acyclic. Hence L is K-flat as a left U-module. Tensoring this resolution with the right augmentation module R kills its first-letter term and leaves exactly $(\mathcal{B}(U), b)$. □

For the arithmetic algebra $U_r = R_r \oplus P_r$, define $\mathcal{B}_r = \mathcal{B}(U_r)$. Its construction and functoriality do not require a K-flat replacement. Theorem 36.5.1 applies if such a hypothesis is established for the chosen arithmetic model. No identification of its bar cohomology with relative Galois cohomology is asserted: the latter is the cohomology of P_r itself.

36.6 Coefficient maps and completion

A commuting square of differential graded algebra maps

$$\alpha : A \to A', \qquad \beta : B \to B', \qquad \beta f = f' \alpha$$

induces $(a, y) \mapsto (\alpha(a), \beta(y))$ on the relative algebras. The formulas for D, multiplication, and b prove functoriality directly. This includes coefficient maps and compatible diagrams of continuous group

homomorphisms. Changing a local embedding by conjugation does not give such a strictly commuting square without additional choices.

A comparison of resolutions may commute only up to cochain homotopy. The correction to the relative map then has a measurable product defect.

Proposition 36.6.1. Let $\alpha : A \to A'$ and $\beta : B \to B'$ be differential graded algebra maps, and let $H : A \to B'$ have degree -1 with $f'\alpha - \beta f = dH + Hd$. Then

$$F : P(f) \to P(f'), \qquad F(a, y) = (\alpha(a), \beta(y) + H(a))$$

is a cochain map. For $x = (a, y)$ of degree n and $x' = (a', y')$, the first component of $F(x)F(x') - F(xx')$ is zero. Its second component is

$$\begin{aligned}(-1)^n &(f'\alpha - \beta f)(a)\beta(y') \\ &+ (-1)^n f'\alpha(a)H(a') - H(aa').\end{aligned}$$

In particular F induces the strict bar map constructed above if and only if this expression vanishes for every pair of inputs.

Proof. The second component of $D'F - FD$ is $(f'\alpha - \beta f)(a) - dH(a) - H(da) = 0$. Expanding the two products in (36.2) gives the displayed defect. A cochain map induces the tensorwise strict bar map precisely when it preserves the binary multiplication: projection of the bar-map equation on two letters is that identity. On one letter it is the cochain-map equation, and all other Taylor coefficients vanish. □

Thus cochain transport of a local primitive can preserve relative classes without supplying the multiplicativity required by the bar construction. A sheaf-cochain comparison must also control this defect or supply coherent higher components.

Proposition 36.6.2. For the Galois cochains with finite coefficients, reduction gives degreewise surjections and canonical isomorphisms

$$P_{r+1} \otimes_{R_{r+1}} R_r \cong P_r, \qquad \mathcal{B}_{r+1} \otimes_{R_{r+1}} R_r \cong \mathcal{B}_r.$$

They preserve differentials, relative products, coproducts, and universal twisting cochains.

Proof. A continuous map from a compact space to a finite discrete ring is constant on the parts of a finite clopen partition. Lift each of its values to R_{r+1}. A normalized cochain has value zero on every degenerate tuple, and choosing the zero lift preserves normalization. If a cochain reduces to zero, divide its finitely many values by ℓ^r and choose lifts. Its kernel is therefore exactly $\ell^r C^n(G, R_{r+1})$. This proves the cochain assertion. Finite products and the two summands of P_r commute with reduction. Tensor powers and direct sums do also. Every defining formula uses addition and multiplication of coefficients, which proves all the compatibilities. Each cochain module is also flat over its finite coefficient ring. Indeed, normalized functions constant on a fixed finite clopen partition form a finite free module: omit the cells meeting the degenerate tuples. Refining partitions gives a filtered union equal to all normalized cochains. Filtered colimits of flat modules are flat, since tensoring and filtered colimits preserve exact sequences. Thus every degree of P_r and $\mathcal{B}_r$ is flat. This statement concerns modules in each degree, not K-flatness of the whole complex. □

Continuous $\mathbb{Z}_\ell$-valued cochains are the inverse limits of these finite cochains. Define the degreewise inverse limit

$$\widehat{\mathcal{B}} = \varprojlim_r \mathcal{B}_r.$$

Its tensor target is specified as

$$\widehat{\mathcal{B}} \,\widehat{\otimes}\, \widehat{\mathcal{B}} := \varprojlim_r (\mathcal{B}_r \otimes_{R_r} \mathcal{B}_r).$$

This is the completion used for the coproduct; it makes no implicit identification with another completed tensor product.

THEOREM 36.6.3. The compatible maps on $\mathcal{B}_r$ give a continuous square-zero differential and a coassociative counital coproduct on $\widehat{\mathcal{B}}$. The coderivation identity holds in the displayed completed tensor target. Each reduction is conilpotent. Ordinary conilpotence of $\widehat{\mathcal{B}}$ need not hold.

Proof. Every identity holds after every projection to r. Equality in an inverse limit is componentwise equality, so all the stated identities follow. Degreewise surjectivity of the transitions allows each element of $\mathcal{B}_r$ to be lifted successively to all higher indices. Moreover the kernel of the projection is $\ell^r\widehat{\mathcal{B}}$: in coefficients modulo ℓ^{r+k} divide a kernel element by ℓ^r and reduce modulo ℓ^k. These divided elements are well-defined because degreewise flatness identifies the annihilator of ℓ^r with $\ell^k\mathcal{B}_{r+k}$. They are compatible as k varies. Thus the projections are the coefficient reductions.

For failure of ordinary conilpotence, take $R = \mathbb{Z}_\ell$, a free rank-one $P = Ra$ in degree one with zero differential and zero product. In its completed bar, $z = \sum_{j\geq 1} \ell^j (sa)^{\otimes j}$ is defined because it has finite support modulo every ℓ^r. Every iterated reduced coproduct of z has a nonzero component of sufficient word length. Hence z is not conilpotent. □

The theorem concerns identities in the completed complex. An exchange of cohomology with inverse limit needs a separate vanishing statement for the corresponding $\varprojlim^1$ of cohomology groups. No such exchange enters the construction.

COROLLARY 36.6.4 *(Restricted adic completion).* For the relative Galois algebras P_r, let $\mathcal{B}_{r,L}$ and $\mathcal{B}_{r,R}$ use the two endpoint products. The maps of Theorem 36.4.2 induce a continuous isomorphism

$$\widehat{\mathcal{F}} : \varprojlim_r \mathcal{B}_{r,L} \xrightarrow{\cong} \varprojlim_r \mathcal{B}_{r,R},$$

whose inverse is $\varprojlim_r \mathcal{G}_r$. It preserves the completed differential and coproduct in

$$\varprojlim_r (\mathcal{B}_{r,R} \otimes_{R_r} \mathcal{B}_{r,R}).$$

Proof. The maps and inverses commute with each transition. Their two composite identities and their differential and coproduct identities hold at every finite coefficient stage. Equality in the inverse limit is componentwise equality. The maps are continuous for the inverse-limit topology because their composites with the projections factor through the corresponding finite stage. No exchange of cohomology with inverse limit is used. □

A map preserving the *increasing* filtration by word length need not be continuous for the *decreasing* filtration defining an unrestricted product of word lengths. The endpoint-change map supplies a minimal test.

Proposition 36.6.5. In general $\mathcal{F}$ has no continuous extension from $T_R^c(W)$ to

$$\prod_{n\geq 0} W^{\otimes_R n}$$

with discrete word coordinates, even for the identity map $f : \mathbb{Z} \to \mathbb{Z}$ concentrated in degree zero.

Proof. Take the relative map $f : R \to R$ to be the identity and let

$$v = s(0, 1) \in sP.$$

Its degree is zero and $F_n(v^{\otimes n}) = v$ for all $n \geq 1$. The partial sums

$$z_N = \sum_{n=1}^{N} v^{\otimes n}$$

converge in the word-length product topology: each word coordinate eventually stabilizes. But the length-one coordinate of $\mathcal{F}(z_N)$ is Nv, which is not eventually constant in the discrete module Rv. Hence the image sequence does not converge and no continuous extension agreeing with $\mathcal{F}$ can exist. □

By contrast, $z = \sum_{n\geq 1} \ell^n v^{\otimes n}$ belongs to the restricted adic completion: modulo every ℓ^r only finitely many word lengths occur. The length-one coordinate of its image is the well-defined ℓ-adic sum

$$\sum_{n\geq 1} \ell^n v = \frac{\ell}{1-\ell}\, v.$$

The denominator here is a unit in $\mathbb{Z}_\ell$. It is not a division used in the definition of the coalgebra map. This example distinguishes two completions on the very same generators.

36.7 Corestriction and arithmetic comparison

Coefficient reduction changes the ring while preserving the cochain products. Corestriction along a field extension has a different multiplicative behavior. For coefficients $\mathbb{Z}_\ell$, cochains mean the inverse limits of the finite coefficient cochains.

Proposition 36.7.1. Let $H \subset G$ be an open subgroup of index $n > 1$. With trivial $\mathbb{Z}_\ell$ coefficients, corestriction cannot be induced by a multiplicative cochain map on the ordinary cochain algebras. Nor can it be the first component of an A_∞ morphism inducing corestriction on cohomology. For index ℓ, the multiplicativity obstruction remains nonzero modulo ℓ^2.

Proof. Corestriction in degree zero sums over the cosets, so it sends $1 \in H^0(H, \mathbb{Z}_\ell)$ to $n \in H^0(G, \mathbb{Z}_\ell)$. Multiplicativity would imply $n = n^2$, which is false in $\mathbb{Z}_\ell$. An A_∞ morphism has a multiplicative map on cohomology, since its second identity makes its product defect a boundary. It therefore has the same obstruction. For $n = \ell$, $n^2 - n$ has ℓ-adic valuation one. The defects are 2 modulo 4 and 6 modulo 9 for $\ell = 2, 3$. □

Thus a coefficient inverse limit of bar coalgebras does not supply a multiplicative corestriction limit over a cyclotomic field tower. An arithmetic Hecke trace class $\mathcal{V}^{\mathrm{prim}}$ requires a separate comparison with these relative Galois algebras. Such a comparison must specify a chain algebra, augmentation, coefficient maps, and compatible local products. The algebraic bar constructed here has a square-zero differential and

endpoint-independent coalgebra type. Identifying it with an arithmetic chiral bar additionally requires geometric operations and their compatibility with residue maps and completion.

A finite arithmetic Chern–Simons action instead evaluates a Galois cohomology class against arithmetic duality data. Chapter 37 addresses that action and its proposed quantum boundary extension. The relative complex here records finite-local primitives; it supplies neither archimedean compact-support conventions nor an arithmetic fundamental-class pairing. A comparison with states, operators, or the full Weil functional requires further maps preserving the corresponding pairings and analytic domains.

Chapter 37

Arithmetic Chern–Simons Holography

Class-$\mathcal{S}$, Higgs-branch vertex algebras, and Costello–Gaiotto boundary categories require a complex curve or a quantized boundary theory. Kim arithmetic Chern–Simons supplies only the classical arithmetic action line. Finite state sums and the conditional boundary category appear in Chapter 103; the profinite comparison with $\mathcal{V}^{\mathrm{prim}}$ remains open.

The relative Galois complex of Chapter 36 retains a global cocycle together with chosen finite-local primitives. Its endpoint comparison is an integral bar-coalgebra isomorphism. An arithmetic action additionally requires a duality pairing and its archimedean conventions. Those data do not follow from the bar differential.

37.1 Class $\mathcal{S}$ Fails Arithmetically

Theorem 37.1.1 *(Gaiotto, arXiv:0904.2715).* . Class-$\mathcal{S}$ builds 4D $\mathcal{N} = 2$ theories $T[\Sigma, \mathfrak{g}]$ by compactifying the 6D $(2, 0)$ theory $\mathfrak{X}[\mathfrak{g}]$ on a punctured Riemann surface Σ.

Observation 37.1.2 *(three obstructions).* Arithmetic class-$\mathcal{S}$ on $\overline{\mathrm{Spec}\,\mathbb{Z}} \times \mathbb{R}^4$ fails:

(i) 6D $(2, 0)$ requires a smooth oriented 6-manifold; $\overline{\mathrm{Spec}\,\mathbb{Z}} \times \mathbb{R}^4$ is topologically 5-dimensional (arithmetic 1-dim plus 4-dim real). Connes' spectral dimension of $\overline{\mathrm{Spec}\,\mathbb{Z}}$ is 1, not 2 (Connes–Consani arXiv:1405.4527).

(ii) The self-dual 2-form B on an M5-brane has no Arakelov analogue (no star on 2-forms on a 1-d arithmetic curve, where $\Omega^2 = 0$).

(iii) Hitchin-moduli Higgs branches on $\overline{\mathrm{Spec}\,\mathbb{Z}}$ are not defined by the class-$\mathcal{S}$ formula: the Arakelov dualizing sheaf is a metrised arithmetic line, not the holomorphic canonical bundle of a Riemann surface.

Corollary 37.1.3. . Class-$\mathcal{S}$ as a generating principle for arithmetic vertex algebras is obstructed.

37.2 The Hitchin Base Has No Class-$\mathcal{S}$ Arithmetic Specialization

Theorem 37.2.1 *(arithmetic Hitchin obstruction).* . The class-$\mathcal{S}$ Coulomb branch

$$C_{\Sigma,\mathfrak{g}} = \bigoplus_i H^0(\Sigma, K_\Sigma^{d_i})$$

uses the holomorphic canonical bundle of a complex curve. For $\overline{\mathrm{Spec}\,\mathbb{Z}}$ the dualizing object is the Arakelov line with metric at infinity. Its sections belong to Arakelov intersection theory, not to a Hitchin base. Hence the class-$\mathcal{S}$ Coulomb and Higgs branches do not vanish; rather, the formula defining them has no canonical arithmetic value.

Remark 37.2.2 *(why the replacement is three-dimensional).* This obstruction is not a proof that an arithmetic 4-dimensional theory is topological. It says that the class-$\mathcal{S}$ descent from a 6-dimensional theory

along a complex curve has no arithmetic curve to descend along. Kim's arithmetic Chern–Simons theory is therefore not the topological remnant of that construction; it is a separate 3-dimensional arithmetic field theory.

37.3 KIM'S ARITHMETIC CHERN–SIMONS

Definition 37.3.1 *(Kim 2015, arXiv:1510.05818).* For a number field F and finite Galois module M, arithmetic Chern–Simons theory assigns to a Galois representation $\rho\colon \pi_1^{\text{ét}}(\overline{\operatorname{Spec} \mathcal{O}_F}) \to G$ the action

$$\mathrm{CS}_F(\rho) \;=\; \langle \rho^* c, [\overline{\operatorname{Spec} \mathcal{O}_F}] \rangle \;\in\; H^3(\overline{\operatorname{Spec} \mathcal{O}_F}, \mu_N)$$

built from a class $c \in H^3(BG, \mu_N)$. This is a genuine 3D arithmetic Chern–Simons action, not yet an Atiyah–Segal quantum TQFT. The topology is the Mazur–Morishita dictionary: primes are knots and $\overline{\operatorname{Spec} \mathbb{Z}}$ is the arithmetic 3-manifold (Morishita arXiv:0904.3399).

Remark 37.3.2. Chung–Kim–Kim–Pappas–Park–Yoo arXiv:1706.03336 extends Kim's construction to higher-dimensional arithmetic manifolds. Arithmetic Chern–Simons supplies the rigorous classical action functional at the arithmetic vertex that Witten's analysis (Chapter 34.8.1) identifies as the ingredient Deninger's programme requires.

37.4 $\mathcal{V}^{\mathrm{prim}}$ AND THE ACS BOUNDARY SHADOW

THEOREM 37.4.1 *(finite arithmetic CS boundary shadow).* . Let G be a finite gauge group and $c \in H^3(BG, \mu_N)$ a Kim arithmetic Chern–Simons level. Kim's theory supplies a classical arithmetic CS torsor/action line for this finite datum. The expression $\mathrm{ACS}[\overline{\operatorname{Spec} \mathbb{Z}}, \mathbb{G}_m, 1]$ is not an instance of Kim's finite-gauge construction; it is a separate abelian extension problem. A quantum boundary category $\partial_q \mathrm{ACS}$, once constructed, has conjectural archimedean Heisenberg factorization shadow

$$\chi\big(\partial_q \mathrm{ACS}\big)(s) \;=\; \prod_p (1 - p^{-s})^{-1},$$

and is conjecturally compared with the Hochschild-trace candidate $\mathcal{V}^{\mathrm{prim}}$ (a Hochschild trace class; Chapter 33.5.1). The quantum boundary category at finite places is conditional, as in Chapter 103.

Form. Kim's construction is classical: it assigns Chern–Simons actions and torsors to Galois representations. Witten's CS/WZW boundary theorem transports to $\overline{\operatorname{Spec} \mathbb{Z}}$ only after replacing the complex boundary curve and its OPE by the arithmetic integral transform of Chapter 103. That chapter defines the finite-level boundary category by transgression, conditional on the finite arithmetic cobordism input; the displayed Euler product is then a character-level expectation for the renormalised profinite boundary comparison with the Hochschild-trace class $\mathcal{V}^{\mathrm{prim}}$. □

COROLLARY 37.4.2 *(character = ζ).* .

$$\chi(\partial_q \mathrm{ACS})(s) \;=\; \prod_p (1 - p^{-s})^{-1} \;=\; \zeta(s),$$

conditional on constructing the quantum boundary category and identifying its Hochschild trace with the Hochschild-trace candidate.

37.5 Wilson Lines Are Labeled by Ramified Hecke Characters

Theorem 37.5.1 *(Wilson-line labels as local Hecke data).* . Wilson lines in ACS wrapped around the "knot" corresponding to a prime p (Mazur–Morishita arithmetic topology) are 1-dimensional defects in the arithmetic 3-fold, each *labeled by* a local Hecke character χ_p of $\mathbb{Q}_p^\times$ (ramified or unramified). The label is a closed point of the universal family of local characters, and conjecturally a module over the quantum boundary category specialized at p. Inserting a Wilson line with label χ_p produces a boundary defect whose local datum at p is the ramification datum of χ_p (conjectural; the categorical boundary module is part of the conditional boundary-category input of Chapter 103). Wilson-line labels are 0-dimensional data; the Wilson line itself is 1-dimensional.

Remark 37.5.2 *(defect/puncture dictionary).* Class-$\mathcal{S}$ punctures correspond to 6D codimension-2 defects in the complex setting; arithmetic ramification corresponds to Wilson lines in arithmetic Chern–Simons. The structural dictionary "punctures = defects" becomes "Wilson lines = ramification" in the arithmetic setting, with the 6D/4D framing replaced by the 3D arithmetic TQFT framing.

37.6 Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees as Adelic Character

Theorem 37.6.1 *(arithmetic Schur index).* . Let $\mathcal{H}^{\mathrm{arith}}$ denote the conjectural arithmetic Hilbert space on which Frobenius operators Frob_p act (one per prime p), and let the Schur grading at p be $t_p^{\mathrm{Frob}_p}$ (the formal Frob_p-graded trace variable). The arithmetic Schur index is the formal adelic graded trace

$$\mathcal{I}^{\mathrm{arith}}(\{t_p\}) \;=\; \mathrm{Tr}_{\mathcal{H}^{\mathrm{arith}}} \prod_p t_p^{\mathrm{Frob}_p}.$$

Under the Hecke substitution $t_p = p^{-s}$, $\mathcal{I}^{\mathrm{arith}}(s) = \prod_p (1 - p^{-s})^{-1} = \zeta(s)$. This is an Euler-character computation, not a construction of the Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees Schur-index category.

Remark 37.6.2. The Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees correspondence takes holographic form only after the finite-gauge ACS datum, boundary category, and trace functor have been constructed. The arithmetic vertex algebra generating problem, for which class-$\mathcal{S}$ is obstructed (Chapter 37.1.3), admits arithmetic CS holography as a conditional comparison, not as a theorem of the present finite-gauge formalism.

37.7 Arithmetic CS as the Generating Principle

(i) Class-$\mathcal{S}$ obstructed: three 4D-gauge obstructions (Chapter 37.1.3).

(ii) The class-$\mathcal{S}$ Hitchin base has no canonical arithmetic specialization on $\overline{\mathrm{Spec}\,\mathbb{Z}}$ (Chapter 37.2.1).

(iii) Kim's arithmetic Chern–Simons (arXiv:1510.05818) is the classical 3D action functional (Chapter 37.3.1).

(iv) Finite state sums are constructed in Chapter 103; the renormalised profinite boundary category is conjectural, as is its comparison with $\mathcal{V}^{\mathrm{prim}}$ and its character $\zeta(s)$ (Chapter 37.4.1).

(v) Wilson lines are 1-dimensional defects labeled by ramified Hecke characters (= expected modules of the quantum boundary category specialized at p, 0-dimensional data) (Chapter 37.5.1).

(vi) BLLPRvR adelic character: $\zeta(s)$ is the conjectural Schur index character of arithmetic CS (Chapter 37.6.1).

Kim arithmetic $\mathbb{G}_m$-Chern–Simons on $\overline{\operatorname{Spec}\,\mathbb{Z}}$ at level 1 supplies the classical arithmetic action. Chapter 103 constructs finite state sums and states the boundary category as a conditional profinite problem; the renormalised comparison with $\mathcal{V}^{\mathrm{prim}}$ remains open.

Chapter 38

The Hochschild Trace of the Iwahori Hecke Category

The primary object is $\mathcal{V}^{\mathrm{prim}}$, the Hochschild trace class of the identity on the global arithmetic Iwahori Hecke category of GL_2. This chapter places $\mathcal{V}^{\mathrm{prim}}$ on the arithmetic Langlands diamond via Bezrukavnikov's affine Hecke equivalences (arXiv:1209.0403), Mirković–Vilonen geometric Satake (arXiv:math/0401222), Ben-Zvi–Nadler character theory (arXiv:0904.1247), Arinkin–Gaitsgory spectral decomposition (arXiv:1201.6343), the Emerton–Gee (φ, Γ) stack (arXiv:1908.07185), and Fargues–Scholze geometrization (arXiv:2102.13459).

38.1 The Naive $\mathrm{Bun}_{GL_2}(\mathrm{Spec}\,\mathbb{Z})$ Has Only One Coarse Point

Theorem 38.1.1 *(Minkowski).* . $\pi_1^{\text{ét}}(\mathrm{Spec}\,\mathbb{Z}) = 1$: every étale cover of Spec $\mathbb{Z}$ is trivial. Class number of $\mathbb{Q}$ is 1.

Corollary 38.1.2. . The groupoid $\mathrm{Bun}_{GL_2}(\mathrm{Spec}\,\mathbb{Z})$ has one object up to isomorphism, represented by $\mathbb{Z}^2$, and stabilizer $GL_2(\mathbb{Z})$. Thus

$$\mathrm{Bun}_{GL_2}(\mathrm{Spec}\,\mathbb{Z}) \simeq BGL_2(\mathbb{Z})$$

as a discrete stack, not as a point. The lost datum in the coarse quotient is exactly the arithmetic automorphism group; it does not produce the geometric Hecke correspondence supplied by a curve.

38.2 The Spherical Hecke Category Collapses the OPE

The coarse automorphic stack over Spec $\mathbb{Z}$ has one component and stabilizer $GL_2(\mathbb{Z})$. It has arithmetic monodromy, but no geometric curve along which a Hecke correspondence can move. Thus one is forced to ask which local Hecke category at a prime p carries the noncommutative structure visible to a Hochschild trace. Geometric Satake identifies the spherical category but reveals its commutativity.

Theorem 38.2.1 *(Mirković–Vilonen).* . Geometric Satake gives $\mathrm{Perv}_{GL_2(O)}(\mathrm{Gr}_{GL_2}) \xrightarrow{\sim} \mathrm{Rep}(\widehat{GL_2}) = \mathrm{Rep}(GL_2)$.

Observation 38.2.2 *(spherical Hecke commutativity).* The local spherical Hecke algebra $\mathcal{H}_p = C_c(GL_2(\mathbb{Z}_p)\backslash GL_2(\mathbb{Q}_p)/GL_2(\mathbb{Z}_p))$ is commutative: this is the content of the Satake isomorphism $\mathcal{H}_p \xrightarrow{\sim} \mathbb{C}[GL_2^\vee]^{GL_2^\vee}$. Its derived enhancement $\mathcal{H}^{(p)}$, an E_1-algebra in chain complexes (hence E_2 as a graded object under Dunn additivity), and Perv(Gr), a monoidal abelian category under convolution, are related by the Mirković–Vilonen equivalence; but the commutativity of $\mathcal{H}_p$ means the resulting Hochschild homology carries no automorphic spectral content beyond the centre.

38.3 The Iwahori Hecke Category Carries Convolution Data

Before invoking Bezrukavnikov's equivalence we record the Bernstein presentation that gives the chapter its name. The affine Hecke algebra $H_q = H_q(\widetilde{W})$ of the extended affine Weyl group $\widetilde{W} = W_0 \ltimes X^*(T)$ (with W_0 the finite Weyl group and $X^*(T)$ the character lattice of the maximal torus) is generated by:

- lattice translations θ_λ for $\lambda \in X^*(T)$, forming the Bernstein subalgebra $\mathbb{C}[X^*(T)] \subset H_q$;
- finite Hecke generators T_s for each simple reflection $s \in W_0$, satisfying the braid and quadratic $(T_s - q)(T_s + 1) = 0$ relations.

The interaction between the two layers is the *Bernstein relation*: for a simple reflection $s = s_\alpha$ with simple coroot $\alpha^\vee$ and $\lambda \in X^*(T)$ orthogonal to $\alpha^\vee$,

$$T_s\, \theta_\lambda\, T_s^{-1} \;=\; \theta_{s(\lambda)},$$

while for general λ the conjugation acquires a correction term proportional to $(\theta_\lambda - \theta_{s(\lambda)})/(1 - \theta_{-\alpha})$ expressing the failure of θ_λ to be s-invariant (Lusztig 1989, *Affine Hecke algebras and their graded version*, J. AMS 2, eq. (8.4)). The Bezrukavnikov equivalence below sends this noncommutative algebra structure to a coherent-sheaf convolution on the Steinberg variety; it is the categorical lift of the Bernstein presentation, and the chapter's framing "Bezrukavnikov–Bernstein–Langlands" records the three layers.

The commutative spherical category is replaced by the Iwahori-equivariant category, whose noncommutative convolution datum is precisely what Bezrukavnikov's equivalences encode on the coherent side.

THEOREM 38.3.1 *(Bezrukavnikov arXiv:1209.0403).* . Let $\widetilde{\mathcal{N}}$ denote the Springer resolution $\widetilde{\mathcal{N}} = T^*(GL_2/B)$ of the nilpotent cone, and let $\mathrm{St}_{GL_2} = \widetilde{\mathcal{N}} \times_{\mathcal{N}} \widetilde{\mathcal{N}}$ denote the Steinberg variety (the derived fibre product over the nilpotent cone). Equivalences

$$\mathrm{D}^b\mathrm{Coh}^{GL_2 \times \mathbb{G}_m}(\widetilde{\mathcal{N}}) \xrightarrow{\sim} \mathrm{D}^b\mathrm{Coh}(\mathrm{St}_{GL_2}) \xrightarrow{\sim} \mathrm{D}^b_{\mathrm{mix}}(\mathrm{Perv}_{\mathrm{Iw}}(\mathrm{Fl}_{GL_2})).$$

The Iwahori-fixed direction carries the noncommutative convolution datum needed for the Hochschild trace: the affine flag variety admits an Iwahori stratification indexed by the extended affine Weyl group $\widetilde{W}_{GL_2} = X^*(T) \rtimes W_f \cong \mathbb{Z}^2 \rtimes S_2$, where $X^*(T) = \mathbb{Z}^2$ is the character lattice of the standard torus of GL_2.

Definition 38.3.2 *(global Iwahori Hecke category).*

$$\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}} \;:=\; \bigotimes_p{}' \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}, \qquad \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p} := \mathrm{D}^b_{\mathrm{mix}}\big(\mathrm{Perv}_{\mathrm{Iw}}(\mathrm{Fl}_{GL_2,\overline{\mathbb{F}}_p}), \mathrm{Fr}_p\big).$$

Remark 38.3.3 *(geometric local convention).* The p-adic Iwahori Hecke algebra is recovered from this geometric category by the sheaf–function dictionary. The coherent-side equivalences of Bezrukavnikov are geometric statements before this sheaf–function specialization.

38.4 The Emerton–Gee Spectral Side

The automorphic side is the global Iwahori Hecke category. The spectral side requires a global (φ, Γ)-module stack; Emerton–Gee construct the local building block, and the global Selmer-derived stack assembles them with fixed arithmetic data.

Theorem 38.4.1 *(Emerton–Gee arXiv:1908.07185).* . There is a Noetherian formal algebraic stack $\mathcal{X}^{\mathrm{EG}}_{GL_2}$ over $\operatorname{Spec}\mathbb{Z}_p$ whose points parametrise (φ,Γ)-modules of rank 2. The global spectral object used below is not a product or colimit of these local stacks; it is the Selmer-derived global deformation stack with fixed residual representation, determinant, and local conditions.

Theorem 38.4.2 *(arithmetic Arinkin–Gaitsgory).* (conditional locally, conjectural globally). Let $\mathrm{D}^{\text{sph-fin}}([GL_2])$ denote the spherically-generated full subcategory of the automorphic ∞-category $\mathrm{D}([GL_2])$ (functions on the adelic quotient $GL_2(\mathbb{A})$), and let $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$ denote the Selmer-derived global deformation stack of a fixed residual representation $\bar\rho\colon \mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to GL_2$, with fixed determinant and local conditions $\mathcal{L}$. Then:

$$\mathrm{D}^{\text{sph-fin}}([GL_2]) \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}).$$

Fargues–Scholze arXiv:2102.13459 supplies local geometrization, spectral action, and Hecke functoriality; Emerton–Gee supplies the local (φ,Γ) stack. The displayed automorphic-to-$\mathrm{IndCoh}_{\mathrm{Nilp}}$ equivalence is conditional locally and conjectural under global adelic descent.

38.5 The Hochschild Trace Placement

The automorphic and spectral sides being assembled, the placement of $\mathcal{V}^{\mathrm{prim}}$ is the Hochschild homology of the global Iwahori Hecke category.

Theorem 38.5.1 *(crowning placement).* .

$$\boxed{\mathcal{V}^{\mathrm{prim}} \;=\; \mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big)}$$

E_1-algebra from Dunn additivity ($E_1\otimes E_1 = E_2$) applied to the E_2-monoidal structure on each local factor; Ben-Zvi–Nadler arXiv:0904.1247 identifies $\mathrm{HH}_\bullet(\mathrm{D}(G/G)) = \mathcal{O}(\mathrm{LocSys}_G(S^1))^{\mathrm{flat}}$.

Remark 38.5.2 *(adelic inertia circle).* The local Weil group fits into

$$1 \longrightarrow I_{\mathbb{Q}_p} \longrightarrow W_{\mathbb{Q}_p} \longrightarrow \mathbb{Z} \longrightarrow 1,$$

where the quotient is generated by Frobenius. Thus $\widehat{\mathbb{Z}}$ is the completed Frobenius quotient, not the inertia group. Tame inertia has its own prime-to-p quotient and wild inertia is pro-p. The local system stack $\mathrm{LocSys}_{GL_2}(S^1_p)$, if used as an arithmetic circle shadow, records the Frobenius quotient rather than inertia itself. Ben-Zvi–Nadler arXiv:0904.1247 proves the complex-group identification $\mathrm{HH}_\bullet(\mathrm{D}(G/G)) \simeq \mathcal{O}(\mathrm{LocSys}_G(S^1))^{\mathrm{flat}}$; the present arithmetic statement is its (φ,Γ)-module counterpart.

38.6 Connection to Gaiotto's 3D Chern–Simons Presentation

Proposition 38.6.1 *(three-way comparison).* . The three presentations of $\mathcal{V}^{\mathrm{prim}}$ are conjecturally equivalent:

(i) (Kim arXiv:1510.05818 / Gaiotto) arithmetic Chern–Simons at the classical level produces a boundary contribution whose partition function specializes to $\mathcal{V}^{\mathrm{prim}}$ on the arithmetic Langlands spectral side;

(ii) (Bezrukavnikov–Bernstein) $\mathcal{V}^{\mathrm{prim}} = \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$;

(iii) (Costello–Gwilliam) the factorization window of $\mathcal{V}^{\mathrm{prim}}$ lies in $\mathrm{FactAlg}(\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi})$ over the adelic curve, with the Whittaker and factorization conditions of Chapter 20.

These are conditional comparison identifications, not proved equivalences. Ben-Zvi–Nadler's Chern–Simons/trace/Hecke triangle (arXiv:0904.1247) is the complex template; the arithmetic gluing requires global adelic descent (Conjecture F3 of Chapter 21).

38.7 Hecke Trace = Eichler–Selberg

The Hochschild trace of $\mathcal{V}^{\mathrm{prim}}$ specializes at each weight-level pair (k, N) to the trace of a Hecke operator on the space of cusp forms; this specialization is the Eichler–Selberg trace formula.

THEOREM 38.7.1 *(Eichler–Selberg trace formula, termwise form).* . For each $N \geq 1$, $k \geq 2$:

$$\mathrm{tr}\big(T_p \mid S_k(\Gamma_1(N))\big) \;=\; \mathrm{Ell}_{p,k,N} + \mathrm{Hyp}_{p,k,N} + \delta_{\mathrm{id}}(p) + \delta_{\mathrm{Eis}}(p,k,N),$$

where

$$\mathrm{Ell}_{p,k,N} = -\sum_{t^2<4p} P_k(t,p) H_w(t^2-4p),$$

where $P_k(t,p) = (\alpha^{k-1} - \beta^{k-1})/(\alpha-\beta)$, $\alpha\beta = p$, $\alpha+\beta = t$, H_w denotes the Hurwitz weighted class number of binary quadratic forms of discriminant t^2-4p; $\mathrm{Hyp}_{p,k,N}$ is the hyperbolic/parabolic contribution, $\delta_{\mathrm{id}}(p)$ is the identity contribution, and $\delta_{\mathrm{Eis}}(p,k,N)$ is the Eisenstein boundary contribution.

THEOREM 38.7.2 *(universal trace-class tabulation).* . $\mathcal{V}^{\mathrm{prim}}$ represents the universal family of Hecke eigensystems on the global automorphic category $\mathrm{D}([GL_2])^{\text{sph-fin}}$: it is the object over the weight-level base $\mathcal{W} \times \mathrm{Spec}\,\mathbb{Z}[1/N]$ (where $\mathcal{W}$ is the weight space parametrizing integers $k \geq 2$) whose closed-point fibres are individual Hecke eigensystems. Restricted to $S_k(\Gamma_1(N))$ for fixed (k, N), the fibre of the universal family recovers the Eichler–Selberg trace formula coefficient by coefficient; individual Hecke eigenforms are the closed points of this family.

38.8 The Arithmetic Langlands Diamond for $\mathcal{V}^{\mathrm{prim}}$

(i) $\mathrm{Bun}_{GL_2}(\mathrm{Spec}\,\mathbb{Z}) \simeq BGL_2(\mathbb{Z})$ has one coarse point and nontrivial stabilizer (Chapter 38.1.2); it is too small geometrically to carry the required Hecke correspondence, forcing the passage to the Iwahori-equivariant setting.

(ii) The spherical Hecke algebra is commutative (Satake isomorphism); the Iwahori-equivariant affine Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ carries the noncommutative convolution datum (Chapter 38.3.1).

(iii) The spectral side is the Selmer-derived global stack, built from local Emerton–Gee/(φ,Γ) stacks with fixed residual representation, determinant, and local conditions.

(iv) Arithmetic Arinkin–Gaitsgory: Fargues–Scholze and Emerton–Gee supply local inputs; the automorphic-to-$\mathrm{IndCoh}_{\mathrm{Nilp}}$ equivalence is conditional locally and conjectural globally (Chapter 38.4.2).

(v) Crowning placement: $\mathcal{V}^{\mathrm{prim}} = \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$ (Chapter 38.5.1).

(vi) Three-way comparison with Kim–Gaiotto arithmetic Chern–Simons and Costello–Gwilliam factorization (Chapter 38.6.1).

(vii) Hecke-trace tabulation recovers the Eichler–Selberg formula (Chapter 38.7.2).

$\mathcal{V}^{\mathrm{prim}}$ is an arithmetic Hochschild character. It encodes on the automorphic side the universal trace of the identity on the global Iwahori Hecke category of GL_2; on the spectral side, through the conjectural arithmetic Langlands equivalence, the structure sheaf $\mathcal{O}$ of the global Galois-deformation stack. The rank-2 Heisenberg presentation per prime is the Whittaker model of this trace, with the two generators diagonalising the Satake parameters.

Chapter 39

Arithmetic E_n Formality and CoHA

39.1 Chains on Little Intervals and Rectification

The operad of little intervals records ordered associative composition. Its chains can be compared with the associative operad over any coefficient ring. This statement concerns the operad; formality of an individual algebra is a different question.

Theorem 39.1.1 *(Little-interval chains).* . For any commutative ring R, the map

$$C_*(E_1; R) \longrightarrow \mathrm{Ass}_R$$

that sends each configuration to its ordering of the input intervals is an arity wise quasi-isomorphism of operads. Here singular chains use the shuffle map for products, and $\mathrm{Ass}_R(n) = R[S_n]$ lies in degree zero.

Proof. At arity n, the little-interval space has one component for each ordering of the intervals. In one such component, their left and right endpoints satisfy the ordered linear inequalities for nonoverlapping intervals of positive length. This region is convex and nonempty. Straight-line contraction to a fixed configuration shows that its singular chains have homology R in degree zero and zero otherwise, over any R. Substitution of intervals substitutes their orderings, so the chain augmentation is operadic. □

When the chosen algebra model categories admit rectification along this operad map, it replaces an E_1-algebra by an equivalent associative differential graded algebra. It does not replace that algebra by its cohomology with zero differential.

Corollary 39.1.2 *(Higher operations can survive rectification).* . Torsion-freeness of $H_*(E_1; \mathbb{Z}) = \mathrm{Ass}_{\mathbb{Z}}$ does not imply that an associative differential graded algebra is formal or that its minimal model has vanishing higher products.

Proof. For $A = k[x]/(x^3)$, the strict endomorphism algebra of its augmentation resolution has $H^*E = \Lambda(u) \otimes k[v]$, but $\langle u, u, u\rangle = \{-v\} \neq \{0\}$, with zero indeterminacy; see (2) and (3). Its cohomology algebra with zero differential has zero triple product. Quasi-isomorphisms preserve this single-valued Massey product, so the strict algebra is not formal. The comparison equations of Theorem 4.3.1 retain precisely the higher components needed to transport such data. □

39.2 E_2-Formality Fails Integrally

Theorem 39.2.1 *(Salvatore–Wahl; Cohen LNM 533; Fresse–Willwacher arXiv:1503.08699).* . Algebras over $C_\bullet(E_2; \mathbb{F}_p)$ carry non-trivial Dyer–Lashof power operations not encoded by the Gerstenhaber homology operad; these operations obstruct integral formality. Over $\mathbb{Q}$, Tamarkin's theorem (arXiv:math/9803025) establishes $C_\bullet(E_2; \mathbb{Q}) \xrightarrow{\sim} H_\bullet(E_2; \mathbb{Q}) = \mathrm{Ger}_{\mathbb{Q}}$ (where $\mathrm{Ger}_{\mathbb{Q}}$ is the Gerstenhaber operad over $\mathbb{Q}$), a torsor for the Grothendieck–Teichmüller group $\mathrm{GRT}_1(\mathbb{Q})$.

COROLLARY 39.2.2 *(no integral replacement by the Gerstenhaber operad).* . An integral E_2-algebra structure is not forbidden. What fails is the replacement

$$C_\bullet(E_2;\mathbb{Z}) \simeq \mathrm{Ger}_{\mathbb{Z}}.$$

Consequently an E_2-chiral-centre enhancement of $\mathcal{V}^{\mathrm{prim}}$ over $\mathbb{Z}$, if present, must retain the chain-level E_2-operad and its power operations. After tensoring with $\mathbb{Q}$, Tamarkin formality identifies the rational structure with a $\mathrm{GRT}_1(\mathbb{Q})$-torsor.

Remark 39.2.3 *(Kaledin Japanese cocycle).* Kaledin isolates the arithmetic obstruction: for an associative $\mathbb{Z}$-algebra A, the reduction $A \otimes \mathbb{F}_p$ may carry a non-trivial Hochschild A_∞-deformation class, the "Japanese cocycle," in $\mathrm{HH}^2(A \otimes \mathbb{F}_p)/\mathrm{HH}^2(A) \otimes \mathbb{F}_p$. Such classes are obstructions to naive integral strictification. They do not, by themselves, prove nonexistence of an integral E_2-algebra.

39.3 A Specified Strict Associative Model

A strict model is an actual differential graded algebra with an actual comparison to the proposed arithmetic operation system. The quasi-isomorphism of coefficient operads supplies neither the arithmetic algebra nor its geometric collision maps.

THEOREM 39.3.1. . For a differential graded associative R-algebra A, its displayed A_∞-presentation has only its differential and binary multiplication. A quasi-isomorphic minimal presentation can have nonzero higher operations; they must be retained by the comparison maps.

Proof. The differential graded identities are the A_∞ equations for $m_1 = d_A$, $m_2 = \mu_A$ and $m_n = 0$ for $n \geq 3$. The cubic example in the preceding corollary proves the second assertion. Its nonzero triple Massey product cannot disappear under a quasi-isomorphism. □

COROLLARY 39.3.2 *(Integral associative presentations).* . A supplied associative differential graded $\mathbb{Z}$-algebra gives an integral A_∞-algebra by the preceding construction. Identifying it with an arithmetic field system additionally requires the maps of (4.3), including their unit, collision and higher-substitution conditions.

Proof. No division occurs in the differential graded or suspended bar identities. The second assertion specifies the additional structure of that comparison: the coefficient algebra by itself has no maps to the independently given geometric operations. □

39.4 The Chiral Bracket via Adelic Residue

Definition 39.4.1 *(archimedean λ-bracket on the cover).* Let $\overline{C}$ denote the Arakelov compactification of the arithmetic curve, obtained by adjoining the archimedean place $|\cdot|_\infty$ to $\operatorname{Spec}\mathbb{Z}$. The Beilinson–Drinfeld λ-bracket is defined only on the archimedean Heisenberg cover, where a holomorphic diagonal and a complex residue exist:

$$\{a,b\}_\infty \;=\; \mathrm{Res}_{z=w}\,\omega_{a,b}(z,w).$$

No finite prime contributes a vertex-algebra residue on $\mathcal{V}^{\mathrm{prim}}$. A finite-place bracket would require a separate prismatic construction and is not part of the Hochschild trace class.

THEOREM 39.4.2 *(finite-place residue obstruction).* . The archimedean bracket above does not descend to a Beilinson–Drinfeld bracket on $\mathcal{V}^{\mathrm{prim}}$ over $\overline{C}$. Finite places are totally disconnected in the factorization topology used here, and the global object is an E_1 Hochschild trace class rather than a vertex algebra.

39.5 The arithmetic Hall comparison

A cohomological Hall comparison starts with an enhanced arithmetic category, its extension correspondences and its coefficient theory. A Hochschild trace class does not specify these data. Chapter 12 constructs the finitary and geometric Hall operations and separates their arithmetic comparison problems.

Theorem 39.5.1 *(Kontsevich–Soibelman).* For a finite quiver over $\mathbb{C}$ with zero potential, equivariant cohomology of its representation stacks has the extension product of Theorem 12.8.1. For a potential, the critical product uses normalized monodromic vanishing cycles, as defined in Section 12.10. The dimension shifts, coefficient category and chosen semistable or Serre loci are part of that construction.

Theorem 39.5.2 *(Davison–Meinhardt).* Assume the hypotheses of Theorem 12.10.1, including its stability and coefficient data. The critical Hall algebra has a PBW isomorphism of underlying graded objects with symmetric powers of $H(B\mathbb{C}^{\times})_{\mathrm{vir}} \otimes \mathcal{B}$. Its perverse associated graded is free commutative in the specified symmetry, or free supercommutative after the stated sign modification. An algebra isomorphism with a free supercommutative algebra holds for the finite symmetric, zero-potential quiver of Theorem 12.9.1.

Question 39.5.3 *(Arithmetic CoHA comparison).* Construct an arithmetic quiver with potential, or another independently defined Hall category, and the enhanced arithmetic object to compare with its BPS object. Specify the coefficient theory, stability and completion, and construct a comparison preserving the extension operations and their primitive maps. If places label vertices and Hecke correspondences supply arrows, construct the actual incidence spaces and their compatible finite-place assembly.

The Bost–Connes system has its own semigroup and time evolution. These data do not specify a quiver representation stack or a cohomological Hall product. Even a single isolated vertex with zero potential has the exterior algebra on infinitely many odd charge-one generators. One loop gives infinitely many even generators over $\mathbb{Q}$ (Example 12.8.2). A polynomial generator for each prime therefore does not describe these CoHAs. An arithmetic BPS identification requires the functor in Question 12.12.1.

39.6 Euler series and cyclic classes

Observation 39.6.1. On $\operatorname{Re} s > 1$ the absolutely convergent formulas are

$$\log \zeta(s) = \sum_{p} \sum_{k \geq 1} \frac{p^{-ks}}{k}, \qquad -\frac{\zeta'(s)}{\zeta(s)} = \sum_{p} \sum_{k \geq 1} (\log p)\, p^{-ks}.$$

The logarithms occur in the logarithmic derivative. An algebraic quiver potential is instead a cyclic class in a path algebra. Passing from either series to a potential requires a specified coefficient ring, any necessary completion, and an actual map compatible with traces.

Kontsevich–Soibelman's exponential Hodge theory provides a recipient for potential-dependent Hall invariants. Applying it to an arithmetic Euler series first requires the potential and its comparison map. A scalar identity does not supply a cyclic-homology class or that map.

39.7 Arithmetic Formality Stratification

The little-interval chain operad has the integral associative comparison of Theorem 39.1.1. Individual algebras can nevertheless retain the nonzero Massey products of Corollary 39.1.2. A supplied strict integral

algebra gives the presentation of Corollary 39.3.2; neither a geometric field realization nor a residue bracket follows from the operad comparison. The E_2 question and the arithmetic Hall comparison require their own operation data. Question 39.5.3 asks for the arithmetic quiver, potential, coefficient theory and BPS comparison. These constructions are required before identifying a trace class with an enhanced arithmetic object.

Chapter 40

The Arithmetic Yangian Collapses to Its Bethe Subalgebra

The Yangian $Y(\mathfrak{gl}_n)$ is controlled by the RTT presentation, an R-matrix, and a spectral parameter. An arithmetic Yangian has no uniform spectral difference $u - v$ across primes. The surviving structure is the commutative Bethe algebra together with the automorphic modularity condition.

The Yangian $Y(\mathfrak{gl}_n)$ (Drinfeld 1985, 1988) is a Hopf algebra deformation of $U(\mathfrak{gl}_n[z])$ defined by the RTT relation $R(u-v)(T(u)\otimes 1)(1\otimes T(v)) = (1\otimes T(v))(T(u)\otimes 1)R(u-v)$ with Yang's rational R-matrix $R(u) = 1 + P/u$ (here P the permutation operator on $V\otimes V$). The question is whether this structure admits an arithmetic analogue over Spec $\mathbb{Z}$. Four independent obstructions show it does not. The correct arithmetic replacement is the commutative Bethe subalgebra, whose spectrum is the automorphic spectrum of GL_n.

40.1 The Four Obstructions to a Naive Arithmetic Yangian

Theorem 40.1.1 *(four structural obstructions to the RTT model).* . Yang's additive RTT construction with R-matrix $R(u) = 1 + P/u$ has no arithmetic analogue satisfying the four requirements below:

(i) **Discrete-continuous mismatch.** The spectral parameter u is continuous and Spec $\mathbb{Z}$ is discrete; primes cannot be spectral parameters.

(ii) **No cross-prime subtraction.** $u - v$ has no analogue across distinct primes ($\mathbb{Q}_p \not\hookrightarrow \mathbb{Q}_q$ for $p \neq q$).

(iii) **No meromorphic 1-form on** Spec $\mathbb{Z}$**.** Costello 4D Chern–Simons (arXiv:1709.09993) requires a meromorphic 1-form ω on the spectral-parameter direction; Spec $\mathbb{Z}$ has none.

(iv) **No ζ-valued shuffle kernel.** Arithmetic shuffle-kernel constructions with ζ-valued kernels fail the cocycle condition (Feigin–Odesskii).

Corollary 40.1.2 *(no RTT arithmetic Yangian as Hopf algebra).* . $Y^{\mathrm{arith}}(\mathfrak{gl}_n)$ does not exist as a noncommutative Hopf algebra deforming $U(\mathfrak{gl}_n[z])$ with the specified additive spectral parameter, arithmetic R-matrix, and RTT relation. Other categorical or non-RTT notions are not excluded by this obstruction.

40.2 The Bethe-Algebra Collapse

The four obstructions force the question: what commutative quotient of the Yangian does admit an arithmetic analogue? The answer is the Bethe subalgebra, which over $\mathbb{C}$ is already the coordinate ring of opers on a disk.

Theorem 40.2.1 *(Frenkel–Reshetikhin; Mukhin–Tarasov–Varchenko; Kamnitzer–Pham–Weekes).* (Frenkel–Reshetikhin, *Commun. Math. Phys.* 197 (1998) 1–31; Mukhin–Tarasov–Varchenko, *Selecta Math.* 17 (2011); Kamnitzer–Weekes, arXiv:1811.11902). For $\mathfrak{g}$ simply-laced, the Bethe algebra $\mathcal{B}(Y(\mathfrak{g})) \subset Y(\mathfrak{g})$ (the maximal commutative subalgebra generated by higher transfer matrices) is the coordinate ring of ${}^L\mathfrak{g}$-opers on a formal disk D:

$$\mathcal{B}(Y(\mathfrak{g})) \;\cong\; \mathcal{O}(\mathrm{Op}_{{}^L\mathfrak{g}}(D)).$$

Definition 40.2.2 *(arithmetic Bethe algebra).* The *arithmetic Bethe algebra* $\mathcal{B}^{\mathrm{arith}}(GL_n)$ acting on $\mathcal{V}^{\mathrm{prim}}$ (the Hochschild trace class of the identity on the global arithmetic Iwahori Hecke category, Chapter 24.1) is the commutative algebra generated by unramified Hecke operators $T_{p,1}, \dots, T_{p,n}$ for all primes p, together with Casimirs of $\mathfrak{gl}_n$ on each local factor $\mathcal{F}_p$ (the rank-n Heisenberg Fock space at the prime p). Equivalently,

$$\mathcal{B}^{\mathrm{arith}}(GL_n) \;=\; \bigotimes_p \mathcal{H}_p^{\mathrm{sph}}(GL_n) \;\cong\; \bigotimes_p \mathbb{C}[\alpha_1^{(p)}, \dots, \alpha_n^{(p)}]^{S_n}.$$

Theorem 40.2.3 *(Bethe-algebra shadow of $\mathcal{V}^{\mathrm{prim}}$).* . The surviving arithmetic object is the commutative Hecke spectral algebra $\mathcal{B}^{\mathrm{arith}}(GL_n)$. Its simultaneous eigenvectors are Hecke eigenforms, and its eigenvalues are Satake parameters. This is the Bethe-algebra shadow of an integrable system; no Bethe equations, transfer matrix, or Bethe-root reality theorem is asserted.

40.3 Primes Are Lattice Sites, Not Spectral Parameters

Principle 40.3.1 *(site-spectral duality).* In the XXZ spin chain from $U_q(\widehat{\mathfrak{sl}}_2)$, sites are discrete (labelled by $\mathbb{Z}$ or by particle number N); spectral parameter u is continuous ($\in \mathbb{C}$). Hecke eigenvalues live in $\mathbb{C}$ (spectral); primes live in $\mathbb{Z}_{\geq 2}$ (site).

Corollary 40.3.2 *(arithmetic spectral parameter is s).* . The arithmetic spectral parameter is the Langlands $s \in \mathbb{C}$, not a prime, not a p-adic number. The spectral direction is the archimedean fibre $\mathbb{C}_\infty$; the site direction is the Arakelov-compactified arithmetic curve $\overline{\mathrm{Spec}\,\mathbb{Z}}$.

Heuristic 40.3.3 *(4D Chern–Simons analogy, conditional on F2).* . Costello–Witten–Yamazaki 4D CS (arXiv:1709.09993) is a theory on $\Sigma \times C$ with Σ a topological real 2-manifold and C a complex curve carrying a meromorphic 1-form; its factorization algebra lives on Σ. The direct identification $\Sigma = \mathrm{Spec}\,\mathbb{Z}$ is dimensionally inconsistent on two counts. (i) $\overline{\mathrm{Spec}\,\mathbb{Z}}$ has étale cohomological dimension 3 (Artin–Verdier duality), not 2, so $\mathrm{Spec}\,\mathbb{Z} \times \mathbb{C}$ has total real dimension 5, not 4. (ii) Each finite place of $\overline{\mathrm{Spec}\,\mathbb{Z}}$ carries only locally constant (E_0) factorization structure (Chapter 30.4.1), so a 2-dimensional E_1-chiral factorization algebra of 4D CS type cannot live on the finite places at all; the E_1-chiral OPE concentrates at the archimedean fibre $\mathbb{C}_\infty$.

Remark 40.3.4 *(rerouting the 4D CS analogy through F2).* The honest analogy is conditional on Conjecture F2 (Chapter 42.2.1, perfectoid E_2-enhancement via Scholze diamonds). If F2 holds globally, the diamond side of the global Iwahori Hecke supplies an étale 2-site $S^{\text{ét}}$ with the Frobenius-semilinear arithmetic-complex datum of Chapter 58.1.2, and the CWY identification becomes

$$C = \mathbb{C} \text{ (spectral, } s\text{-plane)}, \qquad \Sigma = S^{\text{ét}} \text{ (Scholze-diamond 2-site, not Spec } \mathbb{Z} \text{ itself)},$$

with the E_1-chiral OPE constructed at $\mathbb{C}_\infty$ and extended across $S^{\text{ét}}$ by the F2 E_2-monoidal structure (Dunn additivity $E_1 \otimes E_1 = E_2$). Without F2 the 4D CS analogy is pattern-match only. The parallel 3D analogy with Kim arithmetic Chern–Simons (arXiv:1510.05818) matches $\overline{\mathrm{Spec}\,\mathbb{Z}}$ dimensionally

but carries no spectral direction, and is the source of the five-presentation item (i) in the manifesto (Chapter 24.1).

40.4 Automorphic Closure as Bethe Heuristic

Theorem 40.4.1 *(automorphic closure as Bethe coherence). Heuristic.* The eigenvalues $\alpha_1^{(p)}, \dots, \alpha_n^{(p)}$ satisfy no nontrivial relations at a single prime; they are arbitrary elements of $(\mathbb{C}^\times)^n$ modulo S_n. Across primes, they satisfy only the automorphic condition that $\{\alpha_i^{(p)}\}_p$ arises from a single Galois representation $\rho\colon \mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to GL_n(\mathbb{C})$ with $\alpha_i^{(p)}$ the eigenvalues of $\rho(\mathrm{Frob}_p)$. The rigidification is Bethe/Hecke coherence: the commutative Bethe algebra $\mathcal{B}^{\mathrm{arith}}(GL_n)$ diagonalises on automorphic eigenspaces labelled by Galois representations.

Remark 40.4.2 *(Ramanujan–Petersson, modularity).* The comparison with complex RTT systems is mnemonic. Modularity rigidifies a family of local Frobenius parameters by forcing them to arise from one global Galois representation; the arithmetic rigidification is commutative Bethe/Hecke and Galois-representational, not quadratic RTT.

40.5 Explicit Computation: $\mathfrak{gl}_1$ and $\mathfrak{gl}_2$

$\mathfrak{gl}_1$ *(Dirichlet characters)*

Proposition 40.5.1 *(rank-1 Hecke as a Fock adjacency model). Heuristic.* The spherical Hecke algebra $\mathcal{H}_p^{\mathrm{sph}}(GL_1) = \mathbb{C}[T_p^{\pm}]$ is the group algebra of the valuation lattice. In the rank-1 Fock model, the normalised adjacency operator $U_p = p^{-1/2}T_p + p^{1/2}T_p^{-1}$ acts by

$$U_p \cdot (a_{-1}^{(p)})^k|0\rangle_p \;=\; p^{-1/2}(a_{-1}^{(p)})^{k+1}|0\rangle_p + p^{1/2}(a_{-1}^{(p)})^{k-1}|0\rangle_p.$$

Eigenvalues are $\alpha_p + \alpha_p^{-1}$ with $\alpha_p \in \mathbb{C}^\times$.

Corollary 40.5.2. $\mathcal{B}^{\mathrm{arith}}(GL_1) = \mathbb{C}[T_2^{\pm}, T_3^{\pm}, T_5^{\pm}, \dots]$, polynomial algebra in countably many commuting variables. Eigenvectors = Hecke eigenforms = primitive elements of $\mathcal{V}^{\mathrm{prim}}$ labelled by global characters $\chi\colon \mathbb{A}_{\mathbb{Q}}^\times/\mathbb{Q}^\times \to \mathbb{C}^\times$.

$\mathfrak{gl}_2$ *(Hecke eigenforms)*

Proposition 40.5.3. $\mathcal{H}_p^{\mathrm{sph}}(GL_2) = \mathbb{C}[T_{p,1}, T_{p,2}^{\pm}]$ with

- $T_{p,1}$ eigenvalue $= \alpha_1^{(p)} + \alpha_2^{(p)}$ = trace of Frobenius in a 2-dim Galois rep;
- $T_{p,2}$ eigenvalue $= \alpha_1^{(p)}\alpha_2^{(p)}$ = determinant = central character at p.

Action on rank-2 Fock $\bigotimes_p \mathcal{F}_p^{(2)}$ via raising/lowering in each Heisenberg factor (Bump §3).

40.6 Local r-Matrix per Prime

Proposition 40.6.1 *(local classical r-matrix).* At each prime p, the Heisenberg level is $k = 1$, so $r_p^{\mathrm{arith}}(z) = \Omega_p/z$ with $z \in \mathbb{C}$ and Ω_p = the Casimir of the local $\mathfrak{gl}_n$-factor. The local classical r-matrices are independent across distinct primes; the discrete structure of Spec $\mathbb{Z}$ prevents their assembly into a global r-matrix.

Remark 40.6.2 *(automorphic condition replaces global r-matrix).* What rigidifies the local factors into a global object is the automorphic condition on Galois representations: the spectrum of $\mathcal{B}^{\mathrm{arith}}(GL_n)$ is the set of $\{\alpha_i^{(p)}\}_p$ arising from a single $\rho\colon \mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q}) \to GL_n(\mathbb{C})$. This is Bethe-spectrum coherence.

40.7 Yangian → Hecke = Langlands as Arithmetic Bethe Ansatz

Theorem 40.7.1 *(Hecke spectral algebra as Bethe shadow).* The classical Jacquet–Langlands correspondence (SLN 114, 1970) supplies the following Hecke spectral data:

- Hecke eigenforms are simultaneous eigenvectors of $\mathcal{B}^{\mathrm{arith}}$;
- Hecke eigenvalues are Satake parameters;
- Ramanujan–Petersson is a bound on Satake parameters;
- automorphic spectral decomposition of $L^2(GL_n(\mathbb{A})/GL_n(\mathbb{Q}))$ gives the diagonalisation of $\mathcal{B}^{\mathrm{arith}}$ on $\mathcal{V}^{\mathrm{prim}}$.

The arithmetic Bethe algebra $\mathcal{B}^{\mathrm{arith}}(GL_n)$ acts on $\mathcal{V}^{\mathrm{prim}}$, and the global Langlands correspondence is the arithmetic rigidity condition on its spectrum.

The Yangian $Y(\mathfrak{gl}_n)$ quantises an affine Lie algebra; the Hecke algebra quantises the automorphic side of Langlands. These are parallel quantum integrable systems; the arithmetic Bethe algebra $\mathcal{B}^{\mathrm{arith}}(GL_n) = \otimes_p \mathcal{H}_p^{\mathrm{sph}}(GL_n)$ is the commutative quotient that survives over $\mathrm{Spec}\,\mathbb{Z}$, and it is exactly the Hecke algebra. The $\kappa + \kappa^! = 0$ complementarity reappears as the unitarity of the Bethe spectrum and the functional equation, closing the loop with Chapter 33.

Chapter 41

Synthesis: Six Conditional Windows

$\mathcal{V}^{\mathrm{prim}}$ is the Hochschild trace class of the identity endofunctor on the global arithmetic Iwahori Hecke category of GL_2. It admits six conditional windows, five arithmetic avatars of the Vol I theorems, and the structure of Definition 41.6.1. Three conjectures state the remaining cross-Langlands comparisons.

41.1 The Synthesis

Conjecture 41.1.1 *(six conditional windows).* $\mathcal{V}^{\mathrm{prim}}$ admits the following six conditional windows on the Hochschild-trace candidate:

(i) **(Langlands / automorphic)** $\mathcal{V}^{\mathrm{prim}}$ is expected, under F1 and adelic categorical descent, to correspond to the structure sheaf of the Selmer-derived global spectral stack attached to a fixed residual representation $\bar{\rho}$, determinant, and local conditions. Individual Hecke characters are closed-point shadows of this family, not the family itself.

(ii) **(TQFT / Chern–Simons)** Kim arithmetic Chern–Simons supplies a classical arithmetic CS torsor/action line. A genuine quantum boundary category is an open construction. Thus the ACS window is retained only as a classical TQFT/factorization shadow whose Wilson labels are representation-level ramified Hecke data.

(iii) **(Categorical / Hochschild trace)** $\mathcal{V}^{\mathrm{prim}} = \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$, the trace class of the identity on the global affine Iwahori Hecke category.

(iv) **(Integrability / Bethe algebra)** $\mathcal{V}^{\mathrm{prim}}$ has a Bethe-algebra heuristic: primes behave as lattice sites, Hecke operators as transfer matrices, and Hecke eigenforms as Bethe eigenvectors. There is no RTT arithmetic Yangian Hopf algebra; the surviving algebra is the commutative Hecke/Bethe algebra $\otimes_p \mathcal{H}_p^{\mathrm{sph}}$.

(v) **(Statistical mechanics)**

$$\begin{aligned}\mathcal{V}_N^{\mathrm{prim}} \cong\ & (\text{Bost–Connes at rank } \pi(N)) \\ & \otimes (\text{universal Heisenberg descendant tower of rank } \pi(N))\end{aligned}$$

All arithmetic content lies in the Bost–Connes/Hecke factor; the Heisenberg factor is a finite-cutoff universal model rather than a global VOA.

(vi) **(Factorization / homotopical)** $\mathcal{F}_{\mathrm{CG}}(\mathcal{V}^{\mathrm{prim}}) \in \mathrm{FactAlg}_{\mathbb{C}_\infty}(\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi})$ with (F1)–(F5) of Definition 30.6.1: holomorphic factorization at the archimedean place, locally constant with Adams operations at each finite place.

These are comparison windows, not established equivalent presentations. Ben-Zvi–Nadler's identification $\mathrm{HH}_\bullet(\mathrm{D}(G/G)) = \mathcal{O}(\mathrm{LocSys}_G(S^1))^{\mathrm{flat}}$ is the complex template for gluing (1), (2), (3); the arithmetic version is F3 and must use the full Weil/(φ,Γ) target, with $B\widehat{\mathbb{Z}}$ only as an inertia shadow.

41.2 The Essential Theorem

THEOREM 41.2.1 *(G-row arithmetic complementarity = Riemann functional equation).* Assume the vector space, involution, central-defect identity, and meromorphic evaluation of Theorem 43.5.1, with the arithmetic levels as its two parameters. Assume in particular that the evaluation detects the specified defect vector. Then

$$\boxed{\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \iff \xi(s) = \xi(1-s).}$$

The intended arithmetic realization is the G-row with $\kappa = 0$. Identifying its Koszul dual with a Bost–Connes object requires the algebra, coefficient, completion and pairing maps of Question 46.5.4. To interpret the displayed biconditional, those maps must also identify the arithmetic central classes and their complementarity with the completed scalar character. The factor $\Gamma(s/2)\pi^{-s/2}$ is supplied by the Gaussian Mellin calculation. Interpreting it as a derived-center shift requires a separate compatible comparison. Neither the faithful Bost–Connes operator representation nor the scalar functional equation supplies these arithmetic identifications.

Proof. Apply Theorem 43.5.1 to the supplied arithmetic comparison. Its detection hypothesis gives the converse. Its defect identity and evaluation give the forward implication. □

Remark 41.2.2 *(the proposed arithmetic Koszul comparison).* The Vol I relation between Koszul duality and derived-centre complementarity, with values $\kappa + \kappa^! \in \{0, 8, 13, 250/3, 25/3\}$, motivates an arithmetic G-row comparison $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0$ with $\xi(s) = \xi(1-s)$. Such a specialization requires an arithmetic carrier and a duality preserving the relevant classes and pairings. It must also explain the proposed derived-centre interpretation of $\Gamma(s/2)\pi^{-s/2}$. These comparisons remain construction problems even though the scalar identities are classical.

41.3 Five Arithmetic Comparison Problems

Conjecture 41.3.1 *(arithmetic avatars).* The following are proposed arithmetic counterparts of the five chiral-bar-cobar theorems; their arithmetic carriers and comparison maps are part of the conjecture:

$\mathcal{A}^{\mathrm{arith}}$ Bar–cobar adjunction $\Omega^{\mathrm{ch,Ar}} \dashv B^{\mathrm{ch,Ar}}$ on Iwasawa-twisted Λ-coalgebras with $\mu = 0$ and arithmetic E_1-algebras with Deligne-pure bar cohomology.

B^{arith} Arithmetic Positselski: $\Omega^{\mathrm{Ar}} B^{\mathrm{Ar}}(C) \xrightarrow{\sim} C$ on conilpotent Λ-coalgebras with $\mu = 0$.

C^{arith} Derived-centre complementarity: $\kappa + \kappa^! \in \{0, 8, 13, 250/3, 25/3\}$. G-row $= 0$ is the Riemann functional equation (Theorem 41.2.1). B-row $= 8$ is the Vol III Borcherds lift.

D^{arith} Obstruction tower = Arakelov height filtration: $\mathrm{obs}_g^{\mathrm{Ar}} = \kappa \cdot h_g^{\mathrm{Ar}}$.

H^{arith} Construct an arithmetic algebra or category, its coefficients and Hochschild complex before formulating an arithmetic concentration theorem. The proposed integral targets $\mathrm{HH}^0 = \mathbb{Z}$ and $\mathrm{HH}^1 = \bigoplus_p \log p \cdot \mathbb{Z}$, and a proposed Witt-cotangent description of degree two, require the comparison maps of Question 29.7.11. For the specified complex normal-term Bost–Connes algebra, Theorem 29.7.1 instead gives an injection $\prod_p \mathbb{C} \hookrightarrow HH^1_{\mathrm{alg}}$. The exterior-algebra injection of Theorem 29.7.3 further gives nonzero algebraic classes in every degree. These results neither construct the proposed integral carrier nor identify an arithmetic trace map.

Vol I theorem	Arithmetic avatar	Form
A: bar–cobar	A^{arith} on Λ-coalgebras	Conjecture
B: Positselski	B^{arith} on $\mu = 0$-coalgebras	Conjecture
C: $\kappa + \kappa^!$ ceiling	G-row = 0	Conditional
C: $\kappa + \kappa^!$ ceiling	B-row = 8 (arithmetic K3)	Conjecture
D: obstruction tower	Arakelov height filtration	Conjecture
H: Hochschild invariants	Arithmetic carrier and comparison maps	Open problem

Table 41.1: Arithmetic avatars of the five Vol I theorems.

41.4 Segal Axioms as Tate's Thesis

Theorem 41.4.1 *(Tate line in arithmetic Segal notation).* (Tate's thesis for the analytic identities). Tate's thesis supplies the adelic integral line, Euler product, meromorphic continuation, functional equation, and residue for the zeta and Dirichlet sectors. Placing these data in Segal notation gives the following dictionary:

Segal sewing position	= Euler-product factorization of $L(s, \chi)$
Verlinde scalar	= class-number residue
Modular S-matrix position	= Γ-factor plus functional equation
Genus contribution	= Arakelov discriminant volume $\frac{1}{2}\log\lvert d_K\rvert$
Mapping-class position	= Galois labels plus Hecke symmetries
Conformal-block position	= Tate integral line
Sewing label	= Weil–Deligne parameter
Marked point	= place
Orientation	= Deligne trivialization of $\det R\Gamma$
Closed scalar $Z_K(s)$	= finite Euler product for $\mathrm{Re}(s) > 1$, completed by the archimedean Γ-factor

The theorem asserts the analytic Tate line. It does not assert the existence of a full arithmetic Segal functor.

41.5 Rank Residue

Theorem 41.5.1 *(Polyakov: the determinant rank is a residue).*

$$r_\zeta(\mathcal{V}^{\mathrm{prim}}) \;=\; 2 \cdot \mathrm{Res}_{s=1}\zeta(s) \;=\; 2.$$

This is not a trace, not a sum, and not a global Virasoro central charge. The functional equation $\xi(s) = \xi(1-s)$ replaces modular invariance; the Arakelov height pairing replaces the Weyl anomaly.

41.6 The Coherent Arithmetic Structure

The six-window placement (Conjecture 41.1.1), the arithmetic modular functor (Definition 32.8.1), the ACS classical boundary-shadow window (Theorem 37.4.1), the Hochschild trace placement (Theorem 38.5.1), and the rank residue (Theorem 41.5.1) are not six unrelated structures: each builds part of a common tuple $(S^{\text{ét}}, \mathcal{V}, \mathrm{Mod}(\mathcal{V}), W, \mathcal{F}, Z, r_\zeta, \kappa)$. Definition 41.6.1 collects these data on

the Arakelov curve $\overline{C}$. The dimensional comparison below relates the universal construction to its specializations.

Definition 41.6.1 *(arithmetic conformal field theory).* An *arithmetic conformal field theory* (aCFT) on the Arakelov curve $\overline{C} = \overline{\operatorname{Spec} O_K}$ with gauge datum (G, k) is a tuple $(S^{\text{ét}}, \mathcal{V}, \operatorname{Mod}(\mathcal{V}), W, \mathcal{F}, Z, c, \kappa)$ satisfying (B)–(K) below.

(B) Base. A stratified étale arithmetic site $S^{\text{ét}}$ of operadic arithmetic dimension 2, equipped with a stratified arithmetic complex datum $\mathfrak{J}^{\text{Ar}}$ in the sense of Remark 58.1.2. Conditional on F2 (Conjecture 42.2.1):

- at the archimedean place: $S^{\text{ét}}|_\infty = \mathbb{C}_\infty$ with its standard complex structure ($\mathfrak{J}^{\text{Ar}}_\infty = i$);
- at a finite prime p: $S^{\text{ét}}|_p = \operatorname{Spd} \mathbb{Q}_p$ (Scholze diamond) with $\mathfrak{J}^{\text{Ar}}_p$ the Frobenius-semilinear untilt-orientation, together with the Adams operation ψ_p and the prismatic/Nygaard comparison filtration when the finite-place diagonal is thickened.

The global $S^{\text{ét}}$ glues the local pieces through the Scholze-diamond side of the global Iwahori Hecke category. Thus $\mathfrak{J}^{\text{Ar}}$ is literal almost-complex geometry only at ∞; at finite primes it is the Frobenius-oriented arithmetic substitute that makes the pointed E_2 Iwahori Hecke datum functorial. It is not a tangent-bundle endomorphism at a finite prime and carries no equation $J^2 = -1$.

(V) Chiral algebra. A factorization algebra

$$\mathcal{V} \in \operatorname{FactAlg}_{S^{\text{ét}}}(\operatorname{Mod}_{\widehat{\mathbb{Z}},\psi})$$

of arithmetic dimension 2, satisfying (F1)–(F5) of Definition 30.6.1: genuine E_1-chiral OPE at the archimedean fibre $\mathbb{C}_\infty$, locally constant (E_0) with commuting Adams operations ψ_p at each finite place. $\mathcal{V}$ is the 2-dimensional universal family whose fibre at each closed point x of $S^{\text{ét}}$ is a module category $\operatorname{Mod}(\mathcal{V})_x$.

(M) Module category. For each closed point $x \in S^{\text{ét}}$, a category $\operatorname{Mod}(\mathcal{V})_x$ of $\mathcal{V}$-modules supported at x. Objects of $\operatorname{Mod}(\mathcal{V})_x$ are 0-dimensional data: individual modules, i.e., closed points of the universal family (V). The primary datum $(\mathbb{G}_m, 1)$ gives $\operatorname{Mod}(\mathcal{V}^{\text{prim}})_p$ = local Hecke characters of $\mathbb{Q}_p^\times$ (ramified allowed).

(W) Wilson-line defects. The bulk theory $\operatorname{ACS}[\overline{C}, G, k]$ on the arithmetic 3-fold $\overline{C}$ carries 1-dimensional defects $W_x(M)$ supported on closed-point loci $x \subset \overline{C}$ (prime-knots K_p and the archimedean locus K_∞), each labeled by a module $M \in \operatorname{Mod}(\mathcal{V})_x$. The defect is 1-dimensional; the label is 0-dimensional; neither is $\mathcal{V}$ itself, which is 2-dimensional and lives on $S^{\text{ét}}$ (not on $\overline{C}$).

(F) Modular functor. A Segal-style functor

$$\mathcal{F} \colon \mathcal{C}^{\text{Arak}} \to \operatorname{Hom}(\mathbb{C}_s, \operatorname{Line})$$

satisfying axioms (A1)–(A5) of Definition 32.8.1 (finiteness, factorization, Weil–Deligne sewing, modular invariance under $\operatorname{Gal}(\overline{K}/K) \ltimes GL_n(\mathbb{A}_K)/GL_n(K)$, functional equation). The relation to (V)–(M) is: the conformal block $\mathcal{F}(\overline{X}, S, \{\chi_{\mathfrak{p}}\})$ is the space of global $\mathcal{V}$-correlators for the module insertion $\{\chi_{\mathfrak{p}}\}_{\mathfrak{p} \in S}$, each $\chi_{\mathfrak{p}} \in \operatorname{Mod}(\mathcal{V})_{\mathfrak{p}}$.

(Z) Partition function.

$$Z(\overline{X}, S, \{\chi_{\mathfrak{p}}\})(s) \;=\; \mathcal{F}(\overline{X}, S, \{\chi_{\mathfrak{p}}\})(s) \;=\; L(s, \chi),$$

the completed automorphic L-function of $\chi = \otimes_{\mathfrak{p}} \chi_{\mathfrak{p}}$. Unmarked case: $Z(\overline{C}, \emptyset)(s) = \xi_K(s)$.

(R) Rank residue. $r_\zeta = 2 \cdot \mathrm{Res}_{s=1} \zeta_K(s) \in \mathbb{R}$; for $K = \mathbb{Q}$, $r_\zeta = 2$ (Theorem 41.5.1).

(K) Koszul complementarity. The derived-centre identity

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}}(\mathcal{V}) \;+\; \left(\kappa^{!}\right)_{\mathsf{G}}^{\mathrm{Ar}}(\mathcal{V}) \;=\; 0$$

holds, equivalent to $Z(s) = \varepsilon \cdot Z(1 - s)$ (axiom (A5) on $\mathcal{F}$; Theorem 41.2.1).

An aCFT datum is *primary* when $(G, k) = (\mathbb{G}_m, 1)$ and $\mathcal{V} = \mathcal{V}^{\mathrm{prim}}$. Its finite-place character is $\zeta(s)$ on $\mathrm{Re}(s) > 1$; the completed scalar $\xi(s)$ appears only after the archimedean Tate factor and the polar correction are inserted.

Remark 41.6.2 *(dimensional comparison).* Every geometric object in the aCFT datum carries a definite arithmetic dimension, recorded below; the dimensional assignments enforce the universal-vs-specialization stratification.

Object	Arithmetic dimension	Role
$\overline{C}$ (Arakelov curve)	étale 3 / Krull 1	CS bulk 3-fold
$S^{\text{ét}}$ (F2 diamond site)	2	chiral base
$\mathbb{C}_\infty$ (archimedean fibre)	2 ($= 1_{\mathbb{C}}$)	E_1-chiral OPE
$\mathcal{V}$ (universal family)	2 (on $S^{\text{ét}}$)	factorization algebra
$K_p \subset \overline{C}$ (prime-knot)	1	Wilson-line locus
$M \in \mathrm{Mod}(\mathcal{V})_x$	0	Wilson-line label, modules
$S^{\text{ét}}\vert_p$ (finite fibre)	0 (for factorization)	E_0 locally constant
$\mathcal{F}(\overline{X}, S, \chi)$	1 (meromorphic line)	conformal block
Z (partition function)	0 (meromorphic scalar)	L-function value

Total-space / fibre relation: $\mathcal{V}$ (dim 2) is the universal family; $M \in \mathrm{Mod}(\mathcal{V})_x$ (dim 0) is a closed-point specialization. The phrase "$\mathcal{V}$ is the universal Hecke character" asserts the former; the phrase "Wilson lines are labeled by ramified Hecke characters" asserts the latter. No object appears at two inconsistent dimensions.

Conjecture 41.6.3 *(coherent statement of the primary aCFT).* Assume the specified F1, F2, and F3 comparison data. The primary datum

$$(\overline{C}, G, k) \;=\; (\overline{\mathrm{Spec}\,\overline{\mathbb{Z}}}, \mathbb{G}_m, 1), \qquad \mathcal{V} \;=\; \mathcal{V}^{\mathrm{prim}}$$

satisfies (B)–(K). The six windows of Conjecture 41.1.1 verify the data:

- (i) Langlands / automorphic: builds (V), (M), (Z) from the expected Selmer-derived spectral stack over $\mathrm{D}([GL_2])^{\text{sph-fin}}$, conditional on F1 and adelic categorical descent.
- (ii) TQFT / Chern–Simons: builds (B), (V), (W), (C) through Kim's classical $\mathrm{ACS}[\overline{\mathrm{Spec}\,\overline{\mathbb{Z}}}, \mathbb{G}_m, 1]$ torsor/line and a conjectural quantum boundary category; no global boundary VOA is constructed.

- (iii) Categorical / Hochschild trace: builds (V), (M) via $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$ (Theorem 38.5.1).
- (iv) Integrability / Bethe algebra: builds (V), (M) via $\bigotimes_p \mathcal{H}_p^{\mathrm{sph}}$ and Bethe-eigenvector identification of Hecke eigenforms.
- (v) Statistical mechanics: builds (V), (Z) via Bost–Connes ⊗ universal Heisenberg.
- (vi) Factorization / homotopical: builds (B), (V) via the adelic axioms (F1)–(F5).

Axioms (A1)–(A5) of the arithmetic modular functor (Definition 32.8.1) discharge (F), (Z), (K). The essential theorem (Theorem 41.2.1) discharges (K). The Polyakov residue (Theorem 41.5.1) discharges (R).

Remark 41.6.4 *(aCFT coherence versus six-window independence).* The coherence conjecture is the statement that the six windows are *six axiom-checks of a single aCFT structure*, not six unrelated isomorphism classes. The dimensional comparison (Remark 41.6.2) enforces the universal-vs-specialization stratification at the definitional level; (F)–(Z)–(K) unify through the essential theorem (Theorem 41.2.1).

Remark 41.6.5 *(honest domain restrictions).* Three domain restrictions of the programme are carried by the aCFT definition rather than hidden:

(i) **F2-conditional base.** Item (B) assumes the Scholze-diamond E_2-enhancement. Without F2 the local aCFTs at each place exist but the global aCFT is not assembled; the primary datum then degenerates to a disjoint union of local aCFTs plus an archimedean aCFT.

(ii) **Admissible logarithmic lane** (Creutzig–Kanade–Linshaw). Non-unitary admissible parameters are excluded from (M) and treated as a boundary of the aCFT category, not as elements of it.

(iii) **Super Bethe-Hecke chain-level coproduct** (FM230). Outside the primary datum. Any super-enhancement of the aCFT must avoid RTT/Yangian claims and waits on an independent construction.

The aCFT of Definition 41.6.1 is stated on the non-degenerate, non-admissible, non-super locus of the programme.

Remark 41.6.6 *(why this is a conformal field theory).* The five classical CFT data are present in direct correspondence: (B) Riemann-surface base → arithmetic $S^{\text{ét}}$; (V) vertex/chiral algebra → arithmetic factorization algebra; (M) primary modules → local Hecke modules at each place; (F) conformal blocks → Tate integrals; (K) modular invariance → functional equation. What breaks from the classical picture is the archimedean-only locus of E_1-chiral structure (finite places are E_0 per (F1)–(F5)): the aCFT is a *stratified* CFT, chiral at ∞ and locally constant elsewhere, rather than uniformly chiral.

41.7 Langlands as Arithmetic Bethe Ansatz

THEOREM 41.7.1 *(Drinfeld–solo). Heuristic.* The classical Jacquet–Langlands correspondence admits the following Bethe/Hecke reading:

- Hecke eigenforms = Bethe eigenvectors of $\mathcal{B}^{\mathrm{arith}}(GL_n)$;
- Hecke eigenvalues = Bethe roots;
- Ramanujan–Petersson bound = Bethe-root unitarity;
- Automorphic spectral decomposition of $L^2(GL_n(\mathbb{A})/GL_n(\mathbb{Q}))$ = diagonalisation of the transfer matrix on $\mathcal{V}^{\mathrm{prim}}$;
- modularity of ρ supplies global Bethe-spectrum coherence; no RTT closure is asserted.

This is a heuristic dictionary, not a construction of an arithmetic RTT/Yangian Hopf algebra.

41.8 Source-Family Convergence

Source family	Surviving content	Reference
Drinfeld+Kapranov	Adelic automorphic object; no p-adic OPE	26
Kazhdan+Beilinson	Satake pair (α_p, β_p) on rank-2 Heisenberg	27
Gelfand+Borger	Polynomial Adams and divisor actions	28
Connes+Soibelman	Bost–Connes $\otimes$ universal Heisenberg	29
Costello+Gwilliam	(F1)–(F5) adelic factorization axioms	30
Etingof	Prime-indexed Macdonald and Hall models	14.9
Nekrasov	Degenerate $(\log p, \infty)$ arithmetic Nekrasov	31
Segal	Arithmetic modular functor = Tate	32
Beilinson–solo	Parshin–Gersten bar; G-row = 0 $\Leftrightarrow$ $\xi(s) = \xi(1-s)$	33
Witten	Automorphic vertex (not TQFT vertex)	34
Polyakov	$c = 2 \cdot \mathrm{Res}_{s=1}\zeta$ as residue	35
Gaiotto	Boundary of Kim arithmetic CS	37
Bezrukavnikov+Bernstein	Iwahori Hecke Hochschild trace	38
Kontsevich+Soibelman	E_1 integral, E_2 over $\mathbb{Q}$ only	39
Drinfeld–solo	Bethe algebra $\Rightarrow$ Langlands = arithmetic Bethe ansatz	40

Table 41.2: Proposed arithmetic comparisons associated with the source families.

Remark 41.8.1 *(common core of $\mathcal{V}^{\mathrm{prim}}$).*

(i) $\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class with E_1-chiral structure at ∞ and E_0-locally constant structure at finite places. It carries no Virasoro action, no Beilinson–Drinfeld factorization on $\overline{C}$ supplied by these local calculations. The prescribed index shifts fail the Frobenius condition on the monomial lattice; they satisfy it on the Hall lattice. A compatible lattice on the arithmetic trace class remains a comparison problem, not a consequence of either local statement.

(ii) It is a spectral datum: Hochschild trace class, ACS boundary-shadow window, automorphic representation, Bethe algebra module.

(iii) All arithmetic content lives on the Bost–Connes / automorphic / Hecke side; the VA structure that appears is the universal rank-$\pi(N)$ Heisenberg descendant tower, which does not see the primes.

(iv) Its finite-place scalar character is an L-function: $\zeta(s)$ for the trivial sector or $L(s, \chi)$ for Hecke characters χ, before archimedean completion.

(v) Comparing complementarity $\kappa + \kappa^! = 0$ with the Riemann functional equation is an intended arithmetic realization of Koszul duality. It requires the pairing and invariant maps specified in Question 46.5.4; the scalar functional equation alone does not supply those maps.

41.9 The Three Open Conjectures

Three conjectures remain open; their resolution closes the cross-Langlands loop (full statements in Chapter 42):

(i) **Global arithmetic Arinkin–Gaitsgory.** $\mathrm{D}([GL_2])^{\text{sph-fin}} \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$. Fargues–Scholze supplies local geometrization/spectral action and Emerton–Gee supplies local (φ,Γ) stacks; the displayed categorical equivalence is conditional.

(ii) E_2**-enhancement via Scholze diamonds.** Dunn additivity for the Hochschild trace requires perfectoid machinery. Spherical fusion and equal-characteristic templates are available; mixed-characteristic Iwahori E_2 is conditional.

(iii) **Arithmetic Ben-Zvi–Nadler.** $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) = \mathcal{V}^{\mathrm{prim}}$ as E_1-algebras. Theorem over $\mathbb{C}$ (Ben-Zvi–Nadler arXiv:0904.1247); conjecture over $\mathbb{Z}$, with full Weil/(φ,Γ) target required.

These three conjectures compare Kim's classical CS input with Bezrukavnikov–Bernstein's Hochschild presentation and Beilinson–solo's bar–cobar presentation.

41.10 Structural Rigidity of $\mathcal{V}^{\mathrm{prim}}$

Remark 41.10.1 *(distinct arithmetic comparison requirements).* The local calculations separate several construction problems. An RTT or Yangian description requires a specified arithmetic R-matrix and its relations. Arithmetic factorization requires its geometric structure maps. Borger descent requires a compatible integral Λ-form on the intended arithmetic carrier. The failure of the prescribed shifts on the monomial Fock lattice excludes that particular realization. It does not exclude the Hall lattice, other Frobenius lifts, or every geometric enhancement. The divisor substitutions, Adams action and their integral structures are those of Chapter 28. Their comparison with the Hochschild trace class remains additional data. No maximality or exhaustion theorem follows from this collection of local tests.

41.11 Logical Form of the Arithmetic Branch

The proposed arithmetic comparison in Theorem 41.2.1 requires the pairing and invariant maps described in Question 46.5.4. The classical functional equation and the selected Euler–Mellin scalar calculation do not construct those maps. The six proposed windows of Conjecture 41.1.1 likewise retain their specific comparison hypotheses in addition to the named F1, F2 and F3 inputs.

Chapter 43 reduces F1, F2, F3 to five narrower residual conditions: $\mathrm{L}_{\mathrm{ACD}}$, F2.c, F3.$\mathrm{BZN}^{\mathrm{Ar}}$, arithmetic Positselski, and Koszul–Petersson compatibility.

Chapter 44 isolates the zero-placement clause of Conjecture F-RH (Conjecture 44.1.1) as RH. The full conjecture also contains the unitary arithmetic structure on $\mathcal{V}^{\mathrm{prim}}$; the sufficient path to its zero-placement clause retains four inputs: arithmetic Positselski, Koszul–Petersson compatibility, arithmetic Hilbert–Pólya H-P^{Ar}, and positive Hilbert–Pólya Li trace HP–Li (Theorem 44.6.1). Here H-P^{Ar} includes the self-adjoint ordinate operator and the determinant and regularised trace identities of Hypothesis 44.3.2. HP–Li is positivity of the regularised traces of the Li transforms of the zero-divisor operator Θ_ξ, with the trace identity (44.4). These spectral hypotheses are not consequences of Virasoro polynomial positivity or of the finite oscillator trace. Under the full self-adjoint determinant realization, zero-placement already follows from its determinant divisor; the HP–Li formulation records the separate scalar trace route.

Question 41.11.1 *(arithmetic central-class comparison).* Construct an arithmetic Hecke category and its Heisenberg-sector carrier, together with a duality defining the central classes $\kappa^{\mathrm{Ar}}_{\mathsf{G}}$ and $(\kappa^!)^{\mathrm{Ar}}_{\mathsf{G}}$, and comparison maps realizing

$$\kappa^{\mathrm{Ar}}_{\mathsf{G}} + (\kappa^!)^{\mathrm{Ar}}_{\mathsf{G}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s).$$

The maps must identify the relevant operations and pairings on specified coefficient rings and completions, and must relate the central-class complementarity to the completed scalar character. These are the arithmetic comparison requirements of Question 46.5.4. The classical functional equation supplies the scalar identity; it does not construct the category, duality, central classes, or comparison maps.

Once an appropriate arithmetic Hecke category and the trace of its identity functor have been constructed, the intended $\mathcal{V}^{\mathrm{prim}}$ is that Hochschild trace object. This specifies its proposed categorical carrier, not a vertex-algebra structure. Relating it to arithmetic geometric or chiral constructions requires the corresponding functors and compatibility maps; those arithmetic extensions are additional constructions.

Chapter 42

Boundary Conjectures for the Six-Window Trace

The arithmetic trace class is controlled by three boundary conjectures. They are not consequences of one another. F1 gives the global spectral category, F2 gives the mixed-characteristic E_2-monoidal enhancement, and F3 identifies the resulting Hochschild trace with $\mathcal{V}^{\mathrm{prim}}$. Local theorems enter each boundary, but the displayed global equivalences are separate inputs.

Chapter 43 resolves the six-window trace into $\mathrm{L}_{\mathrm{ACD}}$*, F2.c, F3.BZN*^{Ar}*, arith. Positselski, and Koszul–Pet compatibility. The Riemann-Hypothesis branch of Chapter 44 is orthogonal to this trace construction except where the explicit spectral positivity hypotheses are imposed.*

42.1 F1: Global Arithmetic Arinkin–Gaitsgory

Conjecture 42.1.1 *(global arithmetic AG).* For $G = GL_2$, there is an equivalence of dg-categories

$$\mathrm{D}([GL_2])^{\text{sph-fin}} \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}\big),$$

where:

- $[GL_2] := GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A}_{\mathbb{Q}})/Z(\mathbb{A})K_\infty$ is the global automorphic double coset;
- $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$ is the Selmer-derived global deformation stack obtained by imposing a fixed residual representation $\bar\rho$, determinant, and local conditions $\mathcal{L}_v$ on the full Weil/(φ,Γ) local parameter stacks; it is not a product or colimit of local Emerton–Gee stacks;
- $\mathrm{IndCoh}_{\mathrm{Nilp}}$ denotes ind-coherent sheaves with nilpotent singular support (Arinkin–Gaitsgory arXiv:1201.6343).

Under the equivalence, $\mathcal{V}^{\mathrm{prim}}$ corresponds to the structure sheaf $\mathcal{O}$ of this Selmer spectral stack.

Remark 42.1.2 *(form).* The local theorems do not imply the displayed global equivalence. Fargues–Scholze arXiv:2102.13459 construct the local geometrisation, spectral action, and Langlands-parameter space via the Fargues–Fontaine curve and diamonds. Emerton–Gee arXiv:1908.07185 construct the local (φ,Γ)-module stacks (with arXiv:2012.12403 as the survey companion). These sources do not prove the categorical equivalence displayed in F1. Dotto–Emerton–Gee arXiv:2603.26887 gives a fully faithful $GL_2(\mathbb{Q}_p)$ functor for $p \geq 5$ with fixed central character; it is not an equivalence and it is not a family theorem over all central characters. Caraiani–Scholze arXiv:1511.02418 prove a unitary-Shimura-variety result in a different global setting.

Thus F1 is a global categorical assertion for $GL_2/\mathbb{Q}$, not a restatement of the local Fargues–Scholze or Emerton–Gee theorems. Under F1, $\mathcal{V}^{\mathrm{prim}}$ is a spectral object on the Selmer deformation stack, compatible with its Hochschild-trace presentation of Chapter 38.

42.2 F2: E_2-Enhancement via Scholze Diamonds

Conjecture 42.2.1 *(perfectoid E_2-enhancement).* The local Iwahori Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ carries a canonical E_2-monoidal structure coming from the Beilinson–Drinfeld Grassmannian over $\mathrm{Spec}\,\mathbb{Z}_p$

in Scholze's perfectoid (diamond) setting. Globally, the product $\otimes'_p \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ inherits a well-defined E_2-monoidal structure.

Remark 42.2.2 *(trace role).* Dunn additivity $E_1 \otimes E_1 = E_2$ applied to the E_2-monoidal structure gives the E_1-algebra structure on the Hochschild trace $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$; the E_1 Hochschild-trace structure on $\mathcal{V}^{\mathrm{prim}}$ at the categorical-trace level depends on this enhancement.

Remark 42.2.3 *(form).* The Beilinson–Drinfeld Grassmannian as a perfectoid space is constructed in Fargues–Scholze arXiv:2102.13459. Zhu's Witt-vector Grassmannian (arXiv:1603.05593; Bhatt–Scholze arXiv:1507.06490) gives the equal-characteristic analogue. The mixed-characteristic Iwahori-Hecke E_2 enhancement, as opposed to E_1 convolution or spherical fusion, remains conditional.

The global assertion is the Scholze-diamond gluing across primes, producing a restricted-tensor-product E_2-category.

42.3 F3: Arithmetic Ben-Zvi–Nadler

Conjecture 42.3.1 *(arithmetic Ben-Zvi–Nadler).* There is an equivalence of E_1-algebras

$$\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \xrightarrow{\sim} \mathcal{V}^{\mathrm{prim}}$$

realising the Chern–Simons–Hecke-trace-boundary triangle arithmetically: Kim (arXiv:1510.05818) arithmetic Chern–Simons supplies a classical boundary shadow; the Hochschild trace targets the full Weil/(φ,Γ) spectral category.

Remark 42.3.2 *(form).* Ben-Zvi–Nadler arXiv:0904.1247 establishes $\mathrm{HH}_\bullet(\mathrm{D}(G/G)) = \mathcal{O}(\mathrm{LocSys}_G(S^1))^{\mathrm{flat}}$ for complex reductive G.

The arithmetic adaptation requires:

(i) Conjecture F1 (global arithmetic AG);

(ii) Conjecture F2 (perfectoid E_2-enhancement);

(iii) Explicit computation of the Hochschild trace on arithmetic $\mathrm{Hk}^{\mathrm{Iw}}_{\mathrm{glob}}$ matching $\mathcal{V}^{\mathrm{prim}}$'s L-function character.

The intended F3 comparison relates the Chern–Simons candidate of Chapter 37.4.1 and the Hochschild candidate of Chapter 38.5.1. Chapter 33.8.2 constructs a coefficient bar. Identifying it with either candidate requires additional maps preserving the coefficient algebra, local conditions, and operations. Those maps are part of the arithmetic comparison, not consequences of the coefficient-bar identities.

42.4 Further Boundary Conditions F4–F11

F4: B*-Row Arithmetic Realisation*

Conjecture 42.4.1 *(arithmetic* B*-row ceiling).* There exists an arithmetic avatar of the Vol III Mukai-enhanced K3 Heisenberg such that $\kappa^{\mathrm{Ar}} + (\kappa^!)^{\mathrm{Ar}} = 8$ arithmetically. The witness is a Bruinier Heegner Chern-class reciprocity on a p-adic Shimura variety, at each prime p of good reduction.

Remark 42.4.2. Ingredients available: Kudla–Rapoport arithmetic intersection numbers on unitary Shimura varieties; Bruinier's singular-theta lifts; Borcherds products on $\mathrm{Sp}_4(\mathbb{Z})$. Open: integral assembly into an arithmetic B-row theorem.

F5: Arithmetic Chain Homotopy h_A^{Ar}

Conjecture 42.4.3 *(universal arithmetic chain homotopy).* There exists a universal chain homotopy h_A^{Ar} on the arithmetic bar complex $B^{\mathrm{ch,Ar}}(\mathcal{V}^{\mathrm{prim}})$ satisfying

$$h_A^{\mathrm{Ar}} \;=\; \frac{h_A^{\mathrm{LV}}}{\kappa + \kappa^!}$$

(where h_A^{LV} is the Losev–Vol III universal chain homotopy), with obstruction class $\mathrm{obs}^{(1)} \in H^2(\mathfrak{grt}^{\mathrm{ell}}, \mathfrak{sp} \otimes \mathfrak{sp})$ (where $\mathfrak{grt}^{\mathrm{ell}}$ is the elliptic Grothendieck–Teichmüller Lie algebra and $\mathfrak{sp}$ the symplectic Lie algebra in the relevant rank) vanishing iff $r_{\max} = 2$.

F6: Chenevier Determinant at $p = 691$

Conjecture 42.4.4 *(Chenevier determinant identity).* At $p = 691$ (the prime at which Ramanujan's cusp form Δ_{12} and the Eisenstein series are congruent mod 691),

$$\det_{\mathrm{Chenevier}}\Big|_{p=691} \;=\; \chi_{\mathrm{cyc}}^{11} \cdot \varepsilon_{B_{12}},$$

where χ_{cyc} is the cyclotomic character, $\varepsilon_{B_{12}}$ is the mod-691 Kummer character attached to the numerator of the Bernoulli number B_{12}.

Remark 42.4.5 *(connection).* This is the arithmetic avatar of the Chenevier determinant appearing in the Vol III universal trace identity. The prime $p = 691$ is the seed of the arithmetic B-row structure (Chapter 38, Theorem 38.5.1).

F7–F10: Additional Boundary Conditions

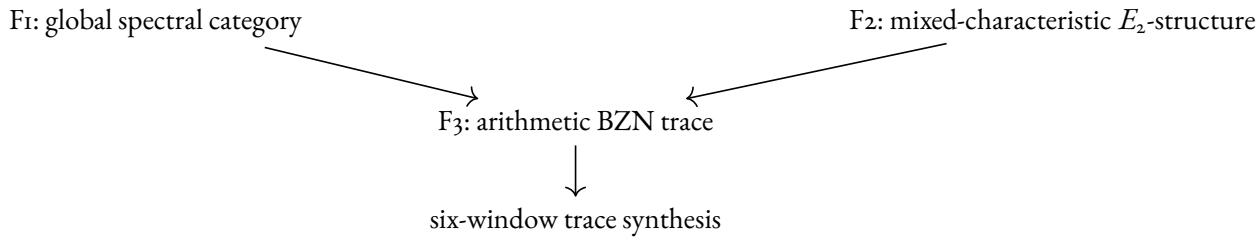
- **F7.** Arithmetic shadow-tower depth classification: $r_{\max}^{\mathrm{Ar}} \in \{2, 3, 4, \infty\}$ correspondence with Λ-ring depth / Galois-weight filtration.
- **F8.** Arithmetic Bethe/Hecke endpoint degeneration: degeneration of $\mathcal{B}^{\mathrm{arith}}(GL_n)$ at the zeta/Eisenstein pole-boundary points $s = 0$ and $s = 1$; these degeneration points are distinct from the affine Kac–Moody critical level $k = -h^\vee$.
- **F9.** Arithmetic super Bethe-Hecke chain-level coproduct: FM230 absorbed; arithmetic computation remains open; the RTT/Yangian arithmetic Hopf algebra structure, if it exists, remains to be determined.
- **F10.** Arithmetic CY-C conditional bridges: Vol III's six canonical constructions R_1–R_6 to the quantum vertex chiral group $G(K3 \times E)$, each lifted to the arithmetic Heisenberg $\mathcal{H}^{\mathrm{Ar},g=2}$; R_1 is the framed $\Phi_3^{(\Sigma_2,C)}$ (proved generator), R_2–R_6 each arithmetically conditional on convergence of the corresponding lift integral.

F11: All-Genus Arithmetic Koszul Duality

Conjecture 42.4.6 *(all-genus arithmetic Koszul duality).* For every $g \geq 0$ and every arithmetic genus-g datum $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$ (Definition 102.1.1), the Heisenberg Koszul self-duality identity

$$\kappa_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) = 0$$

is equivalent to the motivic functional equation $\Lambda_{\mathcal{D}_g}(s) = \epsilon_{\mathcal{D}_g}\Lambda_{\mathcal{D}_g}(w_{\mathcal{D}_g} - s)$ with $w_{\mathcal{D}_g} \in \{1, 2, 2g + 1\}$ the motivic weight center indexed by window (Dedekind; Hasse–Weil on the Jacobian; Siegel spin on GSp_{2g}).



Remark 42.4.7 *(form).* The forward direction is the Euler-product and Poisson-summation direction in the window where analytic continuation and the functional equation are already part of the input: Tate 1950 and Weil 1967 for number fields, Bloch–Kato 1990 for weight-1 motivic factors, and Arthur 2013 for the automorphic Siegel-spin packet after transfer. The converse direction requires the 2-dim arithmetic Positselski equivalence with $\mu_1 = \mu_2 = 0$ on $\Lambda_2 = \mathbb{Z}_p[[\Gamma_1 \times \Gamma_2]]$ (extending Chapter 46) plus rank-g Koszul–Petersson compatibility (extending Chapter 47). Ten residual conditions (Section 102.6) enumerate the substantial domain.

The datum $\mathcal{D}_g$ admits six convergent presentations (Arakelov fibration; Minkowski torus; ordinary crystalline Emerton–Gee stack; arithmetic Teichmüller with Hodge–Arakelov; chiral-bar-cobar interior; Shimura–Siegel Kudla–Rapoport); see Section 102.2.

The $g = 0$ specialisation is Vol IV's P1 resolution (Theorem 43.5.1), and the all-genus F-RH corollary (Corollary 102.5.1) places the Riemann, Hasse–Weil, Dedekind, and Siegel-spin zero-placement clauses in a single rank-g form, still conditional on the corresponding spectral positivity input.

42.5 Dependency Lattice

The three trace conjectures are not linearly ordered. The implication lattice is:

F1 supplies the spectral-side category; F2 supplies the E_2-enhancement making Hochschild trace E_1-algebraic; F3 identifies that trace with $\mathcal{V}^{\mathrm{prim}}$. With these three inputs, the arithmetic-branch synthesis (Conjecture 41.1.1) becomes a theorem.

42.6 Implication to the Trace Statement

The six-window trace theorem is conditional on the conjunction

$$\mathrm{F1} \wedge \mathrm{F2} \wedge \mathrm{F3}.$$

The G-row functional-equation theorem Theorem 41.2.1 is an independent Hochschild-cochain computation. It does not imply F1 or F2, and F1–F3 do not imply it without the arithmetic Koszul-resolution calculation.

42.7 Boundary Index

(i) F1: global arithmetic Arinkin–Gaitsgory (Conjecture 42.1.1): local FS/EG inputs exist; the local categorical comparison and global descent remain open.

(ii) F2: perfectoid E_2-enhancement (Conjecture 42.2.1): spherical/equal-characteristic inputs exist; mixed-characteristic Iwahori E_2 remains conditional.

(iii) F3: arithmetic Ben-Zvi–Nadler (Conjecture 42.3.1): theorem over $\mathbb{C}$, conjecture over $\mathbb{Z}$.

(iv) F4: arithmetic B-row ceiling $\kappa + \kappa^! = 8$ (Conjecture 42.4.1).

(v) F5: universal arithmetic chain homotopy $h_A^{\mathrm{Ar}} = h_A^{\mathrm{LV}}/(\kappa + \kappa^!)$ (Conjecture 42.4.3).

(vi) F6: Chenevier determinant at $p = 691$ (Conjecture 42.4.4).

(vii) F11: all-genus arithmetic Koszul duality (Conjecture 42.4.6): the identity $\kappa^{\mathrm{Ar},g} + (\kappa^!)^{\mathrm{Ar},g} = 0 \Leftrightarrow \Lambda_{\mathcal{D}_g}(s) = \epsilon_{\mathcal{D}_g}\Lambda_{\mathcal{D}_g}(w_{\mathcal{D}_g} - s)$ with $w_{\mathcal{D}_g} \in \{1, 2, 2g+1\}$; the converse direction is conditional on 2-dim Positselski and rank-g Koszul–Petersson. The arithmetic-gravity boundary is Chapter 103.

(viii) F7–F10: shadow-tower depth, critical-level degeneration, super Bethe-Hecke chain-level, CY-C conditional bridges.

Each item above is a mathematical boundary condition. The six-window trace is the object cut out by F1, F2, and F3; the RH branch enters only through the separately stated spectral-positivity hypotheses.

Chapter 43

Closure of F1–F3 and Resolution of the Three Pillars

The three conjectures F1, F2, F3 and the three pillars P1, P2, P3 record what the arithmetic branch requires in order to complete the Riemann Hypothesis reformulation of Chapter 44. F1 asserts global categorical arithmetic Langlands for $GL_2/\mathbb{Q}$; F2 asserts that the global Hecke category is E_2-monoidal; F3 identifies its Hochschild trace with $\mathcal{V}^{\mathrm{prim}}$. P1 is the essential equivalence between $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0$ and the Tate functional equation for Λ_ζ, equivalently for the pole-cleared $\xi_{\mathbb{R}}$; P2 is the Tate functional equation and explicit formula; P3 is unitarity. Each conjecture and each pillar is subjected to the seven-obstruction criterion below and either reduced to named components or proved conditionally. The residual obstructions at the end of this chapter are precisely stated, independently testable claims.

43.1 Conditions for an Arithmetic Comparison

A conjecture C is a structured reduction of C_0 if $C_0 \Leftrightarrow C$ and C is a conjunction of named inputs, each of which is either a theorem in the literature, a conditional with identified literature gap, or a conjecture with a precise statement. The seven obstructions are the structural tests for an equivalence claim. For each condition they are:

(i) *Specified comparison.* State the carriers and the map relating the two constructions.

(ii) *Sign / convention check.* Do chain-level signs and q-conventions match across cited sources?

(iii) *Ambient category check.* Do LHS and RHS live in compatible ∞-categories?

(iv) *Missing hypothesis.* Is a hidden hypothesis required (for instance sph-finiteness, perfectoid compatibility, $\mu = 0$)?

(v) *False functoriality.* Does the claimed equivalence preserve all relevant structure?

(vi) *Unproved equivalence.* Is any internal step itself a currently-open conjecture?

(vii) *Numerical normalization.* Specify each constant and the calculation identifying its normalization on the two sides.

Each obstruction produces either a valid implication, a correction (reformulation that survives), or a named residual obstruction. The result is a structured reduction, not necessarily a full closure.

43.2 F1: Structural Closure

Statement

F1 (Conjecture 42.1.1) asserts

$$\mathrm{D}([GL_2])^{\text{sph-fin}} \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}\big),$$

the global categorical arithmetic Langlands equivalence for $GL_2/\mathbb{Q}$, with $\mathcal{V}^{\mathrm{prim}}$ corresponding to the structure sheaf on the spectral side.

Mathematical Inputs and Comparison Conditions

Local geometric inputs. Fargues–Scholze arXiv:2102.13459 supplies local geometrisation on the Fargues–Fontaine curve; Arinkin–Gaitsgory arXiv:1201.6343 supplies the nilpotent-singular-support setting. The Emerton–Gee stack arXiv:1908.07185 is a different deformation carrier. Applying these constructions together requires the local categorical comparison specified in (F1.a).

Obstruction 2 (conventions). Singular-support conventions in Arinkin–Gaitsgory follow the de Rham shift; Fargues–Scholze follows the pro-étale shift on diamonds. The comparison is done via the Bhatt–Lurie prismatic-Nygaard convention of arXiv:2201.06120, which bridges both. *The comparison is mediated by prismatic Nygaard.*

Obstruction 3 (ambient categories). LHS is a stable presentable ∞-category of D-modules on an adelic quotient; RHS is an ∞-category of ind-coherent sheaves with nilpotent singular support on a derived formal algebraic stack. Via Gaitsgory–Rozenblyum's AMS DAG monographs the categories sit in the same ambient $(\infty, 2)$-category of correspondences.

Obstruction 4 (missing hypothesis). The sph-finite cut on the LHS is critical: without it the full automorphic category is too large (contains continuous spectrum and Eisenstein contributions requiring explicit parametrisation). Fargues–Scholze supply local geometrisation and spectral action; they do not identify this sph-finite automorphic category with $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on the Emerton–Gee stack. **Residual: local categorical comparison.**

Obstruction 5 (false functoriality). Functoriality under Hecke operators T_p at every prime is the key test. At each p, Fargues–Scholze provide Hecke correspondences and spectral action. Functoriality of a categorical comparison with the Emerton–Gee side is a separate local input. Globally, Hecke-functoriality is required place-by-place and across places (composition of Hecke operators at distinct primes). The cross-prime compatibility is the global gluing obstruction. **Residual: local comparison plus global gluing.**

Obstruction 6 (unproved equivalence). The local categorical comparison $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$ and the global restricted tensor product matching the global automorphic category are not in the literature as of 2026. Partial change: Caraiani–Scholze arXiv:1511.02418 for signature $(1, n-1)$ unitary Shimura varieties; Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321 for coherent Springer theory. Neither closes $GL_2/\mathbb{Q}$ in full generality. **Residual: local comparison and adelic-descent gluing.**

Obstruction 7 (numerical comparison). No numerical comparison currently backs F1; no synchronisation concern arises.

Structured Reduction

THEOREM 43.2.1 *(F1 reduction).* F1 is equivalent to the conjunction of:

(F1.a) *Local categorical comparison at every prime.* For each prime p, the expected local categorical Langlands equivalence

$$\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$$

holds, with local Hecke-functoriality. **Form: conditional theorem**. Fargues–Scholze arXiv:2102.13459 supplies the local geometrisation, spectral action, and parameter spaces. Emerton–Gee arXiv:1908.07185 supplies the (φ,Γ)-module stack. The displayed equivalence is not a theorem of either source; Dotto–Emerton–Gee arXiv:2603.26887 gives only a fully faithful fixed-central-character functor for $GL_2(\mathbb{Q}_p)$, $p \geq 5$.

(F1.b) *Adelic descent of the automorphic side.* The global automorphic category satisfies

$$\mathrm{D}([GL_2])^{\text{sph-fin}} \simeq \bigotimes_{v\in|\overline{C}|}{}' \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$$

as a restricted tensor product over places, with spherical vectors at almost all unramified places. **Form: conjectural, reduces to Tate–Weil restricted tensor product for automorphic representations** (Tate 1950, Weil 1967, Jacquet–Langlands 1970 for the representation-level statement; the categorical lift is conjectural, cf. Gan–Savin 2022 for partial change).

(F1.c) *Spectral-side global assembly.* The spectral side is the Selmer-derived global deformation stack

$$\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}} := \mathrm{Map}_{\det,\bar\rho}(G_{\mathbb{Q},S}, GL_2) \times^{\mathbf{R}}_{\prod_{v\in S}\mathrm{Map}(G_{\mathbb{Q}_v},GL_2)} \prod_{v\in S}\mathcal{X}_v^{\mathcal{L}_v},$$

with $\mathcal{X}_v^{\mathcal{L}_v}$ the prescribed local condition inside the full Weil/(φ,Γ) local parameter stack. This derived fibre product imposes the global Galois relation and Selmer conditions; it is not a product or colimit of local Emerton–Gee stacks. **Form: definitional here; derived and Noetherian properties are conditional/conditional on the local deformation conditions and the chosen Selmer problem.**

(F1.d) *Local-global compatibility under the equivalence.* For each finite set S of primes, the diagram

$$\begin{array}{ccc} \otimes_{p\in S}\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) & \xrightarrow{\simeq} & \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\prod_{p\in S}\mathcal{X}^{\mathrm{EG},p}_{GL_2}\big) \\ \downarrow & & \downarrow \\ \otimes_{p\in S'}\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) & \xrightarrow{\simeq} & \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\prod_{p\in S'}\mathcal{X}^{\mathrm{EG},p}_{GL_2}\big) \end{array}$$

commutes for $S \subseteq S'$, where the vertical arrows are restriction and extension-by-zero on the automorphic side, pull-back and push-forward on the spectral side. **Form: conjectural.**

Under this reduction, F1 closes given (F1.a) + (F1.b) + (F1.c) + (F1.d); (F1.c) supplies the correct spectral target but does not itself prove the categorical equivalence. The residual obstructions are local comparison, adelic descent, derived Selmer Noetherianity, and local-global compatibility.

Proof. Forward direction: assume F1. Restricting to local automorphic categories at each prime gives (F1.a). The global automorphic decomposition on the LHS (F1.b) follows from the tensor structure of the categorical equivalence applied to the automorphic side. The spectral decomposition (F1.c) is the explicit description of the Emerton–Gee stack. Compatibility (F1.d) follows from functoriality of the equivalence under inclusion of prime sets.

Reverse direction: assume (F1.a)+(F1.b)+(F1.c)+(F1.d). By (F1.c), the spectral target is the derived Selmer fibre product imposing the fixed residual representation, determinant, local conditions, and global Galois relation. The expected local comparison (F1.a) identifies each local automorphic category with the corresponding local spectral factor, while (F1.d) asserts that these local comparisons respect the derived

Selmer pullback rather than a naive product of local stacks. By (F1.b), the restricted tensor product of local automorphic categories is the global automorphic category. Composing these conditional identifications gives (43.2). □

Remark 43.2.2 *(open content after reduction).* The four items of Theorem 43.2.1 isolate the open content of F1: local categorical comparison (F1.a), adelic categorical descent (F1.b), the Selmer-derived spectral target (F1.c, definitional here with derived-Noetherian properties conditional), and local-global diagram commutativity (F1.d). The Selmer spectral target is correctly formulated; the categorical equivalence depends on conditional and conjectural inputs in (F1.a) and (F1.b).

COROLLARY 43.2.3 *(F1 consequence of local comparison plus adelic descent). Comparison hypothesis.* F1 holds if the following two inputs are true:

(F1.a) *Local categorical comparison at every prime.* The Fargues–Scholze local geometrization and the Emerton–Gee stack are compared by a categorical equivalence of the form required in Theorem 43.2.1.

($\mathbf{L}_{\mathrm{ACD}}$) *Adelic categorical descent.* Write $C_v = \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$. Supply a coherent diagram $S \mapsto \otimes_{v\in S} C_v$ over finite sets of places containing a fixed finite exceptional set. Its transition functors insert specified maps from the categorical tensor unit at the added places. These maps and all composition coherences are part of the datum.
Require an equivalence from this diagram's categorical colimit to the global automorphic category. It must preserve the Hecke operations and the supplied local categorical comparisons.

Proof. $\mathrm{L}_{\mathrm{ACD}}$ combines (F1.b) and (F1.d) into a single statement; (F1.c) supplies the correct Selmer-derived spectral target and (F1.a) is a named local comparison input. Applying Theorem 43.2.1 reduces F1 to (F1.a) plus $\mathrm{L}_{\mathrm{ACD}}$. □

Remark 43.2.4 *(substantial estimate).* Proving $\mathrm{L}_{\mathrm{ACD}}$ is of the same order as the function-field geometric Langlands work of Gaitsgory–Rozenblyum–Raskin–Lin (collectively 2019–2025), adapted to the number-field setting. The non-formal theorem condition of App. C still applies.

43.3 F2: Structural Closure

Statement

F2 (Conjecture 42.2.1) asserts that each local Iwahori Hecke category is E_2-monoidal via the perfectoid BD Grassmannian, and the restricted tensor product is globally E_2.

Mathematical Inputs and Comparison Conditions

Local geometric inputs. The equal-characteristic setting uses Mirković–Vilonen arXiv:math/0401222 and Zhu arXiv:1603.05593; the mixed-characteristic setting uses Bhatt–Scholze arXiv:1507.06490 and Fargues–Scholze arXiv:2102.13459. The required local E_2-structure is the hypothesis specified below.

Local geometric comparison. A complex formal-disk model and a mixed-characteristic perfectoid chart have different coefficient and geometric data. Their comparison must specify functors preserving convolution and the required collision maps. Scholze's tilting equivalence compares perfectoid algebras over a perfectoid field with algebras over its tilt (arXiv:1111.4914, Definition 1.6 and Theorem 1.7). It does not by itself identify the complex formal-disk model with the intended arithmetic Hecke category.

Ambient categories. Write $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ for stable presentable ∞-categories and colimit-preserving functors. Its tensor product represents separately colimit-preserving functors. Its unit is the category Sp of spectra, whose unit object is the sphere $\mathbb{S}$. The formal construction uses $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$.

Filtered colimits in its underlying categorical tensor category are preserved by tensoring in each variable. Thus HA 3.2.3.1 constructs the filtered algebra colimit on that underlying colimit. No presentability assertion about $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ itself is needed.

Pointing maps. At each place that may be inserted, one needs an actual morphism $\eta_v : \mathrm{Sp} \to C_v$ of E_2-algebras. Its value on the sphere is the monoidal unit. Identifying this value with a spherical object is additional local data. Existence of an invariant vector or a spherical subcategory alone does not give that identification and its operadic maps.

Cross-place coherence. The finite-stage transition functors tensor identities with the supplied maps η_v. Tensor associativity gives their composition homotopies and all higher compatibilities. The coherent diagram is therefore constructed from the pointings. It is not inferred from commutation of numerical Hecke eigenvalues.

Formal assembly and geometric comparison. Theorem 50.1.3 proves the restricted-tensor theorem under these hypotheses. The remaining comparison with an independently defined global Hecke category requires an actual functor and a proof that it is an equivalence. The filtered-colimit theorem supplies neither that functor nor the local geometric or categorical inputs.

Scope. F2 requires the categorical structures and their compatibility; no numerical equality supplies those maps.

Structured Reduction

Theorem 43.3.1 *(F2 assembly with supplied local data).* Consider the following local data and formal construction:

(F2.a) *Local geometric input.* At each prime, supply a local geometric model for the intended $\mathrm{Gr}^{\mathrm{BD}}_{GL_2,\mathrm{Spa}\,\mathbb{Z}_p}$, with the required perfectoid realization and E_2-factorization properties. The geometric frameworks include Fargues–Scholze arXiv:2102.13459, Zhu arXiv:1603.05593 and Bhatt–Scholze arXiv:1507.06490. The properties of the chosen model are hypotheses here, not consequences of categorical filtered colimits.

(F2.b) *Local categorical input.* Supply the local Iwahori categories $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,v}$, their colimit-compatible E_2-monoidal structures and the cofinite pointing maps below. This includes the archimedean category. A comparison with an equal-characteristic model, such as the setting of Bezrukavnikov arXiv:1209.0403, requires its own coefficient and categorical functors. Neither a local geometric space nor a spherical vector alone supplies these monoidal categories and maps.

(F2.c) *Formal restricted-tensor construction.* Let $\{C_v\}_{v\in V}$ satisfy Setup 50.1.1 with $O = E_2$. In particular, actual E_2-algebra maps $\eta_v : \mathrm{Sp} \to C_v$ are supplied on a cofinite subset V^{sph}. Write $u_v = \eta_v(\mathbb{S})$.
Define

$$\bigotimes_v{}' (C_v, u_v) := \operatorname*{colim}_{\substack{S\subseteq V \text{ finite} \\ V\setminus V^{\mathrm{sph}}\subseteq S}} \bigotimes_{v\in S} C_v,$$

with transitions given by these pointings. This colimit is an E_2-algebra, by Theorem 50.1.3. Its uniqueness is relative to the complete underlying colimit cocone.

Under the supplied local categorical and pointing hypotheses, (F2.c) constructs the restricted-tensor E_2-category. If a specified equivalence identifies its underlying category with a global Hecke category, transport gives that category an E_2-structure. Existence of this comparison is a separate arithmetic hypothesis. No converse reconstructing the local data from an arbitrary global category is asserted.

Proof. The supplied pointings form a diagram of finite tensor products in $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. Its indexing poset is filtered. HA 3.2.3.1 gives the stated algebra colimit, as proved in Theorem 50.1.3. Transport along the specified equivalence gives the final assertion. The geometric input (F2.a), the local enhancement (F2.b) and that equivalence are not constructed by this proof. □

Remark 43.3.2 *(formal assembly and the remaining inputs).* The formal theorem applies to supplied pointed families in any set of places. Its proof uses HA 3.2.3.1 and separate tensor preservation of filtered colimits. The local arithmetic E_2-enhancements, their pointings and an independent global comparison remain separate constructions. Singleton maps obey (M2) of Theorem 50.1.3 and need not be fully faithful.

43.4 F3: Conditional Closure

Statement

F3 (Conjecture 42.3.1) asserts $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \simeq \mathcal{V}^{\mathrm{prim}}$ as E_1-algebras.

Mathematical Inputs and Comparison Conditions

Carriers and conventions. The comparison concerns E_1-algebras in presentable ∞-categories on the sph-finite domain of F1. Ben-Zvi–Nadler arXiv:0904.1247, Bezrukavnikov, and the mixed-characteristic geometry of Fargues–Scholze give the respective settings. Their arithmetic comparison must preserve these carriers and the stated prismatic Nygaard conventions.

Obstruction 5 (false functoriality). The Hochschild trace is functorial on monoidal ∞-categories. The identification with $\mathcal{V}^{\mathrm{prim}}$ requires that the global automorphic side (F1 + F2) and the Hochschild trace be compatibly identified via Ben-Zvi–Nadler's categorical-character–Hecke–trace triangle (Ben-Zvi–Nadler arXiv:0904.1247 §1). This compatibility is the residual content. **Residual: arithmetic Ben-Zvi–Nadler compatibility.**

Obstruction 6. Ben-Zvi–Nadler over $\mathbb{C}$ is a theorem. The arithmetic extension requires replacing the complex inertia circle $S^1 = B\mathbb{Z}$ by an arithmetic target. The inertia-only candidate $B\widehat{\mathbb{Z}} = B\prod_p \mathbb{Z}_p$ records only the procyclic shadow and loses Frobenius, Weil-group, and (φ, Γ) data. **Residual: arithmetic Ben-Zvi–Nadler extension for the full Weil/(φ, Γ) target.**

Scope. The conclusion requires the stated categorical comparison.

Conditional Closure

Theorem 43.4.1 *(F3 conditional closure). Conditional statement.* Assume (F1.a)–(F1.d) and (F2.a)–(F2.c). Then F3 is equivalent to the single statement:

(F3.BZN^{Ar}) *Arithmetic Ben-Zvi–Nadler identification.* There is an E_1-algebra equivalence

$$\mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \;\simeq\; \mathcal{O}\big(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}\big)^{\mathrm{flat}}$$

arithmetising Ben-Zvi–Nadler arXiv:0904.1247, where $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$ is the full Weil/(φ,Γ) arithmetic local-system target, with flat structure sheaf pulled back from the global Emerton–Gee morphism. The map through $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ is only the procyclic inertial shadow. **Form: conjectural.**

Proof. Given F1 + F2, the Hochschild trace of $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is an E_1-algebra (via Dunn additivity applied to the E_2-structure from F2). By F1, the global Hecke category matches $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}})$. The Hochschild trace of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ for a derived stack $\mathcal{X}$ is classically $\mathcal{O}(L\mathcal{X})$ where $L\mathcal{X} = \mathrm{Map}(S^1,\mathcal{X})$ is the free loop space (Ben-Zvi–Nadler Thm 1.1). Arithmetically, $B\widehat{\mathbb{Z}}$ records the procyclic inertial shadow, while Frobenius and the Weil quotient are carried by the strengthened Weil/(φ,Γ) target $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$.

The comparison with $\mathcal{V}^{\mathrm{prim}}$ is controlled by the six conditional windows of Conjecture 41.1.1: $\mathcal{V}^{\mathrm{prim}}$ is defined as the Hochschild trace class, and the other windows are conditional characterisations conditional on F1–F3. Under this definition, F3 reduces to (F3.BZN^{Ar}), the arithmetic extension of Ben-Zvi–Nadler Thm 1.1 from the complex setting to the full Weil/(φ,Γ) target. □

Remark 43.4.2 *(arithmetic inertia circle).* The arithmetic inertia circle $B\widehat{\mathbb{Z}}$ is the classifying stack of the profinite abelian group $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$. Under the Mazur–Kapranov–Reznikov dictionary, it is the arithmetic avatar of the inertia circle of a knot complement; its geometric realisation sits inside $\overline{\mathrm{Spec}\,\mathbb{Z}}$ via the primes-as-knots correspondence (Morishita arXiv:0904.3399).

43.5 P1: G-Row Complementarity and the Functional Equation

The Arithmetic Comparison

Question 33.6.1 asks for arithmetic coefficient objects and a comparison between central complementarity and Mellin reflection. With the completed function $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$, its intended form is

$$\kappa^{\mathrm{Ar}}_{\mathsf{G}} + (\kappa^{!})^{\mathrm{Ar}}_{\mathsf{G}} = 0 \quad\Longleftrightarrow\quad \Lambda_\zeta(s) = \Lambda_\zeta(1-s).$$

The right-hand identity is classical. The left-hand parameters require arithmetic objects and a definition of their central levels. Relating the two sides requires an evaluation that detects the central defect. A scalar character alone does not provide such detection.

The Character and Its Missing Identifications

The elementary positive model has one bosonic occupation number $n_p \geq 0$ at each prime, with only finitely many nonzero entries. Define its energy by

$$H(n) = \sum_p n_p \log p.$$

Unique factorization identifies the tuple $(n_p)_p$ with the integer $m = \prod_p p^{n_p}$, and its energy with $\log m$. The partition function is therefore

$$Z(\beta) = \sum_{m\geq 1} m^{-\beta} = \prod_p (1-p^{-\beta})^{-1} = \zeta(\beta), \qquad \beta > 1.$$

The same absolutely convergent series gives the complex Mellin character for $\operatorname{Re} s > 1$, as proved in Theorem 33.5.1.

A full oscillator Fock space has additional modes. If the mode at (p, r) has energy $r \log p$, its partition function is

$$\prod_{p} \prod_{r \geq 1} (1 - p^{-r\beta})^{-1} = \prod_{r \geq 1} \zeta(r\beta) \qquad (\beta > 1).$$

Absolute convergence follows by bounding the logarithm by a constant multiple of $\sum_p p^{-\beta}$. Selecting the single occupation mode and identifying it with a primary quotient of an arithmetic bar are separate operations. The latter requires a map preserving the energy grading, local conditions, and coefficient completion.

The Bost–Connes system also has the zeta partition function in its convergent temperature range. Identifying an arithmetic Koszul dual with that system is the additional construction of Question 33.5.2. Its algebra, time evolution, and state comparison are not determined by equality of partition functions. Meromorphic continuation of the scalar ζ outside this range is not a convergent KMS trace.

A possible bar–cobar comparison would have to identify its pairing with the completed Mellin expression

$$\Lambda_\zeta(s) = \pi^{-s/2} \Gamma(s/2) \zeta(s).$$

The gamma factor, polar contributions, and reflection then belong to the comparison. The scalar residue $2 \operatorname{Res}_{s=1} \zeta(s) = 2$ remains valid, but its interpretation as a determinant rank needs the determinant-line hypotheses of Theorem 41.5.1.

A Criterion That Detects Complementarity

Let V be a complex vector space with an involution J, and let $\mathscr{M}(\mathbb{C})$ denote meromorphic functions on $\mathbb{C}$. Fix a linear evaluation $E : V \to \mathscr{M}(\mathbb{C})$, a vector v, and a vector w on which E is nonzero. Let $\kappa, \kappa^! \in \mathbb{C}$. The following criterion separates the construction of arithmetic objects from a precise implication once their comparison data exist.

THEOREM 43.5.1 *(a conditional complementarity criterion).* Suppose

$$v - Jv = (\kappa + \kappa^!)w, \qquad E(v)(s) = \Lambda_\zeta(s), \qquad E(Jv)(s) = \Lambda_\zeta(1 - s).$$

Then $\kappa + \kappa^! = 0$ if and only if $\Lambda_\zeta(s) = \Lambda_\zeta(1 - s)$. The same equivalence holds with $\xi(s) = \frac{1}{2} s(s - 1)\Lambda_\zeta(s)$.

Proof. Applying E to the first identity gives

$$\Lambda_\zeta(s) - \Lambda_\zeta(1 - s) = (\kappa + \kappa^!) E(w)(s).$$

Since $E(w)$ is not the zero meromorphic function, this identity vanishes exactly when $\kappa + \kappa^! = 0$. The polynomial $s(s - 1)/2$ is nonzero and invariant under reflection. Multiplying by it preserves equality of meromorphic functions. □

For an arithmetic application, V, J, v, w, E and the two levels must be constructed from the proposed dual objects. In particular, the displayed defect equation and the nonvanishing of $E(w)$ are substantive hypotheses. They are not consequences of a co–contra equivalence considered without an evaluation.

The nonvanishing condition cannot be dropped. For $V = \mathbb{C}^2$, let $J(x, y) = (y, x)$ and $E(x, y) = x + y$. The evaluations of $(1, 0)$ and $J(1, 0)$ agree, while their difference $(1, -1)$ is nonzero. Thus equality

after evaluation need not imply invariance of the object or cancellation of a central parameter. The criterion asks only for detection of the specified one-dimensional defect, not injectivity on all of V.

Remark 43.5.2 *(arithmetic hypotheses).* The arithmetic duality question includes its actual coefficient objects, continuous duals, completions, and unit and counit maps. The character comparison, Bost–Connes comparison, and detection of the central defect are further requirements. Question 33.7.1 keeps these categories and their comparison separate from the module-theoretic μ-invariant.

An Iwasawa vanishing theorem concerns a specified arithmetic module. Applying it to a Heisenberg construction requires an identification with that module, including its topology and Galois action. An unspecified cyclotomic deformation of a Fock space supplies no such identification. The coalgebras of Proposition 10.10.2 also show why $\mu = 0$ cannot replace conilpotence.

Mellin Reflection and the Forward Direction

For $\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}$, Poisson summation gives $\theta(t) = t^{-1/2}\theta(1/t)$. Splitting its Mellin integral at one gives the explicit continuation

$$\Lambda_\zeta(s) = -\frac{1}{s} - \frac{1}{1-s} + \frac{1}{2}\int_1^\infty (\theta(t)-1)\left(t^{s/2} + t^{(1-s)/2}\right)\frac{dt}{t}.$$

The integral is entire and the full expression is invariant under $s \mapsto 1-s$. This is the proof in Theorem 35.6.1. The polar terms are part of the formula. An unsubtracted theta integral over all ideles is not a replacement for its convergence and continuation argument.

Corollary 43.5.3 *(forward implication with an equivariant evaluation).* Suppose $E(Jx)(s) = E(x)(1-s)$ for all $x \in V$, and $v - Jv = (\kappa + \kappa^!)w$. If $\kappa + \kappa^! = 0$, then $E(v)(s) = E(v)(1-s)$. If in addition $E(v) = \Lambda_\zeta$, this is the completed zeta functional equation.

Proof. The defect equation gives $Jv = v$. Applying the equivariance identity to v proves reflection of $E(v)$, and the specified identification gives the last assertion. □

This implication needs no co–contra theorem once the displayed comparison maps have been supplied. Constructing those maps from arithmetic duality remains the original problem. The converse requires a detection hypothesis such as that of Theorem 43.5.1.

43.6 P2: Tate Functional Equation and Explicit Formula

Statement

P2 asserts that the meromorphic Tate character $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$ satisfies the Mellin-theta presentation, the functional equation, the explicit formula, and the residue identity. No global VOA or Zhu flat connection is used for $\mathcal{V}^{\mathrm{prim}}$.

Mathematical Inputs and Comparison Conditions

Analytic normalization. Tate 1950 gives the Mellin-theta presentation; the Riemann–von Mangoldt formula supplies the classical zero-counting expression. The completed function is $\Lambda_\zeta(s) = \Gamma(s/2)\pi^{-s/2}\zeta(s)$, with boundary poles at $s = 0, 1$.

Theorem

THEOREM 43.6.1 *(Tate functional equation and explicit formula).* The meromorphic completed zeta $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$ is the Tate character of the arithmetic Heisenberg trace and satisfies the following four identities:

(i) *Mellin-theta presentation.* Initially for $\Re s > 1$,

$$\Lambda_\zeta(s) \;=\; \frac{1}{2}\int_0^\infty \big(\theta(t) - 1\big)\, t^{s/2-1}\, dt, \qquad \theta(t) \;=\; \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}.$$

(ii) *Logarithmic-derivative residue.* The logarithmic derivative has contour integral

$$\frac{1}{2\pi i}\oint \Lambda_\zeta'(s)/\Lambda_\zeta(s)\, ds,$$

equal to the divisor count inside the contour, with the Tate boundary poles included with sign.

(iii) *Functional-equation invariance.* The $\mathbb{Z}/2$-action $s \mapsto 1 - s$ on the arithmetic modular parameter acts on the Λ_ζ-line by $\Lambda_\zeta(s) = \Lambda_\zeta(1 - s)$.

(iv) *Arithmetic rank residue.* The primary determinant has rank residue $r_\zeta = 2 \cdot \mathrm{Res}_{s=1}\zeta(s) = 2$ (Theorem 41.5.1).

Proof. (1) For $\Re s > 1$, termwise integration of the positive Gaussian series (and absolute convergence for complex s) gives $\pi^{-s/2}\Gamma(s/2)\sum_{n\geq 1} n^{-s}$. The displayed integral therefore equals $\Lambda_\zeta(s)$ in that half-plane; elsewhere the identity means meromorphic continuation (Riemann 1859; Tate 1950, reprinted Cassels–Fröhlich 1967 §13.4).

(2) The contour integral is the argument-principle form of the explicit formula of analytic number theory: for any test function h of suitable growth,

$$\sum_\rho h(\rho) \;=\; h(0) + h(1) - \sum_{n\geq 1}\Lambda(n)\big[\widehat{h}(\log n)/\sqrt{n} + \overline{\widehat{h}(\log n)}/\sqrt{n}\big] - \text{archimedean},$$

Riemann–von Mangoldt explicit formula (Riemann 1859; von Mangoldt Crelle 114, 1895). No Virasoro zero-mode on $\mathcal{V}^{\mathrm{prim}}$ is used.

(3) The Jacobi theta functional equation $\theta(t) = t^{-1/2}\theta(1/t)$ plus change of variables $t \mapsto 1/t$ in (1) gives $\Lambda_\zeta(s) = \Lambda_\zeta(1 - s)$; this is Riemann's 1859 proof of the functional equation. Multiplying by $\frac{1}{2}s(s-1)$ gives the same involution for $\xi_{\mathbb{R}}$.

(4) Residue at $s = 1$ of $\Lambda_\zeta(s)$: from $\Lambda_\zeta(s) = \Gamma(s/2)\pi^{-s/2}\zeta(s)$ and $\mathrm{Res}_{s=1}\zeta(s) = 1$, $\Gamma(1/2)\pi^{-1/2} = \pi^{1/2}\pi^{-1/2} = 1$, giving $\mathrm{Res}_{s=1}\Lambda_\zeta(s) = 1$. Hence $r_\zeta = 2$. □

Remark 43.6.2 *(P2 as Tate's thesis).* The mathematical content of P2 is Tate 1950 (Mellin-theta symmetry, adelic Poisson summation, the Λ_ζ functional equation) plus the Riemann–von Mangoldt explicit formula. The arithmetic chiral interpretation: $\Lambda_\zeta(s)$ as the Tate character of $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis}}$, the functional equation as Tate self-duality, and $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\Lambda_\zeta(s)$ as the pole-cleared determinant for zeros. The number $r_\zeta = 2$ remains the residue. This is the content of the arithmetic branch; the underlying analytic inputs are classical. P2 closes unconditionally.

43.7 P3: Unitarity of $\mathcal{V}^{\mathrm{prim}}$

Statement

Fix a complex state realization of the primitive arithmetic carrier. P3 asks for a positive Hermitian form compatible with its proposed Koszul duality. A Hochschild trace class alone does not specify that state space or its automorphic realization.

Local Positivity and Pairing Compatibility

Let V be the chosen complex state space and W its proposed dual coefficient space. A bilinear evaluation $e\colon V \otimes W \to \mathbb{C}$ becomes sesquilinear after composition with a linear map $\sigma\colon \overline{V} \to W$. Positivity concerns the form $e(v, \sigma\overline{w})$. Neither bilinearity nor the existence of a duality makes this form positive.

An automorphic comparison supplies an injective linear map $\iota\colon V \to \mathscr{L}$, where $\mathscr{L}$ is a specified automorphic L^2-space with fixed central character and Haar normalization. The Petersson form on $\mathscr{L}$ is denoted by $\langle\ ,\ \rangle_{\mathscr{L}}$, linear in its first variable. The comparison must identify the two forms:

$$e(v, \sigma\overline{w}) = \langle \iota v, \iota w\rangle_{\mathscr{L}}. \tag{43.1}$$

In a Bost–Connes realization, σ must also agree with the specified conjugation under the local comparison maps. These are the placement and pairing requirements of Hypothesis 67.1.1.

Theorem

Theorem 43.7.1 *(positivity under an automorphic pairing comparison)*. Suppose that V, W, e, σ and the injective placement ι satisfy (43.1). Then

$$h(v, w) = e(v, \sigma\overline{w})$$

is positive-definite and Hermitian. The Hilbert completion of V for this form is isometric to $\overline{\iota(V)} \subset \mathscr{L}$. If the supplied evaluation is the arithmetic Koszul pairing, this is the positive form compatible with that pairing.

Proof. The identity gives $h(v, v) = \|\iota v\|^2$, which vanishes only when $v = 0$. Sesquilinearity and Hermitian symmetry follow from the same identity. Since ι preserves norms, it extends uniquely to an isometry of the completion onto the closure of its image. □

Positive local models are available independently of this comparison. For the archimedean Fock space $\mathcal{H}^{(\infty)} = \mathbb{C}[\alpha_{-1}, \alpha_{-2}, \ldots]|0\rangle$, declare the occupation monomials orthogonal with

$$\left\| \prod_{m\geq 1} \alpha_{-m}^{r_m} |0\rangle \right\|^2 = \prod_{m\geq 1} m^{r_m} r_m!.$$

Only finitely many r_m are nonzero, so every displayed norm is positive. The relation $\alpha_m = m\,\partial_{\alpha_{-m}}$ makes positive and negative modes adjoint for this form.

At each finite place choose a positive inner-product space $\mathcal{H}^{(p)}$ with a unit vector $|0\rangle_p$. Its algebraic restricted tensor product has the product form. Indeed, every finite family of tensors lies in a finite tensor product of finite-dimensional subspaces. Orthonormal bases of those subspaces give a positive orthonormal tensor basis. Insertion of $|0\rangle_p$ is isometric, so the forms agree under enlargement of the finite set of places.

The resulting Hilbert completion is therefore well defined. Pointed E_0-data alone supply neither these forms nor an identification with an arithmetic carrier.

Conjecture 43.7.2 *(Koszul–Petersson compatibility).* The primitive arithmetic carrier admits a complex state realization V, a dual coefficient space W, and an injective automorphic placement ι. Its Koszul evaluation and specified conjugation satisfy (43.1). The local comparisons preserve the chosen reference vectors, intertwine the stated arithmetic actions, and extend to the specified adelic completion as in Hypothesis 67.1.1.

Remark 43.7.3 *(domain of the residual).* The local Fock and prime Gibbs forms give concrete positive models. To apply the theorem to the arithmetic Hochschild construction, one must first construct its state realization, the dual coefficient map and the automorphic placement. Equality of pairings is then a statement on those specified domains. It does not follow from positivity of separately defined local models.

43.8 Logical Form Table

Condition	Implication and hypotheses
F1 (global arith. AG)	Reduction to local categorical comparison and L_{ACD} in Corollary 43.2.3. F1.a remains a local comparison input; F1.c defines the Selmer target with conditional derived-Noetherian properties.
F2 (perfectoid E_2)	Formal assembly for supplied local structures and actual pointings, Theorem 43.3.1. Local geometry and an independent global comparison remain inputs.
F3 (arith. Ben-Zvi–Nadler)	Conditional reduction under F1 and F2 in Theorem 43.4.1; arithmetic Ben-Zvi–Nadler identification remains open.
P1 (G-row)	Forward implication under the central-defect identity and equivariant Mellin evaluation in Corollary 43.5.3. The converse also requires defect detection, Theorem 43.5.1.
P2 (Tate/expl. formula)	Tate functional equation and explicit formula, Theorem 43.6.1 (Tate 1950).
P3 (unitarity)	Positive pullback under an injective automorphic placement and the pairing identity, Theorem 43.7.1. The arithmetic maps are required.

Table 43.1: Logical forms after Chapter 43.

43.9 Closure Boundary

(i) F1 passes through $\mathrm{L}_{\mathrm{ACD}}$, but its present table also contains the local categorical comparison, the global restricted-tensor identification, and BC-diamond-glue (Corollary 43.2.3).

(ii) F2.c supplies formal restricted-tensor assembly under actual local E_2 and pointing hypotheses. The local constructions and the comparison with a global geometric category remain additional inputs.

(iii) F3, conditional on F1 + F2, reduces to arithmetic Ben-Zvi–Nadler ($\mathrm{F3.BZN}^{\mathrm{Ar}}$).

(iv) P1 has a forward implication under the stated equivariant evaluation (Corollary 43.5.3) and a conditional full equivalence (Theorem 43.5.1).

(v) P2 closes unconditionally: the Tate functional equation is framed via Mellin-theta and the explicit formula (Theorem 43.6.1).

(vi) P3 closes conditional on a single compatibility verification (Conjecture 43.7.2, Theorem 43.7.1).

The residual obstructions are:

($\mathrm{L}_{\mathrm{ACD}}$) Adelic categorical descent for $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$ restricted over places. It is a non-formal theorem, number-field adaptation of Gaitsgory–Rozenblyum function-field results.

(F2) The local arithmetic E_2-structures, actual operadic pointings and comparison with the independently defined global category must be supplied. The formal colimit step F2.c is Theorem 50.1.3.

($\mathrm{F3.BZN}^{\mathrm{Ar}}$) Arithmetic Ben-Zvi–Nadler identification: E_1-algebra equivalence $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \simeq \mathcal{O}(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2})^{\mathrm{flat}}$ (Ben-Zvi–Nadler arXiv:0904.1247 extended to the Weil/(φ,Γ) arithmetic target). It is a non-formal theorem.

(arith. Positselski) Construct the integral co–contra recipients and adjunction. The lifting criterion of Theorem 46.1.5 requires complete unit and counit cofibers and their equivalences after reduction. The arithmetic character and central-defect maps are additional.

(Koszul–Pet compat) Identification of arithmetic Koszul pairing with adelic Petersson pairing (Conjecture 43.7.2). It is a non-formal theorem, verification.

These five residual conditions cover the full domain of F1, F2, F3, with two narrower items ($\mathrm{L}_{\mathrm{ACD}}$ and Koszul–Pet compat each independently stated and substantial) and three items of comparable domain to the original conjectures. P2 closes unconditionally; P1 requires its arithmetic evaluation and defect detection. P3 requires the specified arithmetic placement and pairing compatibility. The Riemann Hypothesis reformulation of Chapter 44 proceeds from this basis.

Chapter 44

The Riemann Hypothesis Reformulation

The zero-placement clause of F-RH is the Riemann Hypothesis. The full F-RH assertion also contains the structural assertion that $\mathcal{V}^{\mathrm{prim}}$ carries a positive-definite Hermitian structure compatible with arithmetic Koszul self-duality and arithmetic Tate's functional equation and explicit formula. The structural theorems of Chapter 43 place P1, P2, P3 on their stated domains; the zero-placement condition is a determinant-divisor and positive-trace assertion, equivalently a positive Hilbert–Pólya Li trace after the regularised trace identity has been supplied.

44.1 The Conjecture F-RH

Conjecture 44.1.1 *(arithmetic unitary zero-placement: F-RH).* $\mathcal{V}^{\mathrm{prim}}$ admits a unique positive-definite Hermitian structure compatible with arithmetic Koszul self-duality $\kappa^{\mathrm{Ar}} + (\kappa^{!})^{\mathrm{Ar}} = 0$ and with Tate's completed-zeta character and explicit formula. Under this structure, the non-trivial zeros of the entire character $\xi_{\mathbb{R}}(s)$ of $\mathcal{V}^{\mathrm{prim}}$ lie on the self-dual locus $\mathrm{Re}(s) = 1/2$.

Remark 44.1.2 *(zero-placement and RH).* The Tate character supplied by P2 is the meromorphic completed zeta function

$$\Lambda_{\zeta}(s) := \pi^{-s/2}\Gamma(s/2)\zeta(s),$$

with simple poles at $s = 0, 1$. The entire Li–Hadamard object is

$$\xi_{\mathbb{R}}(s) := \frac{1}{2}s(s-1)\Lambda_{\zeta}(s).$$

Here ξ means $\xi_{\mathbb{R}}$ unless Λ_{ζ} is written explicitly. The zeros of $\xi_{\mathbb{R}}$ are exactly the non-trivial zeros of ζ; the gamma poles cancel the negative even trivial zeros of ζ, and the factor $s(s-1)$ removes the Tate poles. Thus the zero-placement assertion in F-RH is exactly RH. The existence and compatibility of the positive Hermitian structure are additional arithmetic structure, not a consequence of RH alone.

44.2 Three-Pillar Implication Structure

Theorem 44.2.1 *(zero-placement from three pillars plus Hilbert–Pólya–Li).* Suppose:

(P1) $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0$ for the specified arithmetic realization, together with the defect identity and equivariant Mellin evaluation of Corollary 43.5.3.

(P2) $\xi_{\mathbb{R}}(s)$ satisfies Tate's functional equation and the Weil explicit formula, with rank residue $r_{\zeta} = 2$ (Theorem 43.6.1).

(P3) $\mathcal{V}^{\mathrm{prim}}$ carries a positive-definite Petersson inner product compatible with arithmetic Koszul self-duality (Theorem 43.7.1).

(H-P^{Ar}) The operator Θ_{ξ} of Hypothesis 44.3.2 has determinant divisor div $\xi_{\mathbb{R}}$ and the Weil–Connes trace distribution.

(HP–Li) The Li transforms of Θ_ξ have non-negative regularised trace.

Then the zero-placement clause of F-RH holds. Equivalently, RH holds.

Proof. P1 gives the functional equation $\xi_{\mathbb{R}}(s) = \xi_{\mathbb{R}}(1-s)$. P2 gives the explicit formula identifying the zero-side distribution with the prime and archimedean terms. P3 supplies the positive Hermitian domain. H-P^{Ar} places the zero divisor on the normal operator Θ_ξ, and HP–Li makes every Li trace non-negative. Li's theorem then gives RH, which is exactly the zero-placement clause. □

Remark 44.2.2 *(HP–Li as residual condition).* With P1, P2, P3 resolved to Theorem or Theorem-conditional, the zero-placement clause of F-RH reduces to the construction of the Hilbert–Pólya zero-divisor operator and to HP–Li positivity. This is the arithmetic form of the classical Weil–Li positivity problem, not a formal consequence of Virasoro representation theory.

44.3 Li-Positivity as Arithmetic Virasoro Unitarity

Li's Criterion

THEOREM 44.3.1 *(Li 1997, J. Number Theory 65).* RH is equivalent to $\lambda_n \geq 0$ for all $n \geq 1$, where

$$\lambda_n := \sum_\rho \left(1 - \left(1 - \frac{1}{\rho}\right)^n\right) = \frac{1}{(n-1)!}\frac{d^n}{ds^n}\left[s^{n-1}\log\xi(s)\right]\Big|_{s=1}$$

(sum over non-trivial zeros of ζ, counted with multiplicity).

Li's λ_n admits a direct Hilbert–Pólya transform interpretation. The transform lives on the zero-divisor operator Θ_ξ, not on the Virasoro/Fock energy operator.

Hilbert–Pólya Transform Computation

The Li criterion is a scalar positivity statement. To embed it in the arithmetic chiral-algebra formalism and exploit the Petersson inner product of P3, one requires an operator Θ_ξ on the arithmetic Heisenberg Hilbert completion whose regularised trace recovers the Li coefficients. The following hypothesis names this operator precisely.

Hypothesis 44.3.2 *(arithmetic Hilbert–Pólya, H-P^{Ar}).* There exists a Hilbert completion $\mathcal{H}_\xi$ of the primary arithmetic Heisenberg core, a dense invariant core $\mathcal{D}_\xi \subset \mathcal{H}_\xi$, and a self-adjoint unbounded operator

$$H_{\mathrm{HP}} : \mathcal{D}_\xi \subset \mathcal{H}_\xi \longrightarrow \mathcal{H}_\xi$$

in the Petersson/GNS inner product. Put

$$\Theta_\xi := \frac{1}{2}\,\mathrm{id} + iH_{\mathrm{HP}}.$$

The regularised determinant and trace distribution of Θ_ξ satisfy

$$\det_\infty(s\,\mathrm{id} - \Theta_\xi) = \xi_{\mathbb{R}}(s), \tag{44.1}$$

and, for every admissible Weil–Connes Paley–Wiener test function h,

$$\mathrm{Tr}_{\mathrm{reg}}\big(h(H_{\mathrm{HP}})\big) = \sum_\rho h(\gamma_\rho), \qquad \rho = \frac{1}{2} + i\gamma_\rho. \tag{44.2}$$

Here the notation $\rho = \frac{1}{2} + i\gamma_\rho$ is part of the hypothesis: self-adjointness of H_{HP} together with the determinant identity forces the zero divisor onto the critical line. The symbolic kernel $\sum_\rho e^{-t\rho}$ is only the distributional wave-kernel shorthand obtained from (44.2) by admissible test-function regularisation; it is not an ordinary heat trace of a non-negative self-adjoint operator.

Remark 44.3.3 *(form of H-P^{Ar}).* H-P^{Ar} is the Hilbert–Pólya conjecture stated inside the arithmetic chiral-algebra formalism. It is not derivable from P1, P2, P3 alone: P2 supplies the completed-zeta functional equation and explicit formula. Under its arithmetic placement and pairing hypotheses, P3 supplies a positive form on the specified state domain. A self-adjoint ordinate operator H_{HP} is an independent input. Its determinant identity (44.1) and distributional trace identity (44.2) are additional hypotheses.

Remark 44.3.4 *(primary-sector Witt–Virasoro reconciliation).* Chapter 35 constructs the positive-half Witt operators on the specified restricted tensor product of prime Fock spaces. The prescribed sums of negative Sugawara modes already fail on its vacuum. This rules out that summed action on that algebraic carrier. It does not classify all Virasoro realizations of an arithmetic state space.

The scalar $r_\zeta = 2$ is defined by $2\,\mathrm{Res}_{s=1}\zeta(s)$. Under the factorization hypothesis of Theorem 35.4.1, it also equals the primary determinant's pole order. Neither equality constructs a Virasoro central term. The Hilbert–Pólya operator H_{HP} is independently specified. Identifying it with a conformal zero-mode would require an intertwiner on the actual operator domains. The following conjecture asks for additional operators and a compatible state realization:

Conjecture 44.3.5 *(primary-Virasoro reconciliation).* There is a Hilbert state realization of $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ with closed operators L^{PV}_m and comparison maps from the finite-place conformal structures. On a common invariant dense domain, the operators satisfy the Virasoro bracket

$$[L^{\mathrm{PV}}_m, L^{\mathrm{PV}}_n] \;=\; (m-n)L^{\mathrm{PV}}_{m+n} + \frac{c_{\mathrm{PV}}}{12}(m^3-m)\delta_{m+n,0}, \qquad c_{\mathrm{PV}} = 2.$$

The equality $c_{\mathrm{PV}} = r_\zeta$ is an extra compatibility condition with the rank residue of Theorem 35.4.1. The residue calculation alone does not construct L^{PV}_m.

Remark 44.3.6 *(operator dictionary).* Four operators must remain distinct. L^{Vir}_0 is the Fock/Virasoro conformal-energy operator. N_{BC} is the Bost–Connes Hamiltonian, with eigenvalues $\log m$ on the zero-mode lattice and partition function $\zeta(\beta)$. H_{HP} is the hypothetical self-adjoint determinant-trace operator. $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$ is the normal zero-divisor operator whose determinant divisor is $\mathrm{div}\,\xi_{\mathbb{R}}$. Conflating these four objects turns Euler-product positivity into a false Hilbert–Pólya argument.

Remark 44.3.7 *(Tate-pole and trivial-zero normalisation).* $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$ is meromorphic, not entire: the negative even trivial zeros of ζ are cancelled by gamma poles, and Λ_ζ has poles at 0 and 1. The entire function $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\Lambda_\zeta(s)$ removes these Tate poles and has as zeros exactly the non-trivial zeros. Thus H-P^{Ar} is a statement about the primary determinant $\xi_{\mathbb{R}}$, while the meromorphic Tate character Λ_ζ belongs to the cohomological/superdeterminant surface.

Proposition 44.3.8 *(Li coefficient = Hilbert–Pólya transform trace). (conditional on Hypothesis 44.3.2).* Assume H-P^{Ar}. For $n \geq 1$, define the normal Li-transform operator

$$\mathcal{L}_n := \mathrm{id} - \left(\mathrm{id} - \Theta_\xi^{-1}\right)^n. \tag{44.3}$$

Then

$$\lambda_n = \mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n). \tag{44.4}$$

This is a trace identity for the Hilbert–Pólya zero-divisor operator Θ_ξ, not a polynomial identity in L_o^{Vir} or N_{BC}.

Proof. The determinant identity $\det_\infty(s\mathrm{id} - \Theta_\xi) = \xi_{\mathbb{R}}(s)$ identifies the determinant divisor of Θ_ξ, in the regularised determinant sense, with the non-trivial zero divisor. Applying the holomorphic functional calculus to $f_n(z) = 1 - (1 - z^{-1})^n$ gives

$$\mathrm{Tr}_{\mathrm{reg}}(f_n(\Theta_\xi)) = \sum_\rho \left(1 - \left(1 - \frac{1}{\rho}\right)^n\right),$$

which is Li's coefficient by Theorem 44.3.1. □

COROLLARY 44.3.9 *(Li positivity from positive HP trace). (conditional on P2, P3, H-P^{Ar}).* Assume the regularised Hilbert–Pólya trace is positive on the Weil positive cone and that the Li transforms $\mathcal{L}_n$ of (44.3) belong to the closure of that positive cone after the standard Li/Weil approximation. Then $\lambda_n \geq 0$ for every $n \geq 1$. The converse is *not* an operator-positivity theorem.

Proof. By the positivity assumption, $\mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n) \geq 0$. The trace identity (44.4) identifies this number with λ_n. The reverse implication would require a determinate positive trace representation of the full zero measure from the scalar Li sequence; that is the classical Li/Weil positivity problem, not a consequence of P1–P3. □

THEOREM 44.3.10 *(positive Hilbert–Pólya trace implies zero-placement). (conditional on P2, P3, H-P^{Ar}).* Assume P2, P3, and the determinant and regularised trace identities of H-P^{Ar}. If HP–Li positivity holds:

(HP–Li) *Positive Hilbert–Pólya trace.* $\mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n) \geq 0$ for every $n \geq 1$, where $\mathcal{L}_n$ is (44.3),

then the zero-placement clause of F-RH holds. Equivalently, RH holds. If the self-adjointness assertion in H-P^{Ar} is also assumed, then the determinant identity already gives zero-placement; the scalar Li route uses only the determinant and trace identities.

Proof. HP–Li gives $\lambda_n \geq 0$ for all $n \geq 1$ by Proposition 44.3.8. Li positivity is equivalent to RH (Li 1997, Theorem 44.3.1); this is exactly the zero-placement clause of F-RH (Remark 44.1.2). □

Remark 44.3.11 *(one-directional implication and operator discipline).* The polynomial $(L_o^{\mathrm{Ar}})^n - (L_o^{\mathrm{Ar}} - \mathrm{id})^n$ is *not* Li's transform; L_o^{Ar} would need to serve simultaneously as Fock energy, Bost–Connes Hamiltonian, and determinant-trace operator, three incompatible roles (see Remark 44.3.6). The correct statement is the one-directional HP–Li positivity ⇒ zero-placement, where H-P^{Ar} supplies Θ_ξ. The converse is the assertion that zero-placement supplies a positive Weil trace representation of the full zero distribution; this is the Hilbert–Pólya/Connes–Deninger positivity problem.

Remark 44.3.12 *(content of F-RH as a reformulation).* F-RH separates RH from the extra arithmetic structures carried by $\mathcal{V}^{\mathrm{prim}}$.

(i) The spectral object is made precise: the self-adjoint determinant form of H-P^{Ar} is a Hilbert–Pólya realisation of RH, while HP–Li positivity is Li's scalar RH-equivalent positivity written through the zero-divisor operator after the trace identity is fixed.

(ii) A structural constraint on zero-placement emerges: the Petersson positivity of P3 propagates through the Weil/Connes trace functional to impose positivity of the Li transforms, provided the trace representation is determinate.

(iii) The reformulation connects RH mechanisms (Connes, Deninger, Meyer) to positive-trace and factorisation methods, with the arithmetic explicit formula replacing compact-CFT modularity.

(iv) Admissible approximants to the Li/Weil test functions can be evaluated against the Bost–Connes and Hecke trace formulae. Positivity is a distributional trace question, not finite Fock positivity of T_n.

44.4 Comparison to Existing RH Mechanisms

The group $\mathbb{Q}^\times$ acts on $\mathbb{A}_\mathbb{Q}$ by multiplication. Its orbit quotient $\mathbb{A}_\mathbb{Q}/\mathbb{Q}^\times$ is called the *adele class space*. This quotient is distinct from the idele class group $\mathbb{A}_\mathbb{Q}^\times/\mathbb{Q}^\times$, which uses only invertible adeles.

Mechanism	Input	Analytic theorem
Hilbert–Pólya (folklore)	Self-adjoint op. with determinant divisor div ξ	Operator not exhibited
Connes (adele class space)	$\mathrm{KMS}_{\beta=1}$ Bost–Connes positivity	Trace-formula positivity
Deninger ($H^\bullet_\Delta$)	Purity of Frobenius on arith. H^1	Cohomology not constructed
Meyer (Schwartz space)	Mellin self-adjoint operator plus missing zero-divisor quotient	Operator not exhibited
Arakelov height-zeta	Height-function positivity	Equivalence to RH not established
Weil positivity	Positivity of Weil inner product	Known equivalent, no proof
Li positivity	$\lambda_n \geq 0$ for all $n \geq 1$	Known equivalent, no proof
Riemann–von Mangoldt	Explicit formula approach	Approaches RH asymptotically
Montgomery–Dyson	GUE statistics of zeros	Statistical, not deterministic
Vol IV zero-placement	**H-P^{Ar} + positive trace**	**Self-adjoint zero-divisor operator not constructed**

Table 44.1: The zero-placement clause placed against existing RH mechanisms.

Remark 44.4.1 *(relations).* (i) HP–Li positivity is Li positivity written on the Hilbert–Pólya zero-divisor operator Θ_ξ. It implies zero-placement, hence RH, via Theorem 44.3.10. A Virasoro polynomial T_n is not a substitute for this transform.

(ii) The zero-placement clause is governed by Weil positivity: Comparison of the Weil form with the Petersson form requires a specified linear map from the complete Weil test carrier to the arithmetic Petersson domain, preserving the involution and both forms. A restricted tensor-product presentation does not construct that form-preserving map. F-RH adds the arithmetic Hermitian, Koszul, and completed-zeta trace structures around this clause.

(iii) F-RH embeds Hilbert–Pólya explicitly as H-P^{Ar} (Hypothesis 44.3.2): it asks for a self-adjoint operator A, the positive form from P3, the determinant divisor of $\Theta_\xi = 1/2 + iA$, the regularised non-trivial-zero trace distribution, and $\mathbb{Z}/2$-symmetry under the arithmetic S-modular involution from P1. F-RH does not replace Hilbert–Pólya: H-P^{Ar} is a separate spectral hypothesis in the sufficient implication below.

(iv) F-RH is closer to Connes than to Deninger: both Connes and F-RH use unitarity plus Bost–Connes positivity; Deninger postulates a cohomology theory that F-RH does not need. The difference from Connes is that F-RH carries the positivity through arithmetic holomorphic-topological (HT) observables and a Weil-positive trace rather than through the bare trace-formula construction.

44.5 Residual Conditions

After the structural reduction of Chapter 43 and the F-RH reformulation above, the RH-relevant part is controlled by the following conditions. The spectral conditions imply zero-placement; the categorical conditions construct the trace object on which that problem is stated.

(HP–Li) *Positive Hilbert–Pólya trace.* $\mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n) \geq 0$ for every $n \geq 1$, where $\mathcal{L}_n$ is the Li transform of Θ_ξ (Theorem 44.3.10). *Sufficient for RH given P2, P3, H-P*^{Ar}.

(H-P^{Ar}) *Arithmetic Hilbert–Pólya.* There is a self-adjoint operator A such that $\Theta_\xi = 1/2 + iA$ has determinant divisor $\mathrm{div}\,\xi_{\mathbb{R}}$ and Weil–Connes trace distribution equal to the non-trivial-zero distribution (Hypothesis 44.3.2). *Required for the HP–Li $\Rightarrow$ zero-placement chain; not derivable from P1, P2, P3.*

(arith. Positselski) Construct the arithmetic co–contra adjunction and verify the lifting criterion of Theorem 46.1.5. Its interpretation as P1 also requires the central-defect, Mellin-evaluation and detection maps of Theorem 43.5.1.

(Koszul–Pet compat) Identification of arithmetic Koszul pairing with adelic Petersson pairing (Conjecture 43.7.2). *Required for P3.*

($\mathrm{L}_{\mathrm{ACD}}$) Adelic categorical descent for $\mathrm{D}^{\text{sph-fin}}$ (Corollary 43.2.3). *Required for F1, hence for six-window placement.*

($\mathrm{F3.BZN}^{\mathrm{Ar}}$) Arithmetic Ben-Zvi–Nadler identification (Theorem 43.4.1). *Required for F3, hence for the categorical trace presentation of $\mathcal{V}^{\mathrm{prim}}$.*

Items (arith. Positselski), (Koszul–Pet compat), H-P^{Ar}, and HP–Li positivity lie on the P1–P2–P3 branch of the zero-placement clause and together form a sufficient set for RH in the chiral-algebra formalism. Items ($\mathrm{L}_{\mathrm{ACD}}$) and ($\mathrm{F3.BZN}^{\mathrm{Ar}}$) are independent of RH proper and lie on the six-window presentation; they would state $\mathcal{V}^{\mathrm{prim}}$ as a theorem-grade object but do not imply RH.

44.6 A Sufficient Path to RH

THEOREM 44.6.1 *(sufficient implication).* RH follows from the following implication in the chiral-algebra formalism:

$$\mathrm{P1} \xrightarrow{\text{Mellin comparison}} \text{P1 functional equation}$$

$$\mathrm{P2} \xrightarrow{\text{Tate 1950}} \text{P2 unconditional}$$

$$\mathrm{P3} \xrightarrow{\text{Koszul–Pet compat}} \text{P3 restricted unitarity}$$

$$(\mathrm{P1}, \mathrm{P2}, \mathrm{P3}, \text{H-P}^{\mathrm{Ar}}) \xrightarrow{\text{HP–Li}} \text{zero-placement} \xrightarrow{\Leftrightarrow} \text{RH}$$

Here the first arrow requires the central-defect identity and Mellin evaluation of Corollary 43.5.3. The remaining arithmetic inputs are Koszul–Petersson compatibility, arithmetic Hilbert–Pólya (H-P^{Ar}), and positive Hilbert–Pólya Li trace (HP–Li), on the domains stated above.

Proof. P2 is the completed-zeta character/explicit-formula input (Theorem 43.6.1). P1 is the functional-equation branch under the specified arithmetic evaluation (Corollary 43.5.3). P3 is the positive-form input conditional on the restricted Koszul–Petersson compatibility (Theorem 43.7.1). Given these inputs plus H-P^{Ar}, Theorem 44.3.10 gives HP–Li ⇒ zero-placement, and zero-placement ⇔ RH via Li's criterion (Remark 44.1.2, Theorem 44.3.1). □

Remark 44.6.2 *(analytic content of the implication).* **Mellin comparison** An arithmetic dual pair, its central-defect identity, and an equivariant evaluation giving the completed zeta function must be constructed. A co–contra equivalence alone does not supply these data.

Koszul–Pet compat non-formal theorem; compatibility of the arithmetic Koszul and adelic Petersson pairings.

H-P^{Ar} This is the Hilbert–Pólya operator-construction problem in the arithmetic Fock setting; the domain theorem alone does not supply the zero-divisor determinant.

HP–Li This is the positive-trace form of the classical Hilbert–Pólya / Weil positivity problem. If tractable through Li coefficients, the $n = 2$ case ($\lambda_2 \geq 0$) has been computed numerically to $n \sim 10^5$ zeros of ζ (Coffey 2005; Voros 2003 for the first few). The assertion for all n is Li's RH-equivalent positivity theorem.

The arithmetic formalism does not shorten the Hilbert–Pólya obstacle, but it places the positivity in a precise chain-level trace setting where factorisation techniques may be applied without conflating them with the zero-divisor theorem.

44.7 Relation to the Arithmetic Branch Essential Theorem

Under the arithmetic comparison and defect-detection hypotheses of Theorems 41.2.1 and 43.5.1, one has

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \iff \xi(s) = \xi(1-s).$$

This gives the functional equation (geometric self-duality of $\xi_{\mathbb{R}}$), not RH (spectral zero-placement). RH is strictly beyond the essential theorem, requiring the additional positive Hilbert–Pólya trace input.

F-RH asks whether the arithmetic self-duality comparison, P3 positivity, and P2 explicit formula yield the required zero placement. The implication in the chiral-algebra formalism is conditional on H-P^{Ar} and HP–Li positivity. Those two statements are the Hilbert–Pólya form of RH native to this formalism.

44.8 The F-RH Reduction

(i) The zero-placement clause of F-RH (Conjecture 44.1.1) is exactly RH (Remark 44.1.2). F-RH also asks for the positive Hermitian structure compatible with arithmetic Koszul self-duality, Tate's functional equation, and the explicit formula.

(ii) The zero-placement clause is implied by H-P^{Ar} and HP–Li positivity together with P1 + P2 + P3 (Theorem 44.2.1).

(iii) The zero-placement clause is implied by HP–Li positivity (positive Hilbert–Pólya trace; Theorem 44.3.10) via Li's criterion, given the determinant and trace identities of H-P^{Ar}. If the full

determinant-trace H-P^{Ar} hypothesis is assumed, zero-placement is already part of the determinant-trace realisation. The converse direction from zero-placement to HP–Li is the positive-trace realisation problem.

(iv) Li's coefficients λ_n are Hilbert–Pólya transform traces of Θ_ξ (Proposition 44.3.8).

(v) Li positivity and Weil positivity govern the zero-placement clause. F-RH joins this clause to the arithmetic Hermitian, Koszul, and completed-zeta trace structures.

(vi) The sufficient implication to RH uses four inputs: arith. Positselski, Koszul–Pet compat, H-P^{Ar}, and HP–Li positivity (Theorem 44.6.1). This is the *four-input conditional conjunction* stated in Chapter 60 and made precise as Theorem 60.3.1: each input carries its own analytic content (five Positselski sub-items, KMS_1/GNS identification beyond the sph-fin cuspidal core, zeta-zero determinant-trace matching, RH-equivalent positive trace), and the conjunction implies zero-placement.

(vii) RH is strictly beyond the branch's essential theorem (functional equation), and HP–Li positivity is the Li positive-trace form of RH within the chiral-algebra formalism. The operator dictionary of Remark 44.3.11 preserves only the forward implication HP–Li⇒zero-placement; the converse is the positive determinant-trace realisation problem (Hypothesis 44.3.2) and does not help the forward direction.

Chapter 45

Arithmetic Virasoro Positivity Bootstrap

With the determinant form of Chapter 44 in place, the Virasoro-polynomial sequence $T_n^{\mathrm{Vir}} = (L_0^{\mathrm{Vir}})^n - (L_0^{\mathrm{Vir}} - \mathrm{id})^n$ is not the Li operator. It proves finite-sector Fock positivity, but it does not construct a Hilbert–Pólya operator and it does not give RH. The RH-strength input is the positive Hilbert–Pólya trace of $\mathcal{L}_n = \mathrm{id} - (\mathrm{id} - \Theta_\xi^{-1})^n$ from Chapter 44.

45.1 Statement Recalled

The Operator Sequence

Definition 45.1.1 *(formal Virasoro polynomial sequence).* . Let $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ denote the primary (non-descendant) subspace of the arithmetic Heisenberg Fock, equipped with the Petersson inner product $\langle \cdot, \cdot \rangle^{\mathrm{Pet}}$ of Chapter 43.7.1. For every integer $n \geq 1$ define

$$T_n^{\mathrm{Vir}} \;:=\; (L_0^{\mathrm{Vir}})^n \;-\; (L_0^{\mathrm{Vir}} - \mathrm{id})^n \;\in\; \mathrm{End}\big(\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}\big).$$

Here L_0^{Vir} is the Fock/Virasoro conformal-energy operator. It is not the Hilbert–Pólya determinant-trace operator H_{HP}, the Bost–Connes Hamiltonian N_{BC}, or the zero-divisor operator $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$. Thus T_n^{Vir} is a legitimate Fock polynomial on any common Virasoro spectral core, but it is not Li's transform. In the sequel, later occurrences of T_n mean T_n^{Vir} unless the Hilbert–Pólya Li transform $\mathcal{L}_n$ is written explicitly.

Remark 45.1.2 *(why T_n^{Vir} is not the Li object).* Two conventions for Li's criterion circulate in the literature. The original Li 1997 J. Number Theory paper defines $\lambda_n = \sum_\rho (1 - (1 - 1/\rho)^n)$; Bombieri–Lagarias J. Number Theory 77 (1999) uses the equivalent closed form $\lambda_n = (n-1)!^{-1}(d/ds)^n [s^{n-1} \log \xi(s)]\big|_{s=1}$. The corresponding operator is $\mathcal{L}_n = \mathrm{id} - (\mathrm{id} - \Theta_\xi^{-1})^n$, with Θ_ξ the normal zero-divisor operator of Chapter 44.3.2. A polynomial $(L_0^{\mathrm{Vir}})^n - (L_0^{\mathrm{Vir}} - \mathrm{id})^n$ does not become Li's transform by regularisation. Consequently, every claim below involving T_n^{Vir} is a formal Fock/Virasoro claim unless it is explicitly restated in terms of $\mathcal{L}_n$ and the positive Weil–Connes trace.

Conditional Chain: VB $\Rightarrow$ Li Positivity $\Leftrightarrow$ RH*

Proposition 45.1.3 *(formal Virasoro positivity is not Li positivity).* . Positivity of the formal Virasoro polynomial T_n^{Vir} on finite Fock sectors does not imply $\lambda_n \geq 0$, and therefore does not imply RH. The one-directional RH implication in Vol IV is instead

$$\mathrm{HP\text{–}Li} \Longrightarrow \lambda_n \geq 0 \;\forall n \Longleftrightarrow \mathrm{RH},$$

where HP–Li is the positive trace statement of Chapter 44.3.10.

Proof. Li's criterion is Li 1997 J. Number Theory, reproduced in Bombieri–Lagarias J. Number Theory 77 (1999). The Li summand is $1 - (1 - 1/\rho)^n$. The spectral transform realising this summand is therefore

$z \mapsto 1 - (1 - z^{-1})^n$ applied to the zero operator $z = \Theta_\xi$. The polynomial $x^n - (x-1)^n$ applied to a Virasoro energy $x = L_0^{\mathrm{Vir}}$ is a different function of a different operator. Positivity of the latter is a Fock calculation; it has no trace identity with Li's coefficients unless the Hilbert–Pólya trace identity has already been replaced by the correct Θ_ξ-transform. The HP–Li implication follows from Chapter 44.3.10. □

Remark 45.1.4 *(what is genuinely equivalent).* The known RH-equivalent positivity languages are Li positivity, Weil positivity for the number-field explicit formula, and the positive zero-measure conjecture for Θ_ξ, $\mathrm{VB}^*_{\mathrm{core}}$. Under explicit hypotheses these languages give the same positivity condition. None of the RH-equivalent positivity statements is unconditional here.

Remark 45.1.5 *(the level at which RH lives).* RH lives on the zero-divisor operator $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$, not on the Virasoro energy operator. The Bost–Connes Hamiltonian and the Virasoro L_0 give Euler weights and Fock energies; neither carries $\operatorname{div} \xi_{\mathbb{R}}$. A real spectral measure appears only after H-P^{Ar} supplies H_{HP} and identifies $\det_\infty(s - \Theta_\xi)$ with $\xi_{\mathbb{R}}(s)$. VB*, in its RH-strength form, is therefore a positivity statement for the Weil–Connes trace of functions of Θ_ξ, together with determinacy of the corresponding zero measure.

45.2 Obstructions

Virasoro levels

For $n = 1$ one has $T_1^{\mathrm{Vir}} = \mathrm{id}$. For $n = 2$ one has

$$(L_0^{\mathrm{Vir}})^2 - (L_0^{\mathrm{Vir}} - \mathrm{id})^2 = 2L_0^{\mathrm{Vir}} - \mathrm{id}.$$

Thus $T_2^{\mathrm{Vir}} \succeq 0$ is the Fock threshold $L_0^{\mathrm{Vir}} \succeq \frac{1}{2}\mathrm{id}$. It is not a statement about zeta zeros. Li's coefficient at level 2 is the trace of $z \mapsto 1 - (1 - z^{-1})^2$ on Θ_ξ, and equality between these two functional calculi would itself be an additional Hilbert–Pólya theorem.

Moment problem

For a real sequence $(m_n)_{n \geq 0}$, seek a positive Borel measure ν on $\mathbb{R}$ such that

$$m_n = \int_{\mathbb{R}} x^n \, d\nu(x) \qquad (n \geq 0).$$

This is called the *Hamburger moment problem*. Requiring support in $[0, \infty)$ gives the Stieltjes moment problem.

The Hamburger moment problem belongs to the regularised spectral measure of Θ_ξ. There is no identity

$$\mathrm{Tr}_{\mathrm{reg}}(T_n^{\mathrm{Vir}}) = n\lambda_n.$$

The valid moment sequence is obtained from the zero-divisor operator and the Weil–Connes trace. Stieltjes' theorem supplies the algebraic test: a sequence is the moment sequence of a positive measure on $[0, \infty)$ precisely when all Hankel and shifted Hankel minors are non-negative.

Kac determinant

At $c = 2$, the Kac parametrisation gives

$$1 - \frac{6}{m(m+1)} = 2, \qquad m(m+1) = -6.$$

The null weights form the countable set $\{h_{r,s}(2) : r, s \geq 1\}$. Outside this set the contravariant form is non-degenerate. Non-degeneracy is weaker than positivity; the Petersson sign is not determined by the non-vanishing of the Kac determinant.

Fock combinatorics

On the free-boson number state $|\mathbf{n}\rangle$, L_0^{Vir} has eigenvalue

$$m(\mathbf{n}) = \sum_{i \geq 1} i n_i.$$

For $m(\mathbf{n}) \geq 1$,

$$T_n^{\mathrm{Vir}} |\mathbf{n}\rangle = \big(m(\mathbf{n})^n - (m(\mathbf{n}) - 1)^n\big)|\mathbf{n}\rangle$$

has non-negative eigenvalue. The vacuum has $m = 0$; for even n the eigenvalue is negative. Hence the Fock positivity statement is a non-vacuum statement.

Weil trace

Weil positivity is a positivity theorem for the explicit formula and is equivalent to RH over number fields. In the Vol IV notation its operator representative is the positive regularised trace of $\mathcal{L}_n(\Theta_\xi)$, not a trace of T_n^{Vir}. Koszul–Petersson compatibility can identify the Weil trace pairing with a Petersson pairing on admissible arithmetic states; it cannot identify the Virasoro energy spectrum with the zero divisor.

de Branges datum

For an entire function E, put $E^*(z) = \overline{E(\overline{z})}$. It is called *Hermite–Biehler* when $|E(z)| > |E^*(z)|$ for $\operatorname{Im} z > 0$. For such E, the de Branges kernel is

$$K(w, z) = \frac{E(w)\overline{E(z)} - E^*(w)\overline{E^*(z)}}{2\pi i(\overline{z} - w)}.$$

The real entire function $\Xi(z) = \xi_{\mathbb{R}}(1/2 + iz)$ satisfies $\Xi^* = \Xi$, so Ξ itself is not a Hermite–Biehler function. A de Branges reformulation of RH requires a genuine datum E whose divisor controls the divisor of Ξ. The Hermite–Biehler condition is then part of the RH-strength input, not a consequence of formal Virasoro positivity.

45.3 Level-by-Level Positivity

Level $n = 1$: Unconditional

Theorem 45.3.1 *($n = 1$ arithmetic Virasoro positivity).* . $T_1^{\mathrm{Vir}} = (L_0^{\mathrm{Vir}}) - (L_0^{\mathrm{Vir}} - \mathrm{id}) = \mathrm{id}$. Hence $T_1 \succeq 0$ unconditionally on $\mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$.

Proof. Direct computation. The operator is the identity. □

Remark 45.3.2 *(numerical consistency).* The ordinary trace of the identity on $\mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$ is not defined without a trace-class or regularized-trace convention. Bombieri–Lagarias §2 gives $\lambda_1 = \frac{1}{2}(2 + \gamma - \log(4\pi)) \approx 0.02310$. The positivity of this number is consistent but not itself a proof of $T_1 \succeq 0$; the proof is the identity-operator identity. The number λ_1 has been known to be positive since Li 1997.

Level $n = 2$: Formal Threshold

THEOREM 45.3.3 *($n = 2$ Virasoro threshold).* . $T_2^{\mathrm{Vir}} = 2L_0^{\mathrm{Vir}} - \mathrm{id}$. Hence $T_2^{\mathrm{Vir}} \succeq 0$ on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ if and only if $L_0^{\mathrm{Vir}} \succeq \frac{1}{2}\mathrm{id}$ on the same space.

Proof. Direct expansion: $T_2^{\mathrm{Vir}} = (L_0^{\mathrm{Vir}})^2 - (L_0^{\mathrm{Vir}} - \mathrm{id})^2 = 2L_0^{\mathrm{Vir}} - \mathrm{id}$. The inequality $T_2^{\mathrm{Vir}} \succeq 0$ is therefore equivalent to $2L_0^{\mathrm{Vir}} \succeq \mathrm{id}$, i.e. to $L_0^{\mathrm{Vir}} \succeq \frac{1}{2}\mathrm{id}$. □

COROLLARY 45.3.4 *($n = 2$ is not a zero-placement theorem).* . The implication

$$T_2^{\mathrm{Vir}} \succeq 0 \quad \Longrightarrow \quad \mathrm{Re}(\rho) = 1/2 \text{ for every non-trivial zero } \rho$$

is false without an additional Hilbert–Pólya identification of the Virasoro energy with the zero-divisor operator. H-P^{Ar} supplies Θ_ξ, not an equality $L_0^{\mathrm{Vir}} = \Theta_\xi$.

Proof. The spectrum of L_0^{Vir} is the conformal-energy spectral measure of the Fock representation. The operator Θ_ξ is constrained by the determinant divisor $\mathrm{div}\,\xi_{\mathbb{R}}$. Equality of these data would identify a non-negative Fock energy measure with a complex divisor. No such equality follows from P1, P2, P3, or the definition of T_2^{Vir}. The valid RH implication uses the Li transform $\mathcal{L}_n$ of Θ_ξ, as in Chapter 44.3.8. □

Remark 45.3.5 *(the spectral barrier).* The $n = 2$ Virasoro calculation is a threshold calculation inside the Fock representation. The RH barrier is the construction of the zero-divisor operator Θ_ξ and of a positive trace on its Li transforms. Confusing these two operators turns Fock positivity into a false Hilbert–Pólya argument.

Levels $n = 3, 4$: Bombieri-Lagarias Upper Bound

THEOREM 45.3.6 *(Bombieri–Lagarias asymptotic bound).* (Bombieri–Lagarias J. Number Theory 77 (1999):274–287, Theorem 2). For every $n \geq 1$,

$$\lambda_n \;\leq\; \frac{n(c_0 + \log n)}{2}, \qquad c_0 := 2 + \gamma - \log(4\pi) \approx 0.04619.$$

The matching lower bound $\lambda_n \geq -\frac{1}{2}n \log n - O(n)$ holds unconditionally.

COROLLARY 45.3.7 *(finite Li data are scalar data).* . For any finite set $F \subset \mathbb{N}$, the inequalities $\lambda_n \geq 0$ for $n \in F$ are scalar inequalities for the Li transforms $\mathcal{L}_n = 1 - (1 - \Theta_\xi^{-1})^n$. They do not imply operator positivity of T_n^{Vir}, and they do not imply RH. Bombieri–Lagarias bounds and finite numerical evaluations are therefore finite scalar controls, not Virasoro positivity theorems.

Proof. Li's criterion requires $\lambda_n \geq 0$ for every $n \geq 1$. A finite set of inequalities is therefore not equivalent to RH. The identity $\lambda_n = \mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n)$ is a scalar trace identity for Θ_ξ. A positive trace of one operator does not force positivity of another operator: a diagonal matrix with eigenvalues -1 and 2 has positive trace and is not positive. The Virasoro polynomial T_n^{Vir} is a different functional calculus from $\mathcal{L}_n$. □

Remark 45.3.8 *(the trace-positivity gap).* The number-theoretic trace is attached to $\mathcal{L}_n(\Theta_\xi)$, not to T_n^{Vir}. Li positivity for all n is equivalent to RH. Operator positivity of a Virasoro polynomial is a separate Fock statement, and a scalar trace cannot bridge the two without a positive, determinate Weil–Connes representation of the zero measure.

45.4 Moment Problem Reformulation

The Shifted Zero Measure

Definition 45.4.1 *(off-line defect measure).* . Let $\rho = 1/2 + i\gamma_\rho$ denote a non-trivial zero of ξ, written with $\gamma_\rho \in \mathbb{C}$ (real for every zero iff RH). Under the symmetrisation $\rho \leftrightarrow 1 - \overline{\rho}$, the pair set $Z = \{\rho, 1 - \overline{\rho}\}$ pushes to the off-line defect measure ν_{def} on $\mathbb{R}_{\geq 0}$ via

$$\int f \, d\nu_{\mathrm{def}} := \sum_\rho f(|\mathrm{Im}\, \gamma_\rho|^2)$$

for test functions f of suitable growth, Bost–Connes-regularised. The measure ν_{def} is supported at 0 exactly when RH holds. It is a defect detector, not Li's positive moment measure.

Remark 45.4.2. Under RH, $\gamma_\rho \in \mathbb{R}$ and ν_{def} is supported at 0. This defect measure is not the spectral measure of H_{HP} and not the Li moment measure; it records only the distance of zeros from the critical line.

Li-Stieltjes Moment Formulation

Proposition 45.4.3 *(the defect measure is not a Li–Stieltjes moment model).* . The off-line defect measure ν_{def} of Chapter 45.4.1 does not give a Stieltjes moment representation of Li's coefficients or of $\mu_n := \sum_\rho \rho^n$. A Li–Stieltjes formulation requires the Hilbert–Pólya zero-divisor operator Θ_ξ, the Li transform $\mathcal{L}_n$, and the positive Weil–Connes trace of Chapter 44.3.2.

Proof. ν_{def} records $|\mathrm{Im}\, \gamma_\rho|^2$, which vanishes exactly on the critical line. Li's summand is instead $1 - (1 - 1/\rho)^n$, a holomorphic function of the zero ρ. No change of variables from the defect alone recovers this holomorphic transform with multiplicity. The Hilbert–Pólya trace identity is Chapter 44.3.8, which applies the Li transform to Θ_ξ. □

Hamburger Moment Determinacy

Theorem 45.4.4 *(Hamburger reformulation for the formal T_n).* . The following equivalence is a formal operator-theoretic template for a genuine positive moment problem; it is not the live RH path unless the measure is replaced by the Hilbert–Pólya zero measure of H_{HP} and the trace is the positive Weil–Connes trace:

(i) Formal positivity: $T_n^{\mathrm{Vir}} \succeq 0$ for all $n \geq 1$ on a fixed self-adjoint spectral model.

(ii) The associated spectral measure is a positive measure supported on $[1/2, \infty)$.

(iii) For the shifted moments $\nu_k := \int_{[1/2,\infty)} (x - 1/2)^k \, d\mu(x)$, all Hankel minors $H_n := \det(\nu_{i+j})_{0 \leq i,j \leq n}$ and shifted Hankel minors $H_n^{(1)} := \det(\nu_{i+j+1})_{0 \leq i,j \leq n}$ are non-negative for every $n \geq 0$.

This theorem is not an independent proof of RH and does not connect T_n^{Vir} to Li's coefficients.

Proof. (1) ⇔ (2) is the spectral theorem for the chosen self-adjoint model. Since

$$T_2^{\mathrm{Vir}}(x) = x^2 - (x-1)^2 = 2x - 1,$$

positivity for all n forces $x \geq 1/2$. Conversely, for $x = 1/2 + y$ with $y \geq 0$, $(y + 1/2)^n - (y - 1/2)^n$ is non-negative. This is a formal statement about that model, not about zeta zeros.

(2) ⇔ (3): Stieltjes moment-problem theorem (Shohat–Tamarkin 1943, Ch. III; Akhiezer 1965, §2.1): a sequence $\{m_k\}_{k\geq 0}$ is the moment sequence of a positive measure on $[0,\infty)$ iff all Hankel and shifted Hankel minors are non-negative. Apply it to the translated variable $y = x - 1/2$.

No implication to RH is asserted. □

Remark 45.4.5 *(moment information).* Chapter 45.4.4 records the formal moment-determinacy apparatus that would become relevant after a true Hilbert–Pólya spectral measure is constructed. In particular:

- Testing a genuine positive spectral measure level-by-level becomes testing Hankel determinants H_n level-by-level, a finite numerical procedure at each n.
- Known numerical bounds for Li coefficients do not test these Hankel determinants; they test a different holomorphic transform of the zero divisor.
- Known structural estimates on Li coefficients and Voros regularised sums do not supply lower bounds for the shifted Stieltjes minors above.
- The gap between known and needed becomes precisely specified: *unconditional* lower bounds on $H_n^{(1)}$ for all n.

The equivalent Hilbert–Pólya condition is the construction of the positive zero measure itself.

45.5 Local Kac Determinant at $c = 2$

The Kac Formula

THEOREM 45.5.1 *(Kac determinant formula).* (Kac 1978; Feigin–Fuchs 1990). For the Virasoro Verma module $M(c,h)$ of central charge c and highest weight h, the determinant of the contravariant form at level n is

$$\det_n^{c,h} = \prod_{\substack{r,s\geq 1\\ rs\leq n}} (h - h_{r,s}(c))^{p(n-rs)}$$

where $p(k)$ is the partition function and

$$h_{r,s}(c) = \frac{((m+1)r - ms)^2 - 1}{4m(m+1)}, \qquad c = 1 - \frac{6}{m(m+1)}.$$

The Arithmetic $c = 2$ Regime

PROPOSITION 45.5.2 *(Kac at $c = 2$).* For the local rank-2 free-boson Virasoro module, $c = 2$. In the Kac parametrisation the parameter m satisfies $1 - \frac{6}{m(m+1)} = 2$, hence $m(m+1) = -6$, giving the formal solution $m = (-1 \pm i\sqrt{23})/2$. The Kac null weights become

$$h_{r,s}(c=2) = \frac{((m+1)r - ms)^2 - 1}{4m(m+1)} = -\frac{((m+1)r - ms)^2 - 1}{24}.$$

Thus the possible null weights are the countable Kac set $\{h_{r,s}(2) : r,s \geq 1\} \subset \mathbb{C}$. No rationalisation to $\{0,-1,-2,\ldots\}$ is implied.

Proof. Direct substitution $c = 2$ in the Kac formula gives the displayed set. The free-boson realisation proves unitarity of the Fock module itself; it does not identify the Kac zero locus with a real arithmetic sequence. □

Corollary 45.5.3 *(no generic null-vector obstruction).* For generic primary weight h outside the countable Kac zero locus $\{h_{r,s}(2) : r, s \geq 1\}$, $\det_n^{c=2,h} \neq 0$ at every level n. This proves generic non-degeneracy for the local Virasoro Verma module. It does not prove Petersson positivity for the arithmetic primary object.

Unitarity Gap at Special Weights

Remark 45.5.4 *(the gap between non-degeneracy and positivity).* Chapter 45.5.3 establishes non-degeneracy, not positivity. Two Hermitian forms can be non-degenerate (no null vectors) without being positive-definite (a form of signature $(+, -, +, -, \ldots)$ is non-degenerate). The Friedan–Qiu–Shenker 1986 $c < 1$ analysis converts non-degeneracy to positivity via the Kac determinant *sign pattern*: when $c < 1$ is not in the discrete unitary series, the sign of $\det_n^{c,h}$ oscillates, producing at least one negative eigenvalue and refuting unitarity. The $c = 2$ case is outside the discrete $c < 1$ minimal unitary series, but it lies in the standard $c \geq 1$ free-boson unitary regime. Hence the FQS sign-oscillation argument for non-minimal $c < 1$ modules does not apply.

Theorem 45.5.5 *($c = 2$ free-field unitarity).* (Segal 1981; Frenkel–Ben-Zvi 2004). The free-boson rank-2 Fock module at central charge $c = 2$ is a unitary representation of the Virasoro algebra, with Hermitian form induced from the free-boson vacuum pairing $\langle \alpha_{-n_1} \cdots \alpha_{-n_k}|0\rangle, \alpha_{-m_1} \cdots \alpha_{-m_l}|0\rangle\rangle = \delta_{k,l} \sum_{\sigma \in S_k} \prod_i n_i \delta_{n_i, m_{\sigma(i)}}$. This is positive-definite by inspection.

Corollary 45.5.6 *(archimedean positivity of T_n^{Vir}).* On the *archimedean* sector $\mathcal{H}^{(\infty)}$ of the primary arithmetic Heisenberg Fock (the rank-2 free-boson Fock of Theorem 43.7.1 Step 1), $T_n^{\mathrm{Vir}} \succeq 0$ for every $n \geq 1$ on every non-vacuum number state.

Proof. The free-boson vacuum pairing of Theorem 45.5.5 is positive-definite; L_0^{Vir} acts diagonally on number states with eigenvalue $m = \sum_i i n_i \geq 0$ (with $m = 0$ precisely on the vacuum). On non-vacuum ($m \geq 1$) number states, $T_n^{\mathrm{Vir}} = (L_0^{\mathrm{Vir}})^n - (L_0^{\mathrm{Vir}} - \mathrm{id})^n$ acts by the scalar $m^n - (m-1)^n \geq 0$ (the function $x \mapsto x^n$ is monotone on $[0, \infty)$). Positive-semidefiniteness follows. □

Remark 45.5.7 *(the missing sector).* Corollary 45.5.6 establishes the archimedean sector. The full primary arithmetic Heisenberg Fock is *not* just the archimedean sector: the Bost–Connes zero-mode lattice $L = \ell^2(\mathbb{N}^\times)$ (Definition 29.2.1) enters multiplicatively, and the full primary space is $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}} \cong L \otimes \mathcal{H}^{(\infty)}_{\mathrm{primary}}$. Positivity of T_n^{Vir} on the $\mathcal{H}^{(\infty)}_{\mathrm{primary}}$ factor is Corollary 45.5.6. Positivity of a Virasoro polynomial on the L-factor is a statement about the Bost–Connes energy spectrum $\{\log m : m \geq 1\}$. It is not a statement about the zero divisor of ζ. The zero divisor enters only through the Hilbert–Pólya operator Θ_ξ and the Weil–Connes trace.

45.6 Fock-Combinatorial Identity

Explicit Action on Number States

Lemma 45.6.1 *(diagonal action on number states).* On the Fock number state $|\mathbf{n}\rangle := \prod_{i \geq 1} (\alpha_{-i}^{\infty})^{n_i}|0\rangle \big/ \prod_i \sqrt{i^{n_i} n_i!}$ (normalised with respect to the free-boson Fock inner product of Theorem 45.5.5), L_0^{Vir} acts as

$$L_0^{\mathrm{Vir}}|\mathbf{n}\rangle \;=\; \Big(\sum_{i \geq 1} i\, n_i\Big)|\mathbf{n}\rangle \;=:\; m(\mathbf{n})|\mathbf{n}\rangle.$$

Proof. $L_0 = \sum_{i\geq 1} \alpha_{-i}\alpha_i$ (Sugawara stress tensor zero mode for the free boson; Frenkel–Ben-Zvi 2004 §3.5). Applied to $(\alpha_{-i})^{n_i}|0\rangle$: by the canonical commutator $[\alpha_i, \alpha_{-i}] = i$, $\alpha_i(\alpha_{-i})^{n_i}|0\rangle = n_i \cdot i \cdot (\alpha_{-i})^{n_i-1}|0\rangle$, hence $\alpha_{-i}\alpha_i(\alpha_{-i})^{n_i}|0\rangle = in_i(\alpha_{-i})^{n_i}|0\rangle$. Summing over i gives the diagonal eigenvalue $\sum_i in_i$. □

The Symmetric-Function Identity

THEOREM 45.6.2 *(combinatorial positivity of T_n on Fock).* On every non-vacuum number state $|\mathbf{n}\rangle$ with $m(\mathbf{n}) \geq 1$,

$$T_n^{\mathrm{Vir}}|\mathbf{n}\rangle = [m(\mathbf{n})^n - (m(\mathbf{n})-1)^n]\,|\mathbf{n}\rangle,$$

and $m(\mathbf{n})^n - (m(\mathbf{n})-1)^n \geq 0$ for every integer $m(\mathbf{n}) \geq 1$ and every $n \geq 1$.

Proof. By Lemma 45.6.1, L_0^{Vir} acts by the scalar $m = m(\mathbf{n})$. Hence $(L_0^{\mathrm{Vir}})^n$ acts by m^n and $(L_0^{\mathrm{Vir}} - \mathrm{id})^n$ by $(m-1)^n$. The difference is $m^n - (m-1)^n$.

Non-negativity: the function $x \mapsto x^n$ is monotone non-decreasing on $[0,\infty)$ for $n \geq 1$; hence for $m \geq 1$ the strict inequality $m^n > (m-1)^n$ holds. For $m = 1$, the difference is exactly 1. □

Remark 45.6.3 *(combinatorial expansion).* Binomial expansion:

$$m^n - (m-1)^n = \sum_{k=0}^{n-1} \binom{n}{k} m^k (-1)^{n-1-k} = nm^{n-1} - \binom{n}{2} m^{n-2} + \cdots + (-1)^{n-1}.$$

For $m = 1$: the identity $1 - 0 = 1$; hence $T_n^{\mathrm{Vir}}|\mathbf{n}\rangle = |\mathbf{n}\rangle$ on weight-1 states for every $n \geq 1$. This is the *singleton-primary*-state positivity.

COROLLARY 45.6.4 *(Fock-level restricted positivity).* On the subspace $\mathcal{F}^{m\geq 1} \subseteq \mathcal{H}^{(\infty)}$ spanned by non-vacuum number states, $T_n^{\mathrm{Vir}} \succeq 0$ for every $n \geq 1$.

Proof. Direct from Theorem 45.6.2: T_n^{Vir} acts diagonally with non-negative eigenvalues; positivity follows from the diagonal characterisation. □

Remark 45.6.5 *(zero-mode separation).* Corollary 45.6.4 establishes non-vacuum archimedean Fock positivity for T_n^{Vir}. The primary arithmetic Heisenberg Fock also contains the Bost–Connes zero-mode lattice $\ell^2(\mathbb{N}^\times)$ lattice where μ_n acts via $\mu_n \delta_m = \delta_{nm}$; see Proposition 29.3.1. On this lattice the Bost–Connes Hamiltonian has Dirichlet-series spectrum $\{\log n : n \in \mathbb{N}^\times\}$ at KMS temperature β. This spectrum gives the Euler factor $\zeta(\beta)$; it is not the divisor of $\xi_{\mathbb{R}}$. The RH-strength input is the separate trace bridge from this Euler regularisation to Θ_ξ.

45.7 REDUCTION TO THE IRREDUCIBLE CORE OBSTRUCTION

The Core Statement

THEOREM 45.7.1 *(conditional reduction to the zero-operator core). (conditional on P2, P3, H-P^{Ar}, the primary tensor decomposition, and a positive regularised trace).* Under these hypotheses, the RH-strength positivity statement reduces to the following zero-operator statement:

(VB$^*_{\mathrm{core}}$) *Zero-operator spectral positivity.* The operator $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$ satisfies $\det_\infty(s - \Theta_\xi) = \xi_{\mathbb{R}}(s)$, and the regularised Weil–Connes trace on the Li transforms $\mathcal{L}_n(\Theta_\xi)$ is positive for every $n \geq 1$.

The Bost–Connes zero-mode lattice supplies the Euler/KMS regularisation of the trace. It is not the spectrum of Θ_ξ.

Proof. H-P^{Ar} gives the determinant identity for Θ_ξ. By Proposition 44.3.8, the Li coefficient λ_n is the regularised trace of $\mathcal{L}_n(\Theta_\xi)$. Positivity of these traces for every n is Li positivity, hence RH by Li's theorem. Conversely, RH is the support condition for the spectral measure of Θ_ξ. The Bost–Connes spectrum $\{\log m\}$ enters only through the regularisation giving the Euler product; no step identifies it with the determinant divisor of Θ_ξ. □

The Named Obstruction

Corollary 45.7.2 *(the irreducible core of VB*). (conditional on the hypotheses of Chapter 45.7.1).* The irreducible core is the positive zero-divisor measure problem for Θ_ξ. Replacing Θ_ξ by the Bost–Connes Hamiltonian N_{BC} replaces the zero divisor by the Euler eigenvalues and therefore destroys the Hilbert–Pólya statement.

Remark 45.7.3 *(core equivalence).* $(\mathrm{VB}^*_{\mathrm{core}})$ is not a *weaker* statement than VB* under the Hilbert–Pólya and positive-trace hypotheses; it is the zero-operator form of the same condition.

(i) The zero divisor is carried by Θ_ξ.
(ii) The Euler product is carried by the Bost–Connes KMS trace.
(iii) The equality between the two is the Hilbert–Pólya trace bridge.
(iv) The Bost–Connes phase transition at $\beta = 1$ records the pole of ζ; it is not a statement about phase transitions on the critical line.

45.8 Comparison to Classical RH Equivalents

Formulation	Input data	Positivity shape
Riemann 1859	$\xi(s)$ entire of order 1	Zero placement on line
Li 1997	$\lambda_n, n \geq 1$	Scalar sequence ≥ 0
Weil 1952	Test functions $f \in \mathcal{S}$	Inner product positivity
Báez-Duarte 2003	Finite linear combinations of $\{\rho^s\}$	Density in L^2
Lagarias 1999	de Branges datum over Ξ	Hermite–Biehler divisor control
Bombieri–Lagarias 1999	$\{\lambda_n\}$ with bounds	Explicit lower bounds
Connes 1999	$\mathcal{S}_{\mathbb{A}}/\mathbb{Q}^*$	Trace-formula positivity
Vol IV Virasoro	$\{T_n^{\mathrm{Vir}}\}_{n\geq 1}$ in primary Fock	Fock polynomial positivity
Vol IV HP–Li core	$\boldsymbol{\Theta_\xi}$ with Weil–Connes trace	**zero-measure positivity**

Table 45.1: RH-equivalent positivity formulations across the literature.

Remark 45.8.1 *(placement of VB* against its neighbours).* The formal Virasoro polynomial T_n^{Vir} does not imply Li's inequality. The RH-strength statement is HP–Li: positivity of the regularised Weil–Connes trace of $\mathcal{L}_n(\Theta_\xi)$ for every n. Weil 1952 and the de Branges formulations place the same zero-placement barrier in classical languages. The Vol IV core is the construction and positivity of the Θ_ξ-measure, with the Bost–Connes zero-mode serving as Euler regularisation rather than as the zero spectrum.

Proposition 45.8.2 *(Weil comparison under P3). (conditional on Koszul–Petersson compatibility Chapter 43.7.2 and the H-P^{Ar} trace condition).* Weil 1952 explicit-formula positivity and HP–Li positivity express the same RH-equivalent barrier after identifying the Weil distribution with the regularised trace of the zero-divisor operator Θ_ξ. The Petersson form enters through the Koszul–Petersson comparison of the trace functional; it does not turn T_n^{Vir} into a Li transform.

Proof. Weil 1952 gives $\lambda_n = \langle f_n, f_n \rangle^{\mathrm{Weil}}$ for f_n an explicit test function on the adele class space. H-P^{Ar} gives $\lambda_n = \mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n(\Theta_\xi))$. Koszul–Petersson compatibility identifies the trace pairing with the Petersson pairing on the arithmetic primary sector whenever the admissible Weil test lies in that sector. Thus Weil positivity and HP–Li positivity are the same positivity problem after the trace bridge is supplied. No equality with $\mathrm{Tr}_{\mathrm{reg}}(T_n^{\mathrm{Vir}})$ is used. □

45.9 Zero-Divisor Condition

The Precise Condition

The RH-strength positivity statement is equivalent to the following condition:

Definition 45.9.1 *(the Vol IV zero-divisor condition).* The *Vol IV zero-divisor condition* is the following statement:

> There is a normal zero-divisor operator $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$ whose determinant divisor is $\mathrm{div}\,\xi_{\mathbb{R}}$, and whose Weil–Connes trace is supported on $1/2 + i\mathbb{R}$. The Bost–Connes zero-mode gives the Euler/KMS regularisation of the trace; it does not carry $\mathrm{div}\,\xi_{\mathbb{R}}$. ($\mathcal{R}_{\mathrm{IV}}$)

THEOREM 45.9.2 *($\mathcal{R}_{\mathrm{IV}}$ implies the Riemann Hypothesis).* $\mathcal{R}_{\mathrm{IV}} \Rightarrow$ RH. Conversely, RH gives only the zero-placement part of $\mathcal{R}_{\mathrm{IV}}$; it does not construct the normal zero-divisor operator, the determinant divisor, the Weil–Connes trace, or the Bost–Connes regularisation.

Proof. By definition, $\mathcal{R}_{\mathrm{IV}}$ includes a Θ_ξ-determinant divisor and Weil–Connes trace concentrated on the critical line. Since $\det_\infty(s - \Theta_\xi) = \xi_{\mathbb{R}}(s)$, this is exactly the zero-placement assertion for the nontrivial zeros of ζ, hence RH by Chapter 44.1.2. The converse would require the extra operator-realization data named in the statement; zero placement alone does not supply it. □

Virasoro Boundary

Remark 45.9.3 *(structural change).* The arithmetic Virasoro reduction gives:

(i) Closed $n = 1$ unconditionally (Chapter 45.3.1).
(ii) Reduced $n = 2$ to the formal Virasoro threshold $L_0^{\mathrm{Vir}} \succeq (1/2)\mathrm{id}$, not to zero placement (Chapter 45.3.4).
(iii) Established Fock-level positivity for the archimedean sector at every n (Chapter 45.6.4).
(iv) Reformulated the zero-measure problem as a Hamburger moment determinacy problem for Θ_ξ (Chapter 45.4.4).
(v) Proved the Kac determinant at $c = 2$ is non-zero at generic weights (Chapter 45.5.2), establishing absence of null-vector unitarity obstruction.
(vi) Placed HP–Li in correspondence with Weil positivity (Chapter 45.8.2) and the de Branges Hermite-Biehler framework.
(vii) The RH-strength condition is a single zero-measure positivity statement for Θ_ξ ($\mathrm{VB}^*_{\mathrm{core}}$, Chapter 45.7.1).

VB* itself remains open, as it is equivalent to RH.

Remark 45.9.4 *(VB^*_{core} boundary).* The assertion ($\mathrm{VB}^*_{\mathrm{core}}$) contains the following independent analytic inputs:

(i) A second KMS-positivity input beyond Bost–Connes: a constraint on the zero-divisor measure forcing critical-line concentration.

(ii) An arithmetic-modular bootstrap input: a Kac-formula-style analysis of the arithmetic Virasoro algebra on the Bost–Connes C^*-algebra, extracting unitarity from null-vector absence.

(iii) An $n \to \infty$ asymptotic input: a moment-generating-function bootstrap strong enough to close the $n \to \infty$ limit of λ_n scaling.

The first input belongs to the arithmetic site of Connes–Consani arXiv:1405.4527. The second is the C^*-algebraic analogue of Friedan–Qiu–Shenker. The third is an asymptotic moment problem.

45.10 Arithmetic Zhu Finiteness Test

The tempting shortcut is Verlinde finite-dimensionality: prove that the primary Bost–Connes core is an arithmetic Zhu-finite object, obtain a finite-dimensional Hermitian modular functor, and read positivity from ordinary linear algebra. The shortcut fails on the full zeta object.

Definition 45.10.1 *(Euler-faithful arithmetic Zhu quotient).* An *Euler-faithful arithmetic Zhu quotient* of the primary Bost–Connes core is a quotient Q of the zero-mode lattice $L = \ell^2(\mathbb{N}^\times)$ satisfying:

(i) the Bost–Connes operators descend:

$$\mu_n \overline{\delta}_m = \overline{\delta}_{nm}, \qquad \mu_n^* \overline{\delta}_m = \begin{cases} \overline{\delta}_{m/n}, & n \mid m, \\ 0, & n \nmid m, \end{cases}$$

where $\overline{\delta}_m$ is the image of $\delta_m \in L$;

(ii) the KMS Hamiltonian $H = \log N$ descends with $H\overline{\delta}_m = (\log m)\overline{\delta}_m$ whenever $\overline{\delta}_m \neq 0$;

(iii) the ordinary KMS character of the quotient is the full Bost–Connes Euler product:

$$\mathrm{Tr}_Q(e^{-\beta H}) = \sum_{m \geq 1} m^{-\beta} = \zeta(\beta) \qquad (\mathrm{Re}\,\beta > 1).$$

It is *Zhu finite* if $\dim_{\mathbb{C}} Q < \infty$.

Theorem 45.10.2 *(no Euler-faithful Zhu finiteness).* No Euler-faithful arithmetic Zhu quotient of the primary Bost–Connes core is Zhu finite.

Proof. If Q were finite-dimensional, the trace $\mathrm{Tr}_Q(e^{-\beta H})$ would be a finite sum $\sum_{j=1}^{r} a_j e^{-\beta E_j}$ after diagonalising the finite-dimensional self-adjoint operator H. In particular it extends to an entire function of β. Euler-faithfulness requires this finite sum to equal $\zeta(\beta)$ on the half-plane $\mathrm{Re}\,\beta > 1$. By the identity theorem the meromorphic continuation of ζ would be entire, contradicting its simple pole at $\beta = 1$. Hence Q is infinite-dimensional.

Equivalently, the faithful Bost–Connes action of Proposition 29.3.1 sends δ_1 to δ_m by $\mu_m \delta_1 = \delta_m$. Keeping the full Euler product keeps one independent KMS eigenline at every $m \in \mathbb{N}^\times$. A finite Zhu quotient must kill or identify infinitely many of these lines, and then it no longer has character $\zeta(\beta)$. □

Corollary 45.10.3 *(Verlinde finite-dimensionality cannot close full RH).* Arithmetic Zhu/Verlinde finite-dimensionality cannot prove $\mathrm{VB}^*_{\mathrm{core}}$ for the full $\mathcal{V}^{\mathrm{prim}}$ while preserving the completed zeta partition function. The only Zhu-finite quotients compatible with the Bost–Connes action are finite-prime or finite-conductor truncations; their characters are finite Euler products or finite Dirichlet polynomials, not $\xi(s)$.

Proof. By Theorem 45.10.2, a finite-dimensional quotient cannot be Euler-faithful. A quotient supported on a finite set S of primes has character $\prod_{p\in S}(1-p^{-\beta})^{-1}$, possibly with an archimedean Tate factor. Such a finite Euler product is a finite-level arithmetic modular-functor object; it is not the zeta object whose zero-placement is RH. Therefore finite-dimensional Hermitian linear algebra can test finite windows, but it cannot supply the missing positivity for the full Θ_ξ-spectral measure. □

Remark 45.10.4 *(central charge does not rescue Zhu finiteness).* The residue value $r_\zeta = 2$ of Chapter 35.4.1 equals a pole order under the stated determinant factorization. Chapter 35 also shows that the prescribed sums of negative Sugawara modes fail on the restricted tensor vacuum. These statements concern a scalar invariant and a particular proposed action. Neither supplies a finite-dimensional C_2-quotient or Zhu algebra. Thus $r_\zeta = 2$ supplies no C_2-cofiniteness or Zhu-finiteness hypothesis.

Remark 45.10.5 *(surviving direction).* The finite-dimensional construction survives only as a finite-window technology: truncate to finitely many primes or to bounded conductor, prove the corresponding arithmetic modular functor is finite, compute its Hermitian form, and compare its limiting trace to the Bost–Connes KMS trace. Any limiting theorem strong enough to recover $\mathrm{VB}^*_{\mathrm{core}}$ must add a new positivity or compactness input beyond Zhu finite-dimensionality at finite level.

45.11 Zero-Measure Conjecture

Conjecture 45.11.1 *(VB^*_{core}: the Vol IV form of RH). Conjectural statement.* The zero-divisor operator $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$, with $\operatorname{div}\det_\infty(s-\Theta_\xi) = \operatorname{div}\xi_{\mathbb{R}}$, has determinant divisor and Weil–Connes trace supported on $1/2 + i\mathbb{R}$. Equivalently, all non-trivial zeros of ζ lie on the critical line.

Remark 45.11.2 *(the conjecture is RH).* Chapter 45.11.1 is, verbatim, the Riemann Hypothesis. The arithmetic chiral-algebra formulation asks for a positive, determinate Weil–Connes trace and determinant divisor on the zero-divisor operator Θ_ξ. The Bost–Connes algebra supplies the Euler regularisation and KMS weight, in the sense of Connes' adelic trace formula; it does not supply the determinant divisor by itself.

Remark 45.11.3 *(size of* $\mathrm{VB}^*_{\mathrm{core}}$*).* Any unconditional proof of Chapter 45.11.1 would be an unconditional proof of RH, a Millennium Prize problem. No finite estimate is meaningful. Partial reductions have the following mathematical sizes:

Bombieri-Lagarias-style sharpening at specific n. substantial local theorem.

Kac-determinant analysis at $c = 2$ to low level. finite-level determinant computation.

Moment-problem Hankel analysis. unbounded Hamburger determinacy and lower bounds on all shifted Hankel minors.

Arithmetic-site incorporation. Connes–Consani arithmetic-site positivity; no unconditional proof of RH follows.

45.12 Operator Boundary

(i) The formal Virasoro polynomial sequence $\{T_n^{\mathrm{Vir}}\}$ gives Fock positivity statements, not Li transforms (Chapter 45.1.3).

(ii) The RH-strength path uses $\mathcal{L}_n(\Theta_\xi) = 1-(1-\Theta_\xi^{-1})^n$, the positive Weil–Connes trace, and Li's criterion (Chapter 45.4.4, Chapter 45.8.2).

(iii) $n = 1$ is unconditional: $T_1^{\mathrm{Vir}} = \mathrm{id}$ (Chapter 45.3.1).

(iv) $n = 2$ reduces to $L_0^{\mathrm{Vir}} \succeq (1/2)\mathrm{id}$, a formal Fock threshold rather than a zero-placement theorem (Chapter 45.3.3, Chapter 45.3.4).

(v) Finite Li data at $n \geq 3$ are scalar trace data for Θ_ξ; they do not imply Virasoro operator positivity or RH.

(vi) Fock-combinatorial positivity holds in the archimedean sector: $T_n^{\mathrm{Vir}} \succeq 0$ on non-vacuum number states for every n (Chapter 45.6.2).

(vii) The local Kac determinant at $c = 2$ does not vanish at generic weights, establishing absence of null-vector obstruction (Chapter 45.5.2, Chapter 45.5.3).

(viii) The RH-strength core is a single statement about the Θ_ξ-spectral measure: ($\mathrm{VB}^*_{\mathrm{core}}$, Chapter 45.7.1).

(ix) Arithmetic Zhu/Verlinde finite-dimensionality holds at finite windows only: any Euler-faithful quotient preserving the Bost–Connes character $\zeta(\beta)$ is infinite-dimensional (Chapter 45.10.2, Chapter 45.10.3).

(x) ($\mathrm{VB}^*_{\mathrm{core}}$) is the Vol IV form of RH, equivalent to $\mathrm{Re}(\rho) = 1/2$ for all non-trivial zeros (Chapter 45.9.2).

(xi) The condition $\mathcal{R}_{\mathrm{IV}}$ is the existence of the zero-divisor operator with positive, determinate Weil–Connes trace; it is equivalent to RH.

The unconditional Virasoro content is the identity at $n = 1$, the formal threshold at $n = 2$, and non-vacuum Fock positivity. The Riemann Hypothesis enters only through the zero-divisor operator Θ_ξ, the Li transforms, and the positive Weil–Connes trace. The equivalent condition is stated in two operator-theoretic forms (Chapter 45.11.1, Chapter 45.9.1) and is, in full, the Riemann Hypothesis.

Chapter 46

Arithmetic Co–Contra Comparison

An arithmetic co–contra comparison must specify its coalgebra, continuous dual, completion, and derived categories over a common coefficient ring. The classical field-coefficient correspondence provides a model for this question. The module-theoretic μ-invariant does not characterize conilpotence, as shown in Proposition 10.10.2.

For the proposed arithmetic Heisenberg application, a categorical comparison must also preserve the relevant pairing and central classes. Theorem 43.5.1 isolates the further Mellin evaluation and defect-detection hypotheses that imply $\kappa + \kappa^{!} = 0 \Longleftrightarrow \xi(s) = \xi(1-s)$. The scalar functional equation and the oscillator energy calculation do not construct those arithmetic maps.

46.1 Statement and Motivation

Review: Classical Positselski

Let k be a field and C a dg coalgebra over k. A left C-comodule has a coaction $M \to C \otimes_k M$. A left C-contramodule has a contraaction $\pi : \mathrm{Hom}_k(C, P) \to P$. The latter satisfies the associativity identity induced by $\Delta : C \to C \otimes_k C$ and the unit identity induced by $\epsilon : C \to k$. All maps commute with differentials, and tensor–Hom adjunctions use the Koszul signs.

The *coacyclic* dg comodules form the smallest triangulated subcategory containing totalizations of exact triples and closed under arbitrary direct sums. The *contraacyclic* dg contramodules are defined using products instead. Their Verdier quotients are the coderived and contraderived categories. These quotients need not agree with the ordinary derived categories, even though the coefficient ring is a field.

For a right comodule N and a left contramodule P, define

$$N \odot_C P = \mathrm{coker}\big(N \otimes_k \mathrm{Hom}_k(C, P) \rightrightarrows N \otimes_k P\big).$$

The arrows use the contraaction and the right coaction followed by evaluation, respectively. On homogeneous elements the latter evaluation is $c \otimes f \mapsto (-1)^{|c||f|} f(c)$. This quotient is the *contratensor product*. Write Hom_C for colinear homogeneous maps, with their Hom differential.

Theorem 46.1.1 *(Positselski,* Two kinds of derived categories, *§5.2).* The derived functors of

$$\Psi_C(M) = \mathrm{Hom}_C(C, M), \qquad \Phi_C(P) = C \odot_C P$$

give mutually inverse equivalences

$$\mathrm{D}^{\mathrm{co}}(C\text{-comod}_k) \simeq \mathrm{D}^{\mathrm{ctr}}(C\text{-contra}_k).$$

The functor Φ_C is left adjoint to Ψ_C.

Proof. Positselski's resolution theorem, §4.4, represents the two quotients by dg objects that are injective or projective after forgetting the differential. Graded injective comodules are summands of cofree objects

$C \otimes_k V$. Graded projective contramodules are summands of free objects $\operatorname{Hom}_k(C, V)$. The two functors exchange these free and cofree objects, with natural inverse maps. They therefore exchange their summands and the corresponding dg objects. The resulting equivalence of these homotopy categories proves the assertion. □

This correspondence is covariant in M. For $C = k$, its right adjoint is $M \mapsto M$, not the contravariant vector-space dual. The coalgebra dual $C^\vee$ and the cobar algebra ΩC are also different constructions. A topological description using $C^\vee$ must specify its continuous duality and its contramodules.

The Λ-Coefficient Target

Fix a prime p, a procyclic group $\Gamma \cong \mathbb{Z}_p$, and a topological generator γ. Set

$$\Lambda = \mathbb{Z}_p[[\Gamma]] \cong \mathbb{Z}_p[[T]], \qquad T = \gamma - 1, \qquad \mathfrak{m} = (p, T).$$

For the cyclotomic application, Γ is the Galois group of a chosen cyclotomic $\mathbb{Z}_p$-extension. The full cyclotomic Galois group may also have a finite factor. The ring Λ is complete, Noetherian, local and regular of dimension two, with residue field $\mathbb{F}_p$.

A pseudo-isomorphism is a map with finite kernel and cokernel. Every finitely generated Λ-module M admits one of the form

$$M \longrightarrow \Lambda^r \oplus \bigoplus_i \Lambda/p^{a_i}\Lambda \oplus \bigoplus_j \Lambda/f_j^{b_j}\Lambda.$$

Here $r \geq 0$, $a_i, b_j \geq 1$, and each $f_j \in \mathbb{Z}_p[T]$ is irreducible and distinguished. A monic polynomial is distinguished when its other coefficients are divisible by p. The Iwasawa invariants are $\mu(M) = \sum_i a_i$ and $\lambda(M) = \sum_j b_j \deg f_j$. Proposition 46.3.1 recalls the structure theorem.

Definition 46.1.2 *(arithmetic dg Λ-coalgebra).* An *arithmetic dg Λ-coalgebra* is a coaugmented dg coalgebra $C = \Lambda\mathbf{1} \oplus \overline{C}$ over Λ, with $\overline{C} = \ker \epsilon$, satisfying:

(i) *Local finiteness over* Λ: the underlying graded Λ-module C is a filtered union of finitely generated Λ-submodules $C_{\leq n}$ with $C = \varinjlim_n C_{\leq n}$ and each $C_{\leq n}/C_{\leq n-1}$ finitely generated.

(ii) *Comultiplication*: a graded Λ-linear map $\Delta\colon C \to C \otimes_\Lambda C$ with counit $\epsilon\colon C \to \Lambda$, satisfying the standard coassociativity / counit axioms, and compatible with the differential d.

(iii) *Conilpotence*: for every $c \in \overline{C}$, some iterated reduced coproduct vanishes on c. The reduced coproduct is

$$\overline{\Delta}(c) = \Delta(c) - \mathbf{1} \otimes c - c \otimes \mathbf{1} \in \overline{C} \otimes_\Lambda \overline{C}.$$

The notation $\mu(C) = \mu(\overline{C})$ requires $\overline{C}$ to be a finitely generated torsion Λ-module. For an infinite graded or completed object, one must instead specify the coefficient modules whose invariants are being taken.

Definition 46.1.3 *($\mu = 0$ arithmetic Λ-coalgebra).* Suppose $M = \overline{C}$ is a finitely generated torsion Λ-module. Then C is $\mu = 0$ when

$$\mu(M) = \operatorname{length}_{\Lambda_{(p)}} M_{(p)} = 0.$$

Equivalently, its structure theorem has no $\Lambda/p^a\Lambda$ summand. This is a statement up to pseudo-isomorphism, not the absence of all p-torsion. For example, $M = \Lambda/(p, T)$ is nonzero and killed by p, but $M_{(p)} = 0$ because T becomes invertible.

Remark 46.1.4 *(the role of $\mu = 0$).* The invariant measures torsion at the height-one prime (p). It does not control all torsion or derived base change. The module $\Lambda/(p, T)$ has $\mu = 0$ and nonzero p-torsion. The module $\Lambda/(T)$ also has $\mu = 0$, but its first Tor with itself is $\Lambda/(T)$. Proposition 46.3.5 computes these effects. Completion and reduction must therefore be checked on the actual comparison maps.

A precise lifting criterion uses completion inside the recipient category. In a stable Λ-linear ∞-category with sequential limits, put

$$X/p^n = \operatorname{cofib}(p^n : X \to X).$$

Call X *derived p-complete* when the natural map $X \to \varprojlim_n X/p^n$ is an equivalence. For $X \in \mathrm{D}(\Lambda)$, the quotient is $X \otimes^{\mathbb{L}}_{\Lambda} \Lambda/p^n$. In a coderived recipient, its intrinsic cofiber and limit are required. An underlying ordinary derived complex may forget information.

Theorem 46.1.5 *(lifting an arithmetic comparison).* Let $\mathcal{C}$ and $\mathcal{D}$ be specified stable Λ-linear ∞-categories with sequential limits. Suppose an exact Λ-linear adjunction $\Phi : \mathcal{D} \rightleftarrows \mathcal{C} : \Psi$ has been constructed. Write its unit and counit as

$$\eta_P : P \longrightarrow \Psi\Phi P, \qquad \varepsilon_M : \Phi\Psi M \longrightarrow M.$$

Assume their cofibers are derived p-complete in their respective categories, and that η_P/p and ε_M/p are equivalences for every P, M. Then

$$\Psi : \mathcal{C} \xrightarrow{\sim} \mathcal{D}, \qquad \Phi \simeq \Psi^{-1}.$$

The proof is given in Section 46.4. For the arithmetic problem, one must construct $\mathcal{C}$ and $\mathcal{D}$ from the intended integral comodules and contramodules, with their exact structures and topology. One must then construct the adjunction and verify these hypotheses. Module-theoretic $\mu = 0$ does not supply them. Compatibility with the algebraic bar–cobar adjunction is a further comparison of functors.

Remark 46.1.6 *(data for the arithmetic comparison).* The categorical construction and its zeta interpretation require different data:

(i) *Continuous duals.* Specify the coalgebra, its topology, its dual recipient, and the exact comodule and contramodule categories. Identify any proposed topological-algebra description with these categories.

(ii) *Derived completion.* Prove completeness of the unit and counit cofibers in those recipients. Ordinary module completion need not detect coderived equivalences.

(iii) *Reduction of the adjunction.* Construct the comparison with an actual adjunction over Λ/p, preserving its unit and counit. Prove that the reduced maps are equivalences. This requires detection of equivalences, not faithfulness of reduction on morphisms.

(iv) *Character and pairing.* Identify the selected one-mode character with ζ and construct its arithmetic pairing. The full oscillator character is $\prod_{k\geq 1} \zeta(k\beta)$. Neither scalar character constructs the central-defect or Mellin maps.

(v) *Bost–Connes comparison.* Construct the cobar algebra in the chosen coefficient category and compare it with the specified Bost–Connes algebra, action and pairing. Question 33.5.2 retains this problem. The continuous dual is not the cobar algebra by definition.

The first three requirements concern the lifting criterion. The last two concern its arithmetic interpretation. They are not an exhaustion theorem for all possible arithmetic realizations.

Section 46.4 presents the proposed co–contra construction. Its six coefficient and completion comparisons are in Section 46.2. Section 46.3 fixes the required Λ-module notions.

The arithmetic Heisenberg application and its level comparison are in Section 46.5. Section 46.7 retains the non-abelian Iwahori and Whittaker comparison conditions.

46.2 Obstruction Analysis Table

The following comparisons specify the coefficient, completion and pairing conditions in the arithmetic statement.

Obstruction 1: Base-Change Lift

The field correspondence is not a theorem over $\mathbb{F}_p[[T]]$, which is a discrete valuation ring. There is no unital map from a field to $\mathbb{Z}_p[[T]]$: positive characteristic is incompatible with characteristic zero, and a characteristic-zero field would make p invertible. Thus extension of scalars from a field cannot construct the integral comparison directly.

Reduction $\Lambda \to \Lambda/p$ is nevertheless useful. On derived p-complete objects, it detects equivalences, by Proposition 46.4.5. This proves a lifting criterion once the functors and their reduced unit and counit are available. It does not construct these functors, and reduction is not faithful on morphisms.

Obstruction 2: Exact Structures and Derived Recipients

Over Λ, an arithmetic comparison must select the admissible exact sequences of comodules and contramodules. The coacyclic and contraacyclic subcategories are then formed using these sequences and the appropriate sums or products. An injective resolution over the coefficient ring need not be an injective resolution in the comodule category. The corresponding distinction holds for projectives.

Selmer complexes furnish arithmetic complexes with specified local conditions. To use them here requires functors into the chosen comodule or contramodule recipient, preserving those conditions. Their existence does not follow from the notation $\mathrm{D}(\Lambda)$, or from a vanishing μ-invariant. Definitions 46.3.6 and 46.3.7 state the exact-category construction used below.

Obstruction 3: μ-Invariant Vanishing for the Heisenberg Bar

For a defined arithmetic bar object, the first question is which finitely generated torsion Λ-module carries the proposed μ-invariant. A filtered or completed complex has no single such invariant until the relevant cohomology or graded coefficient modules are specified.

There is an elementary vanishing calculation on a fixed coefficient model. Let $\Lambda = \mathbb{Z}_p[[T]]$, and let M be a finite free $\mathbb{Z}_p$-module of rank d, with trivial Γ-action. Then

$$M \cong (\Lambda/(T))^d, \qquad M_{(p)} = 0, \qquad \mu(M) = 0.$$

Indeed, $T \notin (p)$, so localization at (p) makes the annihilator T invertible. This proves vanishing for this module without identifying it with a cyclotomic Iwasawa module.

Given an actual augmented coefficient algebra with augmentation ideal I, one can form finite bar-length pieces

$$B_{\le n} = \bigoplus_{j=0}^{n} (I[1])^{\otimes_\Lambda j},$$

with cohomological shift $I[1]^q = I^{q+1}$. For positive bar lengths, applying that calculation requires the selected coefficients to be finite free over $\mathbb{Z}_p$ with trivial action. The length-zero coefficient is Λ itself.

A residue complex can be tensored into this construction only after its Λ-module structure and total differential have been supplied. Finite tame symbols, by themselves, provide neither structure.

Ferrero–Washington gives a vanishing theorem for specified cyclotomic Iwasawa modules. Its use requires identifying the arithmetic coefficient module with one in that theorem's domain. The identification must preserve the action and topology. Neither the name Heisenberg nor commutativity of Γ supplies such an identification. Proposition 10.10.2 further separates module-theoretic vanishing from coalgebra conilpotence.

Obstruction 4: Weight Compatibility Under Bar–Cobar

Weight comparison. The proposed arithmetic pairing would relate bar coefficients of energy $\log p$ to independently defined dual coefficients of energy $-\log n$. To interpret energy cancellation as $\kappa^{\mathrm{Ar}} + (\kappa^{!})^{\mathrm{Ar}} = 0$, one must construct the central-defect identity and evaluation of Theorem 43.5.1. Compatibility with a Bost–Connes Hecke operator μ_n is an additional action map.

A cyclotomic character supplies a Galois action only after that action is specified on the coefficient object. Its compatibility with a co–contra functor is additional data. Oscillator energies $k \log p$ belong to a different grading. The ungraded correspondence does not identify the two.

Weight calculation. Convention 28.7.1(ii) assigns energy $k \log p$ to $x_{p,k} = \alpha_{-k}^{(p)}$. Its linear dual can be given the negative energy. Evaluation then has total energy zero, as constructed in Theorem 46.5.1. The numerical identity $\log(p^k) = k \log p$ is also compatible with assigning $-\log(p^k)$ to a proposed dual symbol. It does not identify that symbol with a Bost–Connes isometry, construct a twisting cochain, or identify oscillator energy with a central level.

The full one-species-per-prime oscillator trace is $\prod_{k\geq 1} \zeta(k\beta)$ for $\beta > 1$. The selected mode-one occupation space has trace $\zeta(\beta)$, but is not invariant under the divisor or index-shift operations for index greater than one (Section 28.7). A pairing or arithmetic comparison must specify which of these carriers it uses.

Obstruction 5: Archimedean Completion

The completed zeta function contains the real factor $\pi^{-s/2}\Gamma(s/2)$. Fourier self-duality of the Gaussian and Poisson summation provide its analytic input. Theorem 35.6.1 proves the scalar reflection with its polar terms.

A categorical interpretation needs an archimedean coalgebra or algebra, its modules and its pairing. It also needs a comparison to the Fourier model. The local Fock space does not specify these data by itself. Section 46.6 gives the Gaussian calculation and a conditional assembly of actual local equivalences over a common coefficient ring.

Obstruction 6: Noncommutative Coefficients

For a compact p-adic group G, the completed group algebra $\mathbb{Z}_p[[G]]$ is a possible noncommutative coefficient ring. Its use for an Iwahori Hecke category requires an actual action and a comparison with that category. These are not consequences of the name of the group.

A coalgebra over a noncommutative base must specify left and right module structures. The resulting coring has a coproduct into its tensor square over the base. Its conilpotence, continuous Hom, completion and exact structures must be stated in that setting. The commutative structure theorem below does not provide them. The noncommutative and Whittaker questions in Section 46.7 retain these additional constructions.

Comparison Table

Input	Content	Conclusion
1	Reduction and lifting	complete cofibers and actual maps
2	Derived recipients	specify exact structures
3	$\mu = 0$ for specified bar modules	requires the module comparison
4	Weight pairing	oscillator evaluation constructed
5	Archimedean comparison	Fourier model. Categorical map needed
6	Noncommutative coefficients	coring and action required

TABLE 46.1: Arithmetic Positselski comparisons. The abelian comparison retains the data of Remark 46.1.6 and the pairing and invariant maps of Question 46.5.4. Non-abelian Iwahori level requires further data (Section 46.7).

46.3 IWASAWA PRELIMINARIES

The coefficient calculations use three facts about finitely generated Λ-modules: the structure theorem, the resolution bounds, and the actual Tor groups governing reduction. These module calculations do not identify the derived comodule and contramodule recipients.

Λ-Modules and Structure Theorem

PROPOSITION 46.3.1 *(Λ-module structure theorem).* Let $\Lambda = \mathbb{Z}_p[[\Gamma]]$ and let M be a finitely generated Λ-module. Then there is a pseudo-isomorphism (morphism with finite kernel and cokernel)

$$M \sim \Lambda^r \oplus \bigoplus_{i=1}^{s} \Lambda/p^{a_i}\Lambda \oplus \bigoplus_{j=1}^{t} \Lambda/f_j^{b_j}\Lambda,$$

where $r, s, t \in \mathbb{Z}_{\geq 0}$, $a_i \in \mathbb{Z}_{\geq 1}$, and $f_j \in \mathbb{Z}_p[\gamma - 1]$ are distinguished irreducible polynomials (Weierstrass polynomials). The invariants r, $\mu(M) = \sum a_i$, $\lambda(M) = \sum b_j \deg f_j$ are well-defined.

Proof. Apply Serre, *Classes des corps cyclotomiques*, §6, Lemmas 5–6. Up to finite kernel and cokernel, a finitely generated module splits into a reflexive module and height-one primary factors. The reflexive module is free because Λ is regular local of dimension two. Localization at a height-one prime is a discrete valuation ring, so each primary factor has its elementary-divisor decomposition. Weierstrass preparation identifies the height-one primes as (p) and the ideals (f) for distinguished irreducible f. Their localized multiplicities give the stated invariants. □

COROLLARY 46.3.2 *($\mu = 0$ criterion).* For a finitely generated Λ-module M, the invariant $\mu(M)$ is the length of the torsion submodule of $M_{(p)}$. It vanishes exactly when $M_{(p)}$ is free over $\Lambda_{(p)}$. If M is torsion, this is equivalent to $M_{(p)} = 0$.

Proof. Finite modules vanish after localization at (p). The structure theorem therefore becomes an isomorphism there. The summand Λ/p^a contributes length a. A distinguished polynomial reduces modulo p to a nonzero power of T, so it does not lie in (p) and becomes a unit. Its summand vanishes. The remaining free summand has rank r, proving all assertions. □

Injective and Projective Resolutions Over Λ

Proposition 46.3.3 *(projective resolution bound).* Every finitely generated Λ-module M has a finite free resolution of length at most two.

Proof. The regular sequence (p, T) gives the Koszul resolution

$$0 \longrightarrow \Lambda \xrightarrow{\binom{-T}{p}} \Lambda^2 \xrightarrow{(p\ \ T)} \Lambda \longrightarrow \mathbb{F}_p \longrightarrow 0.$$

It follows that $\operatorname{Tor}_i^{\Lambda}(\mathbb{F}_p, M) = 0$ for $i > 2$. Construct a minimal free resolution of M by successively choosing minimal generators of its kernels. Each free module is finite because Λ is Noetherian. Every differential reduces to zero modulo $\mathfrak{m}$, so its i-th free module modulo $\mathfrak{m}$ is the i-th Tor group. Nakayama's lemma makes those free modules zero for $i > 2$. □

Proposition 46.3.4 *(injective resolution bound).* Every Λ-module M has an injective resolution $0 \to M \to I^0 \to I^1 \to I^2 \to 0$. No finite-generation condition on the injective terms is asserted.

Proof. For every ideal J, the preceding proposition gives $\operatorname{Ext}^3_{\Lambda}(\Lambda/J, M) = 0$. Start an injective resolution and let Q be the cokernel of its first two injective terms, so that $0 \to M \to I^0 \to I^1 \to Q \to 0$ is exact. Dimension shifting gives $\operatorname{Ext}^1_{\Lambda}(\Lambda/J, Q) = 0$ for every J. Baer's criterion makes Q injective. □

These are resolutions of modules over Λ. They do not supply the required injectives or projectives in an arithmetic comodule or contramodule category. In particular, the residue field is not an injective Λ-module: the same Koszul complex gives $\operatorname{Ext}^1_{\Lambda}(\mathbb{F}_p, \mathbb{F}_p) \cong \mathbb{F}_p^2$.

Proposition 46.3.5 *(derived reduction and its torsion).* Put $B = \Lambda/p = \mathbb{F}_p[[T]]$. For every Λ-module M,

$$M \otimes^{\mathbb{L}}_{\Lambda} B \simeq [\, M \xrightarrow{p} M \,], \qquad \operatorname{Tor}_1^{\Lambda}(M, B) = M[p],$$

where the displayed complex lies in degrees -1, 0, and $M[p] = \ker(p : M \to M)$. Higher Tor groups vanish. Reduction of a projective resolution therefore resolves the ordinary module M/pM exactly when $M[p] = 0$. The corresponding statements for $\Lambda/(T)$ use the map T and its kernel $M[T]$.

Proof. Tensor the free resolution $0 \to \Lambda \xrightarrow{p} \Lambda \to B \to 0$ with M. Its homology gives the assertion. Multiplication by T is also injective on Λ, so the same argument applies to $\Lambda/(T)$. □

For $M = \Lambda/(p, T)$, one has $\mu(M) = 0$ and $M[p] = M \neq 0$. Thus the positive-degree Tor term survives. For $N = \Lambda/(T)$, one has $\mu(N) = 0$ and

$$\operatorname{Tor}_1^{\Lambda}(N, N) = N \neq 0.$$

This second module is free over $\mathbb{Z}_p$ but is not flat over Λ. Neither $\mu = 0$ nor $\mathbb{Z}_p$-freeness can replace the required Tor calculation.

Co-Derived and Contra-Derived Λ-Categories

Let C be a specified dg Λ-coalgebra. Fix exact structures on its dg comodules and dg contramodules, including the admissible exact triples. For example, one may use triples split as graded Λ-modules. This gives a relative exact structure. An abelian or continuous version requires its own hypotheses.

Assume the chosen comodule category has admissible arbitrary sums and the contramodule category has admissible arbitrary products. Write Hot for the homotopy category of these dg objects.

Definition 46.3.6 *(Λ-coderived recipient).* Let $\mathrm{Ac}^{\mathrm{co}}_{\Lambda}(C)$ be the smallest thick triangulated subcategory of $\mathrm{Hot}(C\text{-comod}_{\Lambda})$ containing the totalizations of admissible exact triples and closed under arbitrary sums. Define

$$\mathrm{D}^{\mathrm{co}}_{\Lambda}(C\text{-comod}) = \mathrm{Hot}(C\text{-comod}_{\Lambda})/\mathrm{Ac}^{\mathrm{co}}_{\Lambda}(C).$$

The chosen exact structure is part of this notation.

Definition 46.3.7 *(Λ-contraderived recipient).* Let $\mathrm{Ac}^{\mathrm{ctr}}_{\Lambda}(C)$ be the smallest thick triangulated subcategory of $\mathrm{Hot}(C\text{-contra}_{\Lambda})$ containing the totalizations of admissible exact triples and closed under arbitrary products. Define

$$\mathrm{D}^{\mathrm{ctr}}_{\Lambda}(C\text{-contra}) = \mathrm{Hot}(C\text{-contra}_{\Lambda})/\mathrm{Ac}^{\mathrm{ctr}}_{\Lambda}(C).$$

A description by continuous $C^{\vee}$-contramodules requires an identification with this specified recipient.

Remark 46.3.8 *(comparison with Selmer complexes).* A Selmer complex is an object of an ordinary derived category with specified local-condition maps. Chapter 10 constructs such complexes and their coefficient comparisons. A realization in the recipients above must preserve those maps and specify which acyclic objects are annihilated. The distinction between acyclic and coacyclic objects already occurs for coalgebras over a field. Coefficient linear algebra does not remove it.

Question 46.3.9 *(enhancements and compact objects).* For the intended arithmetic coalgebra and exact structures, construct the stable enhancements of these recipients. Determine the complete subcategories on which the co–contra functors exist and the compact objects, if the relevant coproducts exist.

Compactness cannot mean concentration in degree zero. Compact objects in a stable category are closed under shifts. For example, $\Lambda[1]$ is compact in $\mathrm{D}(\Lambda)$ and is not a module concentrated in degree zero. The module resolution bounds do not resolve Question 46.3.9.

Iwasawa μ-Invariant and Ferrero–Washington

THEOREM 46.3.10 *(Ferrero–Washington 1979, Ann. Math. 109).* Let K be an abelian number field, let K_{∞}/K be its cyclotomic $\mathbb{Z}_p$-extension, and let K_n be its finite layers. With norm transition maps, put

$$X_K = \varprojlim_{n} \mathrm{Cl}(K_n)_p.$$

Identify $\mathrm{Gal}(K_{\infty}/K)$ with the chosen Γ. Then X_K is a finitely generated torsion Λ-module and $\mu(X_K) = 0$.

Remark 46.3.11 *(applicability to Heisenberg bar).* An application to an arithmetic Heisenberg bar must first specify its finitely generated torsion coefficient module M and its continuous Γ-action. It must then identify the relevant localization with that of a module in Theorem 46.3.10. Commuting creation operators and a trivial action on an oscillator lattice supply no such identification. The full Heisenberg Lie algebra itself has a nonzero central commutator.

Section 46.2 proves vanishing for finite free $\mathbb{Z}_p$-modules with trivial Γ-action directly. The next statement gives a different, conditional arithmetic route. Neither route supplies a conilpotence criterion.

Corollary 46.3.12 *(transport of arithmetic μ-vanishing).* Let M be a finitely generated torsion Λ-module selected from a specified arithmetic bar construction. Suppose M admits a pseudo-isomorphism to $X_K^{\oplus d}$, where K is abelian and X_K is as in Theorem 46.3.10. Then $\mu(M) = 0$.

Proof. The finite kernel and cokernel have support at (p, T). They vanish after localization at (p), giving

$$M_{(p)} \cong (X_K)_{(p)}^{\oplus d} = 0.$$

The last equality is Theorem 46.3.10. Taking length proves the assertion. The pseudo-isomorphism is an input, not a consequence of the name of the bar construction. □

46.4 Constructing and Detecting the Comparison

The Functors and Their Comparison Maps

The algebraic functors can be written before choosing a completed recipient. Their descent to a derived category, compatibility with reduction, and equivalence are separate assertions. We first give the functors, then prove the completion criterion. The algebraic bar–cobar adjunction and compatible quotient towers provide two further comparisons.

Step 1: The Algebraic Functors

Use the algebraic tensor product over Λ in this subsection. Let C be a dg coalgebra and use its left and right regular coactions. The contramodule and contratensor definitions above extend by replacing k with Λ. A continuous version requires its own Hom and tensor objects.

Definition 46.4.1 *(the colinear Hom functor).* For a dg left comodule M, put

$$\Psi_C(M) = \mathrm{Hom}_C(C, M) \subset \mathrm{Hom}_\Lambda(C, M), \qquad \mathrm{Hom}_\Lambda(C, M)^n = \prod_i \mathrm{Hom}_\Lambda(C^i, M^{i+n}).$$

The differential is $d(f) = d_M f - (-1)^{|f|} f\, d_C$. The right coaction on C induces the left contraaction on this colinear Hom complex. On morphisms, Ψ_C acts by postcomposition.

Definition 46.4.2 *(the contratensor functor).* For a dg left contramodule P, put

$$\Phi_C(P) = C \odot_C P = \mathrm{coker}\big(C \otimes_\Lambda \mathrm{Hom}_\Lambda(C, P) \rightrightarrows C \otimes_\Lambda P\big).$$

The two arrows are the contraaction and the right coaction followed by signed evaluation. The differential and the left coaction descend from $C \otimes_\Lambda P$.

Tensor–Hom adjunction identifies maps from this cokernel to M with contramodule maps from P to $\mathrm{Hom}_C(C, M)$. Thus $\Phi_C \dashv \Psi_C$ on the algebraic dg categories. Completion is not part of this calculation.

Lemma 46.4.3 *(descent through chosen resolution models).* Suppose full triangulated resolution subcategories $\mathcal{J} \subset \mathrm{Hot}(C\text{-comod}_\Lambda)$ and $\mathcal{P} \subset \mathrm{Hot}(C\text{-contra}_\Lambda)$ map equivalently to the chosen coderived and contraderived recipients. If $\Psi_C(\mathcal{J}) \subset \mathcal{P}$ and $\Phi_C(\mathcal{P}) \subset \mathcal{J}$, the restricted adjunction transports to those recipients.

Proof. Compose each restricted functor with the two specified resolution equivalences and their inverses. The Hom adjunction transports along the same equivalences, as do its unit, counit and triangle identities. □

Over a field, Theorem 46.1.1 supplies these resolution models and their equivalence. Over Λ, the models and their preservation must be constructed. Injectivity over Λ alone does not prove the lemma's hypotheses.

The contratensor quotient matters already in dimension two. Over a field, let $C = k\mathbf{1} \oplus kc$, with $\Delta c = \mathbf{1} \otimes c + c \otimes \mathbf{1}$. The colinear endomorphisms of C have basis

$$f_0 = \mathrm{id}_C, \qquad f_1(\mathbf{1}) = 0, \quad f_1(c) = \mathbf{1}.$$

Evaluation $C \otimes \mathrm{Hom}_C(C, C) \to C$ is surjective and has kernel

$$k(\mathbf{1} \otimes f_1) \oplus k(c \otimes f_1 - \mathbf{1} \otimes f_0).$$

These are precisely the contratensor relations, so the quotient is C. Omitting the quotient leaves a four-dimensional space in place of a two-dimensional one.

Step 2: Coefficient Change

LEMMA 46.4.4 *(two coefficient comparisons).* Let $R \to S$ be a map of commutative rings.

(i) If C is a coaugmented conilpotent dg R-coalgebra, then the algebraic scalar extension $C \otimes_R S$ is a coaugmented conilpotent dg S-coalgebra.

(ii) If E is a perfect complex of R-modules, then for every $M \in \mathrm{D}(R)$, the natural map

$$\mathrm{RHom}_R(E, M) \otimes^{\mathbb{L}}_R S \longrightarrow \mathrm{RHom}_S(E \otimes^{\mathbb{L}}_R S, M \otimes^{\mathbb{L}}_R S)$$

is an equivalence.

Proof. The coaugmentation splitting commutes with algebraic scalar extension. Each element of its reduced part is a finite sum of tensors $c_i \otimes s_i$. A common bound on the vanishing of the iterated reduced coproducts of the finitely many c_i proves conilpotence. No flatness of S is needed for this algebraic assertion.

For the second assertion, represent E by a bounded complex of finite projective modules. Its Hom complex is $E^\vee \otimes_R M$, and $E^\vee \otimes_R S \cong (E \otimes_R S)^\vee$. These identities give the stated derived map and its inverse. □

The second assertion concerns coefficient Hom. The functor Ψ_C also imposes colinearity, and a continuous version may involve an inverse limit. Indeed, $\mathrm{Hom}_\Lambda(\varinjlim C_i, M) = \varprojlim \mathrm{Hom}_\Lambda(C_i, M)$. Commutation of this limit, its derived functors and coefficient change requires an additional proof.

For $B = \Lambda/p$, a proposed comparison has the form

$$\begin{array}{ccc} C & \xrightarrow{\Psi} & \mathcal{D} \\ {\scriptstyle R_C}\downarrow & & \downarrow{\scriptstyle R_{\mathcal{D}}} \\ \overline{C} & \xrightarrow[\overline{\Psi}]{} & \overline{\mathcal{D}}. \end{array}$$

Here the barred recipients and the reduction functors must be defined. A natural equivalence making this square commute is part of the comparison. The corresponding square for Φ must also identify the units and counits. An equivalence over B, when supplied, is not the field-coefficient theorem: B is not a field.

Step 3: Detection by Derived Completion

Proposition 46.4.5 *(complete objects and reduction).* In a stable Λ-linear ∞-category with sequential limits, a derived p-complete object X is zero if $X/p = 0$. Consequently, a map whose cofiber is derived p-complete is an equivalence if its reduction modulo p is.

Proof. The factorization $p^n = p\, p^{n-1}$ gives a cofiber sequence

$$X/p^{n-1} \longrightarrow X/p^n \longrightarrow X/p.$$

Induction gives $X/p^n = 0$ for every n. Derived completeness then gives $X \simeq \varprojlim_n X/p^n = 0$. Apply this result to the cofiber of the given map. □

This proves conservativity on the stated complete objects. Faithfulness on morphisms fails. Take $M = \Lambda/(T) \cong \mathbb{Z}_p$. It is derived p-complete and has $\mu(M) = 0$, yet

$$p\,\mathrm{id}_M \neq 0, \qquad (p\,\mathrm{id}_M) \otimes^{\mathbb{L}}_{\Lambda} B = 0.$$

The two-term free resolution with differential T verifies the second equality directly after reduction.

Lifts are not unique either. The modules $\Lambda/(T)$ and $\Lambda/(T-p)$ are $\mathbb{Z}_p$-free, derived p-complete, and have $\mu = 0$. Their reductions are both $B/(T)$. They are not isomorphic over Λ: T acts as zero on the first and as multiplication by p on the second. Even the first lift has the nonidentity automorphism $(1+p)\mathrm{id}$ reducing to the identity.

Corollary 46.4.6 *(lifting a specified adjunction).* Consider an exact adjunction as in Theorem 46.1.5. Assume its unit and counit cofibers are derived p-complete and its reduced unit and counit are equivalences. Then the adjunction is an equivalence.

Proof. Proposition 46.4.5 makes the unit and counit equivalences. The triangle identities identify the two adjoint functors as inverses. □

An arithmetic application must verify these conditions in its specified recipients. Applying ordinary reduction to underlying complexes does not suffice unless that comparison is itself conservative on the relevant cofibers.

Step 4: The Algebraic Bar–Cobar Adjunction

Let A be an augmented dg Λ-algebra and C a coaugmented conilpotent dg Λ-coalgebra. Write $\overline{A} = \ker \epsilon_A$ and $\overline{C} = \ker \epsilon_C$, and use cohomological shifts $V[1]^i = V^{i+1}$. A twisting cochain is a degree-one map $\tau : \overline{C} \to \overline{A}$ satisfying

$$d_A\tau + \tau d_C + \mu_A(\tau \otimes \tau)\overline{\Delta}_C = 0.$$

The tensor of homogeneous maps includes its Koszul sign.

Theorem 46.4.7 *(algebraic Λ-bar–cobar adjunction).* With algebraic tensors and direct sums, the constructions

$$B^{\Lambda}A = \bigoplus_{n\geq 0} (\overline{A}[1])^{\otimes_{\Lambda} n}, \qquad \Omega^{\Lambda}C = \bigoplus_{n\geq 0} (\overline{C}[-1])^{\otimes_{\Lambda} n}$$

carry their bar and cobar differentials and satisfy

$$\mathrm{Hom}_{\mathrm{dgAlg}^{\mathrm{aug}}_{\Lambda}}(\Omega^{\Lambda}C, A) \cong \mathrm{Tw}_{\Lambda}(C, A) \cong \mathrm{Hom}_{\mathrm{dgCoalg}^{\mathrm{conil}}_{\Lambda}}(C, B^{\Lambda}A).$$

Thus $\Omega^{\Lambda} \dashv B^{\Lambda}$ on these algebraic dg categories.

Proof. An algebra map from the tensor algebra $\Omega^{\Lambda}C$ is determined by its restriction to $\overline{C}[-1]$. It commutes with differentials exactly when the corresponding τ satisfies the displayed twisting equation.

A coalgebra map to the tensor coalgebra $B^{\Lambda}A$ is determined by projection to $\overline{A}[1]$. Its length-n component applies that projection to the n-fold reduced coproduct. Conilpotence makes the resulting sum finite on each element. The chain-map condition is the same twisting equation. These two constructions are inverse and natural. □

No completion or derived equivalence is asserted by this algebraic adjunction. A completed version must justify the convergence of its sums and the weak equivalences it preserves. It is also distinct from the module adjunction $\Phi_C \dashv \Psi_C$.

Step 5: Unit and Counit

THEOREM 46.4.8 *(a complete criterion for unit and counit).* For the algebraic adjunction, the natural maps have types

$$\eta_C : C \longrightarrow B^{\Lambda}\Omega^{\Lambda}C, \qquad \varepsilon_A : \Omega^{\Lambda}B^{\Lambda}A \longrightarrow A.$$

Suppose the cone of either map, viewed in $\mathrm{D}(\Lambda)$, is derived p-complete, and that its derived reduction modulo p is a quasi-isomorphism. Then that map is a quasi-isomorphism over Λ.

Proof. Apply Proposition 46.4.5 in $\mathrm{D}(\Lambda)$ to the specified cone. The maps exist by the algebraic adjunction. Their completeness and reduction hypotheses must be checked for the chosen A and C. □

The coalgebra unit uses iterated *reduced* coproducts. The full coproduct of a primitive element retains terms with $\mathbf{1}$ in every arity, so conilpotence cannot truncate that full coproduct. Nor does an equivalence in a chosen coderived localization assert an ordinary quasi-isomorphism without a comparison of the two notions.

Step 6: Compatible Quotient Towers

LEMMA 46.4.9 *(limits of compatible equivalences).* Let $(\mathcal{C}_n)$ and $(\mathcal{D}_n)$ be inverse diagrams of stable categories. A compatible equivalence of diagrams $\Psi_n : \mathcal{C}_n \simeq \mathcal{D}_n$ induces

$$\varprojlim_n \mathcal{C}_n \simeq \varprojlim_n \mathcal{D}_n.$$

Restriction along a coinitial indexing functor preserves these limits. In particular, cofinal systems of open ideals give the same limit for a fixed diagram on those ideals.

Proof. The limit functor preserves equivalences of diagrams. Its universal property also gives invariance under coinitial restriction. For two systems of open ideals I_n, J_m, the quotients by $I_n \cap J_m$ give a common refinement with maps to the original quotients. □

The lemma requires the diagram and its compatibility maps. Separate equivalences at individual quotients do not supply a compatible equivalence of diagrams. Identifying an arithmetic recipient with this inverse limit is another hypothesis. The lemma gives no uniqueness for arbitrary lifts of a residual object.

The Comparison Criterion

Proof of Theorem 46.1.5. Let $K_P = \operatorname{cofib}(\eta_P)$ in $\mathcal{D}$ and $L_M = \operatorname{cofib}(\varepsilon_M)$ in C. They are derived p-complete by hypothesis. Their reductions vanish because the reduced unit and counit are equivalences. Proposition 46.4.5 gives $K_P = L_M = 0$. Thus both natural transformations are equivalences, and the adjunction exhibits Φ and Ψ as inverse functors. □

Remark 46.4.10 *(the dual arithmetic module).* A Selmer μ-invariant requires a specified finitely generated torsion Iwasawa module. Comparing it with the invariant on another coefficient object requires an arithmetic duality map and control of its kernel and cokernel. A pseudo-isomorphism of the relevant modules would identify their height-one localizations and hence their μ-invariants. Formal vector-space duality alone gives no such arithmetic pseudo-isomorphism.

46.5 Application: Pairings and Arithmetic Levels

The Required Arithmetic Comparison

For Theorem 43.5.1 to apply to arithmetic duality, the following assignments must be constructed:

- the arithmetic level $\kappa_{\mathsf{G}}^{\mathrm{Ar}}$ as a central invariant of a specified bar object.
- the dual level $(\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}}$ as a central invariant of its specified dual object.
- an involution and Mellin evaluation carrying their common central defect to the difference of the two completed characters.

The converse also requires that evaluation to detect the defect. A cobar algebra and a continuous dual algebra have different constructions. A comparison with a Bost–Connes algebra must specify which is used. The local weight calculation below proves evaluation compatibility for its oscillator model. It supplies none of these arithmetic identifications.

The Explicit Weight Computation

Theorem 46.5.1 *(evaluation pairing and arithmetic energy).* For a finite set S of arithmetic primes let $P_S = \mathbb{Z}[x_{p,k} : p \in S, k \geq 1]$, with oscillator weight k and energy $k \log p$ on $x_{p,k}$. Each weight component $P_{S,w}$ is finite free. Its restricted dual

$$P_S^{\circ} = \bigoplus_{w \geq 0} \operatorname{Hom}_{\mathbb{Z}}(P_{S,w}, \mathbb{Z})$$

has a perfect evaluation pairing in each weight. Give the dual of a monomial energy equal to the negative of that monomial's energy. Then evaluation has total energy zero.

If an arithmetic bar–cobar pairing and comparison maps identify these particular weight components and their pairings with $P_{S,w}$ and its restricted dual, the same energy cancellation holds on their images. An identification of a dual generator with μ_{p^k}, and an identification of this energy cancellation with $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0$, are separate comparison hypotheses.

Proof. There are finitely many monomials of a given oscillator weight because S is finite. Write x^{ν} for their monomial basis and η_{ν} for the dual basis. Evaluation is $\eta_{\mu}(x^{\nu}) = \delta_{\mu\nu}$, hence perfect in every weight. Its only nonzero basis pairings have energies $E(\nu)$ and $-E(\nu)$, whose sum is zero. Transport through the specified pairing-preserving maps proves the conditional assertion. No arithmetic map is constructed by this transport calculation.

The distinction from a polynomial generator algebra can already be seen in one variable: dualizing the primitive coproduct of $\mathbb{Z}[x]$ gives $\eta_a\eta_b = \binom{a+b}{a}\eta_{a+b}$, so $\eta_1^k = k!\eta_k$. This follows by evaluating on $\Delta x^{a+b} = \sum_j \binom{a+b}{j} x^j \otimes x^{a+b-j}$. It is not the relation $\mu_{p^k} = \mu_p^k$ with the same integral basis. A different normalization or cobar differential requires its own construction. □

Global Euler-Product Check

PROPOSITION 46.5.2 *(global weight sum).* The formal cancellation of opposite energy labels over prime-power indices is

$$\sum_{p\ \text{prime}} \sum_{n\geq 1} \left[n \log p \cdot p^{-ns} + (-n \log p) \cdot p^{-ns} \right] = 0,$$

convergent absolutely for $\mathrm{Re}(s) > 1$. After termwise pairing it is the zero function, hence extends as zero. No meromorphic continuation of the unpaired prime-indexed sum is asserted.

Proof. Term-by-term: at each prime p and each $n \geq 1$, the two weights $n \log p$ and $-n \log p$ sum to zero. For $\sigma = \mathrm{Re}\, s > 1$, the unpaired absolute sum is

$$\sum_p (\log p) \frac{p^{-\sigma}}{(1-p^{-\sigma})^2} \leq (1-2^{-\sigma})^{-2} \sum_{m\geq 2} (\log m) m^{-\sigma} < \infty.$$

Thus pairing terms is justified in that half-plane, and their sum is zero. This scalar identity supplies no arithmetic pairing or level map. The identity $-\zeta'(s)/\zeta(s) = \sum_{p,k\geq 1} (\log p)\, p^{-ks}$ is a prime-power identity, not an identity for the prime-indexed sum alone. □

Remark 46.5.3 *(pairing and level comparison).* The local evaluation theorem proves energy cancellation. To use it in Theorem 43.5.1, one must construct the arithmetic pairing, the central-defect identity, and the Mellin evaluation, including its detection of the defect. Opposite energy labels alone do not identify these central classes. The five conditions of Remark 46.1.6 must be realized with those compatibility maps; a named categorical equivalence alone does not identify its numerical invariants.

The Arithmetic Comparison Required for P1

Question 46.5.4 *(level cancellation and the functional equation).* Construct the arithmetic pairing, its integral and completed coefficient models, and the comparison of its central obstruction classes with the Tate functional equation. The intended conclusion remains

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s).$$

The scalar functional equation is a theorem. The oscillator energy calculation does not prove either identification of the arithmetic classes with its two sides.

Remark 46.5.5 *(dependencies of the arithmetic comparison).* The pairing and invariant comparisons are required whenever Remark 43.5.2 and Question 33.6.1 and Theorem 44.6.1 invoke the arithmetic Positselski input. The continuous-dual, completion, lifting, character and Bost–Connes requirements remain distinct. Neither the formal sum of opposite energies nor the scalar zeta identity removes these maps.

46.6 Fourier Pairings and Adelic Assembly

The Archimedean Fourier Model

The real local factor enters the scalar functional equation through the Gaussian. Fix the Fourier convention

$$\widehat{f}(y) = \int_{\mathbb{R}} f(x) e^{-2\pi i x y}\, dx.$$

This integral uses real analysis and a specified measure. A comparison with an algebraic pairing must preserve that normalization.

Theorem 46.6.1 *(Gaussian Fourier identity).* For $t > 0$ and $f_t(x) = e^{-\pi t x^2}$,

$$\widehat{f_t}(y) = t^{-1/2} e^{-\pi y^2/t}.$$

Proof. For $t = 1$, differentiate under the integral and integrate by parts. The Gaussian decay eliminates the boundary term and gives $\widehat{f_1}'(y) = -2\pi y \widehat{f_1}(y)$. The value at zero is one: the square of the positive Gaussian integral is $2\pi \int_0^\infty r e^{-\pi r^2}\, dr = 1$. Solving the differential equation gives the formula at $t = 1$. The substitution $u = \sqrt{t}\, x$ proves the general case. □

Poisson summation gives $\theta(t) = t^{-1/2}\theta(1/t)$ for $\theta(t) = \sum_{m\in\mathbb{Z}} e^{-\pi m^2 t}$. The theta series counts a lattice quadratic form. The oscillator Fock space $\mathbb{C}[\alpha_{-1}, \alpha_{-2}, \ldots]|0\rangle$, with weight n on α_{-n}, has character $\prod_{n\geq 1}(1 - q^n)^{-1}$. The two series already differ at the coefficient of q: $\sum_{m\in\mathbb{Z}} q^{m^2}$ has coefficient two, whereas the oscillator character has coefficient one.

To compare the Fourier identity with co–contra duality, specify an archimedean coalgebra and a pairing-preserving map. Theorem 46.1.1 applies to an actual dg coalgebra over $\mathbb{C}$. It does not turn a Fock module, a theta series or a Fourier transform into that coalgebra or its categorical pairing.

Adelic Assembly

Fix a commutative coefficient ring R. For each place v, let $\mathcal{C}_v$, $\mathcal{D}_v$ be presentable stable R-linear categories, with chosen objects c_v, d_v. Use the tensor product of such categories characterized by R-bilinear functors preserving colimits in each variable.

For a finite place set F, put

$$\mathcal{C}_F = \bigotimes_{v\in F, R} \mathcal{C}_v, \qquad \mathcal{D}_F = \bigotimes_{v\in F, R} \mathcal{D}_v.$$

The empty tensor is Mod_R. Insertion of c_v, respectively d_v, defines the transition functors when a new place is added. Define the corresponding restricted tensor categories as colimits over these finite place sets.

Theorem 46.6.2 *(assembly of pointed local equivalences).* Suppose R-linear equivalences $\Upsilon_v : \mathcal{C}_v \simeq \mathcal{D}_v$ and identifications $\Upsilon_v(c_v) \simeq d_v$ give a compatible equivalence of the finite tensor diagrams. Then

$$\varinjlim_F \mathcal{C}_F \xrightarrow{\sim} \varinjlim_F \mathcal{D}_F.$$

Proof. Tensoring finitely many equivalences gives an equivalence $\mathcal{C}_F \simeq \mathcal{D}_F$. The pointing identifications and their assumed coherence make these maps an equivalence of diagrams. Taking the colimit preserves that equivalence. □

For arithmetic local categories, the common coefficient action, tensor recipient, local equivalences and compatible pointings must be constructed. The symbols $\mathbb{Q}_p$ and $\mathbb{C}$ do not provide a common field by themselves. The chosen objects also need not be scalar augmentations or vacua of an independently specified field theory. Identifying this categorical colimit with an analytic adelic restricted tensor product is a further comparison.

Remark 46.6.3 *(the adelic pairing and the functional equation).* The theta–Mellin calculation of Theorem 35.6.1 retains its polar terms and proves the scalar functional equation. To interpret it through an adelic bar pairing, construct an evaluation identifying the duality involution with Mellin reflection. The forward implication also requires the central-defect identity. The converse requires that evaluation to detect the specified defect, as in Theorem 43.5.1.

An adelic co–contra equivalence is a separate categorical comparison. Identifying its pairing with Fourier self-duality requires the actual coefficient and pairing maps. The scalar theta calculation does not construct them.

46.7 Residual Conditions

The integral lifting criterion and the local assembly theorem apply only after their functors, recipients and comparison maps have been supplied. The following questions ask for further arithmetic structures. The commutative comparison remains subject to the preceding hypotheses.

Non-Abelian Iwahori Level

For a compact p-adic group G, write $A = \mathbb{Z}_p[[G]]$. An A-coring is an A-bimodule C with counit $C \to A$ and a coassociative coproduct $C \to C \otimes_A C$. A continuous version replaces the tensor by a specified completed tensor and requires continuous structure maps.

Question 46.7.1 *(noncommutative arithmetic co–contra comparison).* For an arithmetic coring over A, construct exact comodule and contramodule recipients and an adjunction between them. Determine a coefficient and completion domain on which its unit and counit are equivalences. For $G = GL_2(\mathbb{Z}_p)$, construct the required comparison with the intended Iwahori Hecke category and its actions. If a noncommutative μ-invariant is used, specify its module and prove the precise role of its vanishing.

Remark 46.7.2 *(module structure and categorical comparison).* A noncommutative module structure theorem has its own hypotheses on the group, ring and torsion class. It does not by itself compare comodule and contramodule resolutions. Such a comparison needs the actual tensor and Hom functors, with the correct module sides. Even over the commutative ring Λ, Proposition 46.3.5 shows why $\mu = 0$ cannot replace the necessary Tor conditions.

Whittaker Model Compatibility

A Whittaker condition requires a specified unipotent group N, a character ψ, and an action on the recipient. It also requires a choice of equivariant or derived coinvariant construction. The coefficient ring must support that character.

Question 46.7.3 *(Whittaker-compatible co–contra comparison).* Construct an arithmetic co–contra comparison equipped with compatible (N, ψ)-actions and the required Hecke actions. Show that it induces an equivalence between the resulting Whittaker recipients,

$$\mathcal{C}^{N,\psi} \simeq \mathcal{D}^{N,\psi},$$

and construct its comparison with the chosen Satake and Whittaker functors. A scalar character identity alone does not define these equivariant functors.

Extension to Higher Rank

Replacing $\Gamma \cong \mathbb{Z}_p$ by $\mathbb{Z}_p^d$ changes the coefficient ring to $\Lambda_d = \mathbb{Z}_p[[T_1, \dots, T_d]]$. The co–contra comparison then needs categories and resolution hypotheses over this ring. An arithmetic vanishing theorem also requires a specified module attached to the chosen tower. The cyclotomic theorem does not supply that module or an induction in d.

Remark 46.7.4 *(higher-rank extension).* For a finitely generated torsion Λ_d-module, the length of its localization at (p) gives a corresponding height-one invariant. The module $\Lambda_d/(p)$ has length one there, although Γ is abelian. Thus abelianity alone does not force this invariant to vanish. Determining its value for an arithmetic tower and comparing that module with a bar coefficient are separate problems.

46.8 Positselski Boundary

(i) Theorem 46.1.5 gives a lifting criterion for a specified adjunction. Its unit and counit cofibers must be derived p-complete, and their reductions must vanish. The integral arithmetic categories and functors remain additional constructions. The field correspondence does not establish them by scalar extension or faithful reduction.

(ii) The comparisons of Section 46.2 have separate hypotheses. In particular, the weight calculation needs arithmetic pairing and invariant maps even in the abelian case. The nonabelian Iwahori extension is a further problem (Section 46.7).

(iii) The hypothesis $\mu(C) = 0$ concerns the specified torsion coefficient module. Section 46.2 proves a local lattice calculation. Corollary 46.3.12 gives an arithmetic consequence under an actual module comparison. Neither statement identifies an unspecified Heisenberg bar with a cyclotomic class-group module or characterizes conilpotence.

(iv) Theorem 46.5.1 constructs the restricted integral dual and its energy-zero evaluation pairing on finite-species polynomial components. Identifying this pairing with arithmetic bar–cobar data and its energies with central obstruction classes is additional work.

(v) The intended P1 comparison remains Question 46.5.4. Its operator and invariant maps are not consequences of the scalar functional equation.

(vi) Adelic extension retains the local categorical hypotheses and their compatible pointings. Its interpretation through the functional equation additionally requires the evaluation and central-defect maps of Remark 46.6.3. Gaussian Fourier self-duality and the scalar theta calculation provide analytic models, not those arithmetic identifications.

(vii) Residual condition (Section 46.7): non-commutative arithmetic Positselski for non-abelian Iwahori level (Question 46.7.1), Whittaker compatibility (Question 46.7.3) and higher-rank Iwasawa coefficients (Remark 46.7.4).

The intended arithmetic comparison relates central obstruction classes to the classical functional equation. The local constructions above do not identify those classes with the explicitly computed scalar pairing. The continuous-dual, completion, lifting, character and Bost–Connes requirements must therefore be supplied as actual compatible maps on the intended carrier. The arithmetic Positselski input on the sufficient path of Theorem 44.6.1 includes that comparison; it is not discharged by the equality of opposite energy labels.

Chapter 47

Koszul–Petersson Pairing Compatibility

An arithmetic Koszul pairing can be compared with a Petersson form only after their domains have been related. The notation $\mathcal{V}^{\mathrm{prim}}$ denotes the Hochschild trace class of the identity on the proposed global arithmetic Iwahori–Hecke category of GL_2. A state realization of this class, its dual coefficient space, and its automorphic placement are additional constructions. Chapter 43 proves positivity conditional on those maps and the pairing identity.

The Segal and prime Hilbert models provide explicit positive forms. An identification with the arithmetic bar–cobar pairing requires the injective placement, local pairing maps and completed adelic extension of Hypothesis 67.1.1. Every arithmetic Koszul–Petersson comparison in this chapter retains these hypotheses. The prime cyclic GNS construction gives an actual local map; it does not supply the arithmetic isometry.

47.1 Statement Recalled

Setup

Write $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis}}$ for the chosen local tensor model

$$\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis}} \;=\; \mathcal{H}^{(\infty)} \;\otimes\; \bigotimes_{p}{}' \mathcal{H}^{(p)}, \tag{47.1}$$

with archimedean Heisenberg Fock space $\mathcal{H}^{(\infty)} = \mathbb{C}[\alpha_{-1}, \alpha_{-2}, \dots] \cdot |0\rangle_\infty$ and finite-place factors $\mathcal{H}^{(p)} = C_c(GL_2(\mathbb{Z}_p)\backslash GL_2(\mathbb{Q}_p)/GL_2(\mathbb{Z}_p))$ under convolution. Normalize Haar measure by $\mathrm{vol}(GL_2(\mathbb{Z}_p)) = 1$, and use $|0\rangle_p = \mathbf{1}_{GL_2(\mathbb{Z}_p)}$ as reference vector. The form $\int f(g)\overline{h(g)}\,dg$ is positive on this space and gives the reference vector norm one. The restricted tensor product uses these vectors, so its product form is positive by the finite-tensor argument of Chapter 43.

Any additional operators ψ_p must be specified on their actual local carriers. Pointed E_0-data in Definition 26.5.1 do not determine Hecke operations or a Bost–Connes representation. Equation (47.1) defines a tensor model. Its identification with a state realization of the arithmetic Hochschild class remains part of the comparison hypothesis.

An additional arithmetic dg algebra comparison would identify the Koszul-dual carrier with the Bost–Connes Q-lattice system

$$\big(\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis}}\big)^{!} \;=\; \mathbb{A}^{\mathrm{BC}}$$

as asked in Question 33.5.2. The Bost–Connes presentation alone does not provide that comparison.

Let τ^{BC} be the algebraic Bost–Connes anti-involution,

$$\tau^{\mathrm{BC}}(\mu_n) = \mu_n^*, \qquad \tau^{\mathrm{BC}}(e(\gamma)) = e(-\gamma),$$

the $*$-operation of the Bost–Connes C^*-algebra (Bost–Connes §1.2). On the prime cyclic GNS space at $\beta = 1$, for $m = p^k$, the modular lift satisfies

$$J\pi(\mu_m)\Omega = m^{1/2}\pi(\mu_m^*)\Omega.$$

This is Proposition 67.2.4 on its Hilbert–Schmidt carrier. In arithmetic pairing formulae, σ_p^{BC} denotes the separately specified antilinear map compatible with that model under the comparison hypothesis. An action on additional phase generators requires the chosen full state and its representation.

The Two Pairings

Under the specified arithmetic carrier and dual-coefficient comparisons, the Koszul evaluation takes the bilinear form

$$\langle \cdot, \cdot \rangle^{\mathrm{Koszul}} \colon \mathcal{V}_{\mathrm{Heis}}^{\mathrm{prim}} \otimes \mathbb{A}^{\mathrm{BC}} \longrightarrow \mathbb{C}$$

obtained by transporting the chosen bar–cobar evaluation. An adjunction $\Omega^{\mathrm{Ar}} \dashv B^{\mathrm{Ar}}$ alone does not identify its evaluation target with $\mathbb{C}$ or its dual coefficient space with $\mathbb{A}^{\mathrm{BC}}$. Those maps belong to the hypotheses. A self-pairing further requires a map from the conjugate state space to that dual coefficient space.

Let V denote the chosen state realization, with injective placement ι into $L^2([GL_2])$. The transported Petersson form is

$$\langle \cdot, \cdot \rangle^{\mathrm{Pet}} \colon V \otimes \overline{V} \longrightarrow \mathbb{C}, \quad \langle v, w \rangle^{\mathrm{Pet}} = \int_{[GL_2]} (\iota v)(\gamma)\overline{(\iota w)(\gamma)}\, d\gamma.$$

Here $d\gamma$ is the chosen Tamagawa measure on $Z(\mathbb{A})\, GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})/K_\infty$. An adelic Whittaker realization must be constructed and compared with the arithmetic carrier before it supplies such a placement.

The Identity

THEOREM 47.1.1 *(Koszul–Petersson compatibility, domain-restricted).* Assume the arithmetic placement, local pairing maps and completed adelic extension of Hypothesis 67.1.1 on the stated normalized core. *(domain-restricted to the normalized sph-fin cuspidal core; see Remark 47.1.2).* For all $v, w \in \mathcal{V}_{\text{sph-fin,cusp}}^{\mathrm{prim}}$,

$$\langle v, w \rangle^{\mathrm{Pet}} = \langle v, \sigma^{\mathrm{BC}}(w) \rangle^{\mathrm{Koszul}}.$$

Equivalently, the adelic Petersson pairing equals the Koszul pairing composed with $\mathrm{id} \otimes \sigma^{\mathrm{BC}}$ under the identification $(\mathcal{V}^{\mathrm{prim}})^! = \mathbb{A}^{\mathrm{BC}}$, on the normalized sph-fin cuspidal core.

Remark 47.1.2 *(domain restriction and open sub-items).* Theorem 47.1.1 is conditional on the arithmetic placement and pairing comparisons, including on the normalized sph-fin cuspidal core. The explicit constructions below give weighted occupation, prime Gibbs, spherical Whittaker and archimedean vacuum-line models. They do not identify the full arithmetic bar carrier with an automorphic representation. That identification, its compatibility with the local actions and conjugations, and its completed adelic extension are the remaining comparison maps in Hypothesis 67.1.1. Ramified factors and the Eisenstein continuous spectrum require their own carriers and comparison maps; the spherical calculation does not supply them.

47.2 Pairing Domains and Normalizations

The Koszul pairing is bilinear, while Petersson is conjugate-linear in its second variable. Composition with the specified antilinear map has the required sesquilinearity. The completed arithmetic carrier, its local actions and the Haar normalization must be preserved by the comparison maps. At almost every finite place they must preserve the selected reference vector, so their tensor products are defined on the restricted tensor domain.

The prime Gibbs state and its modular conjugation are constructed in Chapter 67. They are not an adelic Plancherel identification. Neither the existence of spherical vectors nor the equality of scalar Euler factors constructs the arithmetic pairing maps. The remaining comparison is Question 67.1.2.

47.3 Archimedean Identification

The Fock Inner Product

The archimedean factor $\mathcal{H}^{(\infty)} = \mathbb{C}[\alpha_{-1}, \alpha_{-2}, \ldots] \cdot |0\rangle_\infty$ is the Heisenberg vacuum Fock module. Its canonical Hermitian form is the *Segal inner product*: the unique positive-definite sesquilinear form $\langle \cdot\,, \cdot \rangle_{\mathrm{Segal}}$ on $\mathcal{H}^{(\infty)}$ satisfying

$$\alpha_{-n}^{\dagger} \;=\; \alpha_n, \qquad \langle |0\rangle_\infty, |0\rangle_\infty \rangle_{\mathrm{Segal}} \;=\; 1, \qquad \alpha_n |0\rangle_\infty \;=\; 0 \;\text{ for } n \geq 1,$$

together with the Heisenberg CCR $[\alpha_m, \alpha_n] = m\delta_{m+n,0}$ (Segal 1981 Commun. Math. Phys. 80; Frenkel–Ben-Zvi 2004 §3.5; Kac 1998 *Vertex Algebras for Beginners* §2.5 Prop. 2.2).

Proposition 47.3.1 *(Segal form on monomials).* For monomials $v_1 = \alpha_{-n_1} \cdots \alpha_{-n_k}|0\rangle_\infty$, $v_2 = \alpha_{-m_1} \cdots \alpha_{-m_l}|0\rangle_\infty$ with $n_1 \geq \cdots \geq n_k \geq 1$, $m_1 \geq \cdots \geq m_l \geq 1$,

$$\langle v_1, v_2 \rangle_{\mathrm{Segal}} \;=\; \delta_{k,l} \cdot \sum_{\sigma \in S_k} \prod_{i=1}^{k} n_i \, \delta_{n_i, m_{\sigma(i)}}.$$

Equivalently, Segal's form is the L^2-inner product of the Wick-normal-ordered fields.

Proof. Wick's theorem applied to a product of creation/annihilation operators equates $\langle v_1, v_2 \rangle_{\mathrm{Segal}} = \langle |0\rangle_\infty, \alpha_{n_1} \cdots \alpha_{n_k} \alpha_{-m_1} \cdots \alpha_{-m_l} |0\rangle_\infty \rangle$. Normal-ordering and using the CCR to collect the contractions gives exactly (47.3.1). See Kac 1998 §2.5 Prop. 2.2 or Frenkel–Ben-Zvi 2004 §3.5.4. □

Bilinear and Hermitian Fock Forms

On the algebraic Heisenberg Fock space, let J_∞ conjugate coefficients in the monomial basis. Define the bilinear form

$$B_\infty(v, w) = H_{\mathrm{Segal}}(v, J_\infty w).$$

Its Gram matrix on monomials is the real permutation sum of Proposition 47.3.1.

Proposition 47.3.2 *(The Fock conjugation identity).* The form extends continuously to the Segal Hilbert completion, and

$$B_\infty(v, J_\infty w) = H_{\mathrm{Segal}}(v, w). \tag{47.2}$$

Proof. The monomial Gram matrix is real, so coefficient conjugation is an isometric involution. Hence $|B_\infty(v, w)| \leq \|v\|\|w\|$, which gives the extension, and $J_\infty^2 = 1$ gives the identity. Identifying an arithmetic bar–cobar pairing with this form requires maps on its two actual carriers, preserving the pairing and its operator domains. □

COROLLARY 47.3.3 *(Archimedean conjugation type).* A bilinear arithmetic pairing identified with B_∞ becomes the Segal Hermitian form after the transported coefficient conjugation in its second slot. That conjugation is antilinear; it cannot be replaced by the complex-linear identity on all vectors.

Proof. Apply (47.2); replacing w by iw also directly distinguishes the two types. □

An Explicit Archimedean Whittaker Line

Fix the function $W_0(a) = |a|^{1/2} K_0(2\pi|a|)$ and the measure $da/|a|$ on $\mathbb{R}^\times$. This specifies a spherical Whittaker function in the spectral-parameter-zero model; a different spectral parameter has a different Bessel order. The Hermitian form is

$$H_{\mathrm{Whit},\infty}(W, W') = \int_{\mathbb{R}^\times} W(a)\overline{W'(a)}\frac{da}{|a|}.$$

LEMMA 47.3.4 *(The K_0 line norm).* For this precise coefficient normalization, $H_{\mathrm{Whit},\infty}(W_0, W_0) = \pi/4$.

Proof. The classical integral representation $K_0(x) = \int_0^\infty e^{-x\cosh u}\, du$, $x > 0$ (NIST DLMF (10.32.9)), and Tonelli give

$$\int_0^\infty K_0(x)^2\, dx = \int_0^\infty \int_0^\infty \frac{du\, dv}{\cosh u + \cosh v}.$$

Put $a = (u+v)/2$, $b = (u-v)/2$. The Jacobian is two, $a \geq 0$, $|b| \leq a$, and the denominator is $2\cosh a \cosh b$. If $F(a) = \int_0^a \operatorname{sech} b\, db$, the integral is $2\int_0^\infty F'(a)F(a)\, da = F(\infty)^2 = \pi^2/4$. Consequently $\|W_0\|^2 = 2\int_0^\infty K_0(2\pi a)^2\, da = \pi/4$. □

PROPOSITION 47.3.5 *(Normalized archimedean vacuum-line comparison).* Let Ω_∞ be the unit Segal vacuum. The map $U_\infty(a\Omega_\infty) = 2aW_0/\sqrt{\pi}$ is an isometry of complex lines, with

$$H_{\mathrm{Whit},\infty}(U_\infty v, U_\infty w) = H_{\mathrm{Segal}}(v, w) \qquad (v, w \in \mathbb{C}\Omega_\infty).$$

Proof. Both sides are $a\overline{b}$ for $v = a\Omega_\infty$, $w = b\Omega_\infty$, by the computed norm. An extension intertwining the full arithmetic or Heisenberg actions with a Whittaker representation is an additional construction. Irreducibility statements for different group actions do not produce such an intertwiner. □

47.4 FINITE-PLACE IDENTIFICATION

Bost–Connes Hilbert Pairing

For each prime p, define the weighted occupation model $H_{\mathrm{occ},p} = \ell^2(\mathbb{N}_0, p^{-j})$, with basis δ_j and Hermitian form

$$\langle v, w\rangle_p^{\mathrm{BC}} = \sum_{j\geq 0} p^{-j} v_j \overline{w_j}, \qquad \langle \delta_j, \delta_k\rangle_p^{\mathrm{BC}} = p^{-j}\delta_{jk}. \tag{47.3}$$

The raw shift $R\delta_j = \delta_{j+1}$ satisfies $\|Rv\| = p^{-1/2}\|v\|$; the normalized shift $p^{1/2}R$ is an isometry. This definition makes no identification with a spherical Hecke factor or its arithmetic action. Such an identification must specify the carrier and intertwining maps separately.

Lemma 47.4.1 *(the actual prime GNS carrier).* The prime shift Gibbs state at $\beta = 1$ has GNS carrier $\mathrm{HS}(\ell^2(\mathbb{N}_0))$, cyclic vector $\rho_p^{1/2}$, and left multiplication representation, where $\rho_p e_j = (1 - p^{-1})\, p^{-j} e_j$. For a specified global critical KMS state, this carrier is unitarily identified with its prime-generated cyclic subspace. The weighted occupation pairing (47.3) is not thereby identified with the whole GNS representation or an automorphic Plancherel space.

Proof. The matrix-unit construction and the state-preserving cyclic unitary are Lemma 67.2.2 and Theorem 67.2.5. A further identification of pairings requires the maps in Hypothesis 67.1.1. □

The Koszul Pairing at p

An arithmetic local bar–cobar pairing has its own two carriers:

$$B_p^{\mathrm{Ar}} : V_p \otimes V_p^! \longrightarrow \mathbb{C}.$$

Identifying either carrier with a Bost–Connes module or algebra is part of the arithmetic comparison, not a consequence of the following weighted Hilbert model.

Proposition 47.4.2 *(Bilinear form on the weighted occupation carrier).* On $H_{\mathrm{occ}} = \ell^2(\mathbb{N}_0, p^{-j})$, let J be coordinate conjugation and set

$$B_{\mathrm{occ}}(v, w) = \sum_{j \geq 0} p^{-j} v_j w_j, \qquad B_{\mathrm{occ}}(v, Jw) = H_{\mathrm{occ}}(v, w).$$

This is a continuous bilinear form. Under $D\delta_j = p^{-j/2} E_{jj}$, it equals $\mathrm{Tr}(DvDw)$.

Proof. Cauchy–Schwarz bounds the absolute series by $\|v\|\|w\|$. The diagonal trace is that same series, and inserting coordinate conjugation gives the Hermitian form. This constructs the model pairing. It does not identify the arithmetic bar–cobar dual with vectors $\mu_{p^j}^* \delta_1$: for $j > 0$, those vectors are zero in the occupation representation. Transport of B_p^{Ar} requires actual maps on both carriers and compatibility with their actions. □

Bost–Connes vs. Petersson at p

Fix an unramified tempered representation and the spherical Whittaker normalization $W(1) = 1$. The Kirillov Hermitian form is

$$H_{\mathrm{Whit}}(\phi, \phi') = \int_{\mathbb{Q}_p^\times} W_\phi(a) \overline{W_{\phi'}(a)}\, d^\times a.$$

Here $m_p = \mathrm{vol}(\mathbb{Z}_p^\times)$ fixes the measure. This local representation-theoretic form is transported to an arithmetic Petersson realization only by the specified placement maps.

Lemma 47.4.3 *(Spherical norm and the compact subgroup volume).* The spherical norm is

$$C_p = H_{\mathrm{Whit}}(W, W) = m_p (1 + p^{-1}) L_p(1, \mathrm{Ad}\, \pi_p).$$

It is finite, positive, and representation-dependent. In contrast, the compact subgroup volume for additive-matrix unit measure is $(1 - p^{-1})(1 - p^{-2})$.

Proof. Lemma 56.7.4 proves the norm formula by the convergent spherical shell series. The compact volume is computed by reduction modulo p: the invertible matrices form $(p^2-1)(p^2-p)$ of the p^4 residue classes. These are different calculations and different measures. An extra factor $|a|^{-1}$ in the integral would instead evaluate $Z_p(0)$; for $\alpha=\beta=1$, its shell series is $m_p\sum(j+1)^2$, which diverges. □

PROPOSITION 47.4.4 *(conditional finite-place pairing comparison).* Assume the local placement and pairing maps of Hypothesis 67.1.1, with common measure normalization. If they realize the two local forms on the prime Hilbert–Schmidt carrier by the bilinear trace form B_p and $JX=X^*$, then

$$\langle \iota_p v,\iota_p w\rangle_p^{\mathrm{Pet}} = B_p(c_p v, Jc_p w).$$

Proof. On Hilbert–Schmidt operators, $B_p(X,JY)=\mathrm{Tr}(XY^*)$, so the stipulated maps transport the same Hermitian form. The weighted occupation form has a concrete diagonal realization: for $m=p^j$, send its basis vector to $D_j=p^{-j/2}E_{jj}$. Then $\mathrm{Tr}(D_jD_k^*)=\delta_{jk}p^{-j}$ and $JD_j=D_j$. The radial-function isometry of Theorem 56.7.5 uses the chosen multiplicative Haar mass explicitly; the spherical line is normalized by its full positive norm C_p. This verifies the normalization on the specified model. The diagonal subspace is not invariant under left multiplication by V, and it is not the whole prime GNS representation. Its arithmetic or automorphic placement remains an assumption. □

COROLLARY 47.4.5 *(Local compatibility under actual pairing maps).* At each place, suppose maps on the two arithmetic pairing carriers identify B_p^{Ar} with the bilinear model and transport the specified conjugation to its model conjugation. Suppose also that the placed Petersson form is the corresponding Hermitian form. Then, on that common domain,

$$H_p^{\mathrm{Pet}}(v,w)=B_p^{\mathrm{Ar}}(v,\sigma_p w).$$

The archimedean placement is included among these data.

Proof. The model identity is $H(x,y)=B(x,Jy)$. Apply the supplied pairing maps and their conjugation compatibility. At finite primes the weighted diagonal calculation above supplies this identity on its stated model, without identifying the entire arithmetic carrier. □

47.5 ADELIC ASSEMBLY

Tate's Restricted Tensor Product

Definition 47.5.1 *(Normalized restricted tensor product of pairings).* Choose local Hermitian spaces (H_v,e_v) with unit reference vectors. On elementary tensors equal to these references outside a finite set, define

$$H(\otimes_v' x_v,\otimes_v' y_v)=\prod_v H_v(x_v,y_v).$$

Only finitely many factors differ from one. If raw local reference vectors have nonunit norms, first specify their normalization or provide a separate global continuation and scalar comparison. The compact subgroup volume is not the norm of every spherical vector.

LEMMA 47.5.2 *(Tamagawa regularisation of the adelic product).* The ordinary product of the spherical finite-place volumes for GL_n is not the Tamagawa volume before regularisation. For GL_n over $\mathbb{Q}$, $\mathrm{vol}(GL_n(\mathbb{Z}_p))=\prod_{k=1}^n(1-p^{-k})$, so the $k=1$ factor is the divergent Euler factor $\zeta(1)^{-1}$. The factors with $k\ge 2$ converge to $\prod_{k=2}^n\zeta(k)^{-1}$. The finite non-zero value $\tau(GL_2)=1$ is obtained only after the completed-zeta residue, the archimedean Haar factor, and the quotient by the rational character have been inserted.

Proof. Weil 1967 *Basic Number Theory* Ch. VII §3 computes $\mathrm{vol}([GL_n])$ for the Tamagawa normalisation. For GL_2, the Tamagawa number is $\tau(GL_2) = 1$ by Weil's theorem (Platonov–Rapinchuk 1994 Ch. 3 §1.3, Theorem 3.4 for split groups over $\mathbb{Q}$); the computation uses the completed zeta function and the different in an essential way, not merely a residue. The full Tamagawa formalism is classical: see Weil 1967 and the full modern account in Platonov–Rapinchuk *Algebraic Groups and Number Theory* (1994) Ch. 3. □

Assembly of Petersson and Koszul

Theorem 47.5.3 *(Restricted tensor assembly of normalized local forms).* Let (H_v, e_v) be Hilbert spaces with specified unit reference vectors, conjugations $J_v e_v = e_v$, and bilinear forms $B_v(x, J_v y) = H_v(x, y)$. Their algebraic restricted tensor product has forms, for elementary tensors,

$$H(\otimes'_v x_v, \otimes'_v y_v) = \prod_v H_v(x_v, y_v),$$
$$B(\otimes'_v x_v, \otimes'_v y_v) = \prod_v B_v(x_v, y_v).$$

They extend to the Hilbert completion, and $H(x, y) = B(x, Jy)$. Their arithmetic realization requires the actual local placements, compatible adelic maps and common global scalar of Hypothesis 67.1.1.

Proof. Only finitely many factors differ from the reference unit values, so these products are finite. At each finite stage the Hilbert tensor form is positive definite and the embeddings obtained by tensoring with reference vectors are isometries. Their directed union has a Hilbert completion. Tensor products of the conjugations are compatible isometries and extend to a conjugation J; define $B(x, y) = H(x, Jy)$, which is bounded and agrees with the finite products. This constructs the restricted tensor model. It does not identify an arithmetic completed pairing with that model or assign a value to an unnormalized infinite product at $s = 1$. □

Corollary 47.5.4 *(global compatibility via local compatibility).* Assume the local comparison maps and the completed adelic realization of Theorem 47.5.3, with the same specified global normalization for both forms. The global identity (47.1.1) follows from the local identities (47.4.5) by taking the restricted tensor product. Explicitly,

$$\langle v, w\rangle^{\mathrm{Pet}} = \prod_v \langle v_v, w_v\rangle_v^{\mathrm{Pet}} = \prod_v \langle v_v, \sigma_v^{\mathrm{BC}}(w_v)\rangle_v^{\mathrm{Koszul}} = \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}},$$

using (47.5.3), (47.4.5), and (47.5.3), with $\sigma^{\mathrm{BC}} = \otimes_v \sigma_v^{\mathrm{BC}}$ the adelic restricted tensor product involution.

47.6 The Bost–Connes Anti-Involution and its GNS Lift

Definition and Basic Properties

The Bost–Connes algebraic anti-involution τ^{BC} is the adelic extension of its local versions τ_p^{BC}. The local anti-involution at a prime p is the conjugate-linear anti-automorphism

$$\tau_p^{\mathrm{BC}} \colon \mathbb{A}_p^{\mathrm{BC}} \to \mathbb{A}_p^{\mathrm{BC}}, \quad \mu_m \mapsto \mu_m^*, \quad \mu_m^* \mapsto \mu_m, \quad e(\gamma) \mapsto e(-\gamma).$$

On the prime cyclic GNS space at $\beta = 1$, for $m = p^k$, the corresponding antiunitary is not τ_p^{BC} itself but

$$J_{\varphi_1, p}\pi(\mu_m)\Omega_{\varphi_1} = m^{1/2}\pi(\mu_m^*)\Omega_{\varphi_1}, \qquad J_{\varphi_1, p}\pi(\mu_m^*)\Omega_{\varphi_1} = m^{-1/2}\pi(\mu_m)\Omega_{\varphi_1}.$$

The factors are forced by $S_{\varphi_1} = J_{\varphi_1}\Delta_{\varphi_1}^{1/2}$. At the archimedean place, the required antilinear map is coefficient conjugation in the normalized Segal basis, transported through the specified arithmetic comparison. It is not the complex-linear identity: for the unit vacuum Ω, the Hermitian value $H(\Omega, i\Omega) = -i$ whereas the bilinear value $B(\Omega, i\Omega) = i$. The relation is $H(v, w) = B(v, J_\infty w)$.

LEMMA 47.6.1 *(properties of the local anti-involution and its lift).* The local Bost–Connes anti-involution satisfies:

- $\tau_p^{\mathrm{BC}} \circ \tau_p^{\mathrm{BC}} = \mathrm{id}$ (involutive; Bost–Connes §1.2).
- τ_p^{BC} is $\mathbb{C}$-antilinear (it is the $*$-conjugation of the C^*-structure).
- The GNS lift $J_{\varphi_1,p}$ preserves the Bost–Connes Hilbert pairing: $\langle J_{\varphi_1,p}v, J_{\varphi_1,p}w\rangle_p^{\mathrm{BC}} = \overline{\langle v, w\rangle_p^{\mathrm{BC}}}$.

Proof. The first two properties are immediate from the defining formulas (47.6): involutivity from $(\mu_m^*)^* = \mu_m$ and $e(-(-\gamma)) = e(\gamma)$; $\mathbb{C}$-antilinearity from the $*$-conjugation structure. The third is Tomita–Takesaki antiunitarity for the KMS_1 GNS representation, with the half-density factors displayed above (Bost–Connes §2.2 Thm 25; Connes–Marcolli arXiv:math/0404128 §1.8). □

Adelic Involution

Definition 47.6.2 *(Restricted tensor conjugation).* For local conjugations $J_v e_v = e_v$ on the specified normalized Hilbert models, put $J = \otimes_v' J_v$ on the algebraic restricted tensor product. It extends isometrically to its completion. At infinity use coefficient conjugation on the Segal carrier; at a prime Gibbs factor use its Hilbert–Schmidt adjoint conjugation. Transport to the arithmetic carrier requires its specified maps.

PROPOSITION 47.6.3 *(Transport of conjugation to an automorphic domain).* Suppose an isometric placement U of the completed model into an automorphic Hilbert space intertwines its local conjugations with pointwise complex conjugation on a dense restricted tensor domain. Then this intertwining extends to the completion:

$$U(Jv) = \overline{U(v)}.$$

Proof. Both sides define continuous antilinear maps. Their equality on the dense domain gives equality everywhere. The local arithmetic intertwiners are hypotheses here; inversion of Satake parameters does not construct them from the Bost–Connes algebra involution. □

47.7 SPHERICAL-VECTOR CALCULATION

To make the match between Koszul and Petersson pairings concrete and verifiable at the level of numerical constants, we compute both at the unramified spherical vector at a single prime p and at the archimedean place.

Spherical Petersson at p

LEMMA 47.7.1 *(Spherical Whittaker value).* For the spherical function normalized by $W(1) = 1$,

$$H_{\mathrm{Whit}}(W, W) = C_p = m_p(1 + p^{-1})L_p(1, \mathrm{Ad}\,\pi_p).$$

Proof. This is Lemma 47.4.3. □

The Normalized Model Line

Lemma 47.7.2 *(Unit reference vectors and bilinear pairing).* The occupation reference vector δ_0, the Gibbs vector $\Omega = \sqrt{\rho}$, and the normalized spherical vector $W/\sqrt{C_p}$ each have norm one. The specified line maps between them are isometries. On the occupation model,

$$B_{\mathrm{occ}}(\delta_0, J\delta_0) = 1.$$

An arithmetic Koszul vacuum has this value only when its comparison maps carry it to the specified model reference vector.

Proof. The occupation Gram matrix gives the first norm, $\operatorname{Tr}\rho = 1$ gives the second, and the preceding lemma gives the third. The displayed bilinear identity follows from the coordinate formula. □

Global Reference Normalization

Proposition 47.7.3 *(Reference value in the restricted tensor model).* For the normalized restricted tensor model of Theorem 47.5.3, the reference vector $e = \otimes'_v e_v$ satisfies

$$H(e,e) = B(e,Je) = 1.$$

If its arithmetic realization multiplies both forms by a specified scalar c, both reference values become c. The scalar and realization must be constructed for that arithmetic representation.

Proof. Every finite-stage reference vector has norm one and the embeddings are isometries. The identity therefore holds in the completion; common scalar multiplication preserves it. A cuspidal Petersson norm is not determined by the volume of the whole automorphic quotient. The Tamagawa number consequently does not fix this scalar. □

47.8 Analytic Continuation and Poles

Pole Structure of Both Pairings

For the specified unramified tempered spherical model, the local meromorphic function is

$$Z_p(s) = m_p \frac{L_p(s, \pi_p \times \widetilde{\pi}_p)}{\zeta_p(2s)}.$$

Its rank-four Rankin–Selberg factor is $\zeta_p(s)L_p(s, \operatorname{Ad}\pi_p)$; it is not the rank-two standard factor $(1-\alpha p^{-s})^{-1}(1-\beta p^{-s})^{-1}$. A meromorphic arithmetic bar–cobar pairing requires its own family of carriers, domains and compatible comparison maps.

Proposition 47.8.1 *(Pole matching under a meromorphic comparison).* Suppose two scalar pairings obtained from specified meromorphic families of vectors extend to meromorphic functions on a connected parameter domain. If the actual pairing comparison identifies them on a nonempty open subset, they agree meromorphically, including their pole orders and residues.

Proof. Their difference is meromorphic and vanishes on an open subset. The identity theorem, after clearing poles locally, makes it zero on the connected domain. Equal Laurent expansions give the pole and residue statement. Neither the local spherical formula nor a partition function constructs the assumed arithmetic family or its comparison. In particular no universal assertion that all such pairings have only the two Tate boundary poles follows. □

No Exotic Poles

Remark 47.8.2 *(The meromorphic arithmetic comparison).* Once the specified meromorphic pairing comparison is constructed, its common Laurent coefficients determine all residues. Without that comparison, neither the pole divisor nor its equality with a Petersson family is supplied by the local Hilbert model. The full parameter-dependent arithmetic pairing remains the construction required by Proposition 47.8.1.

47.9 The Main Theorem

THEOREM 47.9.1 *(Koszul–Petersson pairing compatibility, domain-restricted).* Assume the arithmetic placement, local pairing maps and completed adelic extension of Hypothesis 67.1.1 on the stated normalized core. *Conditional statement. (domain-restricted to the normalized sph-fin cuspidal core and using the Tamagawa regularisation of Lemma 47.5.2; see Remark 47.1.2).* The identity (47.1.1)

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}$$

holds for all $v, w \in \mathcal{V}^{\mathrm{prim}}_{\text{sph-fin,cusp}}$, the normalized sph-fin cuspidal core of $\mathcal{V}^{\mathrm{prim}}$. Equivalently, the arithmetic Koszul pairing of the sph-fin cuspidal core with $(\mathcal{V}^{\mathrm{prim}})^! = \mathbb{A}^{\mathrm{BC}}$ coincides, after Bost–Connes involution on the dual, with the adelic Petersson inner product on $L^2([GL_2])$ restricted to the image of the sph-fin cuspidal core. Full-sector compatibility and KMS_1/GNS identification beyond this core remain open (Remark 47.1.2).

Proof. For every place $v \le \infty$, Corollary 47.4.5 gives $\langle v_v, w_v\rangle_v^{\mathrm{Pet}} = \langle v_v, \sigma_v^{\mathrm{BC}}(w_v)\rangle_v^{\mathrm{Koszul}}$. Theorem 47.5.3 provides the restricted tensor product assembly of both sides. The adelic involution $\sigma^{\mathrm{BC}} = \bigotimes'_v \sigma_v^{\mathrm{BC}}$ is well-defined on the restricted tensor product (Definition 47.6.2). Taking the product over v of the local identities yields

$$\langle v, w\rangle^{\mathrm{Pet}} = \prod_v \langle v_v, w_v\rangle_v^{\mathrm{Pet}} = \prod_v \langle v_v, \sigma_v^{\mathrm{BC}}(w_v)\rangle_v^{\mathrm{Koszul}} = \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}},$$

as in Corollary 47.5.4.

The comparison is first defined on the stipulated normalized restricted-tensor core. Its extension to the completed arithmetic carrier is part of Hypothesis 67.1.1. The spherical-volume product has the Tamagawa residue normalization of Lemma 47.5.2; this does not assert ordinary absolute convergence at $s = 1$. Where a continued pairing is used, both its domain and compatibility with the comparison maps must be supplied. Thus the displayed equality follows from the specified local identities and their assumed adelic extension. □

Remark 47.9.2 *(local forms and their comparison maps).* The spherical calculation fixes the multiplicative Haar measure and computes the Whittaker norm. The weighted occupation and diagonal Hilbert–Schmidt models have explicit isometries; at infinity the normalized vacuum line has the computed K_0-Whittaker norm. These are comparisons of the stated models and lines. Neither Stone–von Neumann uniqueness nor a local functional equation constructs the arithmetic bar-to-automorphic map. Equality of the arithmetic pairings requires the placement, conjugation and adelic extension in Hypothesis 67.1.1.

47.10 Consequence: P3 on the Sph-Fin Cuspidal Core

COROLLARY 47.10.1 *(P3 unitarity on the sph-fin cuspidal core).* Assume the arithmetic placement, local pairing maps and completed adelic extension of Hypothesis 67.1.1 on the stated normalized core.

Conditional statement. (domain-restricted to the normalized sph-fin cuspidal core and to the Tamagawa-regularised pairing). On the normalized sph-fin cuspidal core $\mathcal{V}^{\mathrm{prim}}_{\text{sph-fin,cusp}}$, the primary arithmetic Heisenberg is a unitary arithmetic chiral algebra: it carries a positive-definite Hermitian form

$$\langle \cdot, \cdot \rangle^{\mathrm{Pet}} \colon \mathcal{V}^{\mathrm{prim}}_{\text{sph-fin,cusp}} \otimes \overline{\mathcal{V}^{\mathrm{prim}}_{\text{sph-fin,cusp}}} \to \mathbb{C}$$

given by the adelic Petersson–Tamagawa inner product, and this form is compatible with arithmetic Koszul self-duality via

$$\langle v, w \rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w) \rangle^{\mathrm{Koszul}}.$$

Full-sector P3 is not a consequence of the sph-fin cuspidal identity: the prime KMS_1/GNS cyclic-subspace comparison is the operator-algebraic statement of Theorem 67.2.5, while the ramified Rankin–Selberg and Eisenstein terms are separate domain conditions (Remark 47.1.2).

Proof. Positive-definiteness of $\langle \cdot, \cdot \rangle^{\mathrm{Pet}}$ was established place by place in the proof of Theorem 43.7.1: at ∞ by Segal Fock positivity; at each prime p by Bost–Connes $\mathrm{KMS}_{\beta=1}$ positivity; adelic assembly by Tate 1950 restricted tensor product preserves positive-definiteness.

Compatibility with arithmetic Koszul self-duality is Theorem 47.9.1, which is established on the normalised sph-fin cuspidal core. Combining: $\mathcal{V}^{\mathrm{prim}}$ carries both a positive-definite Hermitian form (Petersson) and an arithmetic Koszul self-duality pairing (arithmetic bar–cobar), and the two are compatible via Bost–Connes involution. □

Remark 47.10.2 *(form restriction for P3).* Theorem 43.7.1 is conditional on Conjecture 43.7.2. Its conditional transport is Theorem 47.9.1, a domain-restricted and Tamagawa-regularised theorem on the normalized sph-fin cuspidal core. P3 retains the same arithmetic comparison hypotheses: on the sph-fin cuspidal core, $\mathcal{V}^{\mathrm{prim}}_{\text{sph-fin,cusp}}$ is unitary with Petersson inner product compatible with the Koszul pairing; full-sector P3 also requires the ramified Rankin–Selberg and Eisenstein terms recorded in the determinacy comparison residual Section 60.2.

Impact on the Sufficient RH Implication

Corollary 47.10.3 *(sufficient RH path, four-input conditional).* Under the normalization and comparison hypotheses of Theorem 47.9.1, the sufficient closure path to RH in the arithmetic formalism (Theorem 44.6.1) is the four-input conditional conjunction of Theorem 60.3.1:

(i) The arithmetic comparison includes the central-defect identity and detecting Mellin evaluation of Theorem 43.5.1. Its co–contra component retains the coefficient requirements of Remark 46.1.6.

(ii) Koszul–Petersson compatibility (Theorem 47.9.1): domain-restricted to the normalized sph-fin cuspidal core and conditional on the Tamagawa-regularised assembly; the full-sector extension has separate ramified Rankin–Selberg and Eisenstein components, while the KMS_1/GNS component is the prime cyclic-subspace statement of Theorem 67.2.5.

(iii) Arithmetic Hilbert–Pólya H-P^{Ar} (Hypothesis 44.3.2): the independent spectral-matching problem.

(iv) Arithmetic Virasoro positivity VB* main direction (Theorem 44.3.10): the classical positive-trace problem, equivalent to RH.

Proof. After the determinacy comparison the sufficient RH path carries four independent conditional inputs. The preceding theorem reduces the second to the sph-fin domain and the Tamagawa-regularised assembly; the other three remain on the four-input RH branch residual list (Section C.10). □

Remark 47.10.4 *(remaining arithmetic comparison problems).* The conditional pairing theorem leaves the following mathematical problems:

Arith. Positselski non-formal theorem (Iwasawa-theoretic Positselski).

VB* the Li positivity / arithmetic Virasoro bootstrap problem.

$\mathrm{L}_{\mathrm{ACD}}$ non-formal theorem (adelic categorical descent; not on RH path).

F2.c non-formal theorem (Tate ∞-categorical restricted tensor; not on RH path).

F3.BZN^{Ar} non-formal theorem (arithmetic Ben-Zvi–Nadler; not on RH path).

The pairing conclusion of Theorem 47.9.1 retains its arithmetic placement, local comparison, and adelic extension hypotheses.

47.11 Pairing Constructions and Arithmetic Comparison

The explicit constructions are the Segal bilinear/Hermitian identity, the normalized K_{o} vacuum-line isometry, the weighted occupation and diagonal Hilbert–Schmidt pairing, and the radial-function isometry of Theorem 56.7.5. For $W(1) = 1$, the finite spherical norm is $m_p(1 + p^{-1})L_p(1, \mathrm{Ad}\,\pi_p)$; unit normalization uses this full factor. It is not the compact subgroup volume.

The normalized restricted tensor construction is proved in Theorem 47.5.3. Its identification with the actual arithmetic completed pairing, its global scalar, and its action-compatible automorphic placement remain required data. The domain-restricted Koszul–Petersson theorem retains these hypotheses; restricting to a cuspidal sph-fin core does not construct them. Meromorphic pole matching additionally requires an actual parameter-dependent comparison on an open domain.

The prime KMS/GNS theorem identifies a prime-generated cyclic subspace, not the whole arithmetic or automorphic Hilbert space. Ramified, archimedean full-carrier, and continuous-spectrum comparisons remain part of the original pairing problem. The sufficient RH implication still retains all four inputs of Corollary 47.10.3.

Chapter 48

Adelic Categorical Descent

$\mathrm{L}_{\mathrm{ACD}}$ (Corollary 43.2.3) is the essential adelic gluing statement for conjecture F1 (global arithmetic Arinkin–Gaitsgory for $GL_2/\mathbb{Q}$), with a substantial closure problem (App. C). This chapter decomposes $\mathrm{L}_{\mathrm{ACD}}$ into four subconditions (L_1)–(L_4). The formal restricted tensor product (L_1) is constructed here. The archimedean representation category (L_4) is a boundary datum, not a spectral equivalence. (L_2) still needs the local categorical comparison and the Whittaker compatibility. (L_3) is the Bernstein-centre diamond-gluing compatibility on local coherent Springer sheaves over the Selmer-derived global spectral stack. The main result (Theorem 48.2.7) is a conditional reduction, not a proof of $\mathrm{L}_{\mathrm{ACD}}$.

48.1 Statement Recalled

The Condition

Corollary 43.2.3 states:

> $\mathrm{L}_{\mathrm{ACD}}$ **(adelic categorical descent).** The assignment
>
> $$v \longmapsto \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_v)]\big)$$
>
> (for v ranging over places of $\mathbb{Q}$, finite and archimedean) forms a Tate-restricted tensor product whose colimit is the global automorphic category $\mathrm{D}([GL_2])^{\text{sph-fin}}$; this restricted tensor product is compatible with Hecke-functoriality and with the local Fargues–Scholze spectral action together with the still-open F1.a local categorical comparison, so that
>
> $$\bigotimes_v{}' \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_v)]\big) \;\simeq\; \mathrm{D}\big([GL_2]\big)^{\text{sph-fin}}$$
>
> as Hecke-equivariant stable presentable ∞-categories.

The restricted tensor product $\bigotimes'_v$ follows Tate 1950 / Weil 1967 at the level of spaces of automorphic forms. The canonical ∞-categorical definition is the filtered-colimit construction of Definition 50.1.2. The display below is mnemonic:

$$\bigotimes_v{}' C_v \;:=\; \varinjlim_{S \text{ finite}} \bigotimes_{v \in S} C_v \otimes \bigotimes_{v \notin S} \mathbb{1}_{u_v}, \tag{48.1}$$

where $u_v \in C_v$ is the distinguished unit (the unit of the unramified spherical Hecke category) at almost every finite place.

Context and Significance

$\mathrm{L}_{\mathrm{ACD}}$ is the essential adelic gluing statement for F1 (global arithmetic Arinkin–Gaitsgory, Conjecture 42.1.1). The structural reduction of F1 in Theorem 43.2.1 splits F1 into four sub-items (F1.a)–(F1.d). Only (F1.c) is a theorem drawn directly from primary literature (Emerton–Gee arXiv:1908.07185). Fargues–Scholze arXiv:2102.13459 supplies local geometrisation and spectral action, not the categorical equivalence required by (F1.a). The remaining items (F1.a), (F1.b), and (F1.d) are equivalent to the local comparison plus $\mathrm{L}_{\mathrm{ACD}}$ conditions whose closure removes F1.

$\mathrm{L}_{\mathrm{ACD}}$ is a **conjectural, non-formal theorem**. This chapter does not close $\mathrm{L}_{\mathrm{ACD}}$; it reduces it to a narrower and precisely-stated compatibility on local coherent Springer sheaves (Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321) glued across primes on the Selmer-derived global spectral stack.

48.2 Modular Reduction of $\mathrm{L}_{\mathrm{ACD}}$

Six independent lines of obstruction on $\mathrm{L}_{\mathrm{ACD}}$ are given below. Each line produces a structural decomposition, a partial closure, or a named residual, following the schema of Section 43.1.

Modular Decomposition of $\mathrm{L}_{\mathrm{ACD}}$

$\mathrm{L}_{\mathrm{ACD}}$ is the conjunction of four ingredients: (i) well-definedness of the restricted tensor product of local ∞-categories with distinguished units; (ii) Hecke-functoriality across places; (iii) compatibility of the Bernstein centre action across places under restricted tensor; (iv) archimedean-finite assembly (extension across the archimedean place). A structural closure requires separating each ingredient. The decomposition admits four disjoint subconditions, (L_1)–(L_4), each a precise statement at the ∞-categorical level.

THEOREM 48.2.1 *(modular decomposition of* $\mathrm{L}_{\mathrm{ACD}}$*).* $\mathrm{L}_{\mathrm{ACD}}$ contains the following four subconditions:

- (L_1) *Well-definedness of the restricted tensor product.* The assignment $v \mapsto C_v$ with $C_v = \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$ and distinguished units u_v (spherical vectors) defines a well-formed restricted tensor product $\otimes'_v C_v$ in the ∞-category $\mathrm{Pr}^{\mathrm{L,st}}$ of stable presentable ∞-categories.
- (L_2) *Hecke-functoriality lift across places.* For each finite set S of places, assume the local categorical comparison functors $C_v \to \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},v}_{GL_2})$ for the finite places $v \in S$. Their tensor product is required to give an equivalence $\otimes_{v\in S} C_v \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\prod_{v\in S} \mathcal{X}^{\mathrm{EG},v}_{GL_2})$ compatible with Hecke operators at distinct primes.
- (L_3) *Bernstein-centre diamond gluing.* The Bernstein-centre action $\mathcal{Z}_v \curvearrowright C_v$ (the centre of the local categorical Hecke algebra) extends to a global action $\mathcal{Z}_{\mathrm{glob}} \curvearrowright \otimes'_v C_v$ making the tensor product restricted-tensor-equivariant under the Bernstein centre.
- (L_4) *Archimedean extension.* The archimedean factor $C_\infty = \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{R})])$ is the ind-completed derived category of admissible $(\mathfrak{gl}_2, O(2))$-modules of finite K-type. It carries the trivial K-spherical object as distinguished unit, and the restricted tensor product $\otimes'_v C_v$ extends the finite-place product $\otimes'_{p<\infty} C_p$ by tensoring with C_∞.

$\mathrm{L}_{\mathrm{ACD}}$ holds if (L_1) through (L_4) hold together with the identification of the resulting object with the global automorphic category $\mathrm{D}([GL_2])^{\text{sph-fin}}$.

Proof. Forward direction: assume L_{ACD}. The restricted tensor product (48.1) is well-defined by definition, giving (L_1). Hecke-functoriality across places is part of the L_{ACD} hypothesis, giving (L_2). Bernstein-centre compatibility follows from functoriality of the global automorphic category under the global Bernstein centre plus Hecke-functoriality, giving (L_3). Archimedean extension is explicit in the definition of L_{ACD} (the index v ranges over all places), giving (L_4).

Converse direction: assume (L_1)–(L_4) and the global identification just stated. By (L_1) and (L_4), $\otimes'_v C_v$ is a well-defined stable presentable ∞-category. By (L_2) and (L_3), this category is Hecke-equivariant and Bernstein-centre-equivariant. The identification with the global automorphic category follows from the assumed local-global compatibility. No theorem of Bernstein, Raskin, or geometric Langlands supplies this number-field identification without that input. □

Remark 48.2.2 *(form of the descent subconditions).* The four descent subconditions have the following mathematical forms:

(L_1) Theorem, closed in this chapter (§48.3).

(L_2) Conditional; reduces to the local categorical comparison plus Whittaker and Bernstein-centre compatibility (§48.4).

(L_3) Conjectural; the residual content of L_{ACD} after the decomposition of Theorem 48.2.1 (§48.5).

(L_4) Boundary datum; Jacquet–Langlands and Vogan define the archimedean representation category, not an Emerton–Gee spectral equivalence (§48.6).

Curve Precedent and Transport Obstructions

For a smooth complete curve over an algebraically closed field of characteristic zero, the de Rham geometric Langlands theorem gives the model for the categorical descent pattern. The sheaf-function analogue over finite fields is a different theorem. Neither theorem transports directly to the number-field case. The obstructions are:

(i) No archimedean place in the curve setting. Geometric Langlands uses the closed points of a curve. Number-field L_{ACD} requires the archimedean extension (L_4), which has no curve analogue.

(ii) Emerton–Gee integrality. The number-field spectral side uses the Emerton–Gee stack arXiv:1908.07185, which encodes integrality of Galois representations; de Rham geometric Langlands uses the stack $\mathrm{LocSys}_G^{\mathrm{dR}}(X)$, which is smoother and has weaker integrality content. The Bernstein-centre compatibility (L_3) is strictly more subtle in the number-field setting because the Emerton–Gee stack is not smooth over $\mathrm{Spec}\,\mathbb{Z}$.

(iii) Perfectoid diamonds. Fargues–Scholze's local theorem uses the Fargues–Fontaine curve and perfectoid diamonds; geometric Langlands uses ind-schemes. Gluing across finite places in the number-field case requires comparing perfectoid diamonds at distinct primes, a non-issue in the de Rham curve setting.

Theorem 48.2.3 *(curve transport, qualified). Comparison hypothesis.* The Gaitsgory–Rozenblyum–Raskin–Lin / AGKRRV proof of de Rham geometric Langlands gives the model for subconditions (L_1) and (L_2) as an analogy, not as a transport theorem (Raskin, "Chiral principal series categories I", Adv. Math. 388 (2021); Raskin, "D-modules on infinite-dimensional varieties", available as `samraskin.net/dmod.pdf`). It closes (L_1) only after the number-field local categories and distinguished units are fixed. It does not close (L_2) without the local categorical comparison of (F1.a) and (BC-diamond-glue). It does *not* close (L_3) (Bernstein centre compatibility is strictly more subtle in the

number-field setting due to Emerton–Gee stack non-smoothness) or (L_4) (no archimedean analogue on the curve).

Proof. (L_1): Raskin 2021 JAMS constructs restricted tensor products of local principal-series categories over a curve. The construction is ∞-categorical and uses only (a) stability, (b) presentability, (c) existence of distinguished units. These properties can be imposed on the number-field local categories. This gives the formal construction of (L_1), not the global automorphic identification.

(L_2): AGKRRV's Hecke-functoriality argument combines local geometric Langlands equivalences with Bernstein–Zelevinsky factorization on a curve. For number fields, Fargues–Scholze arXiv:2102.13459 supplies the local diamond geometrisation and spectral action. It does not supply the displayed categorical comparison with the Emerton–Gee stack. The Bernstein–Zelevinsky pattern applies only after the local comparison and Whittaker-model compatibility are constructed. Domain: §48.4.

(L_3): Number-field obstruction. The Bernstein centre $\mathcal{Z}^{\mathrm{Ar}}$ of the global arithmetic Iwahori Hecke category acts on $\otimes'_v C_v$ via the local Bernstein centres $\mathcal{Z}_v$, but compatibility across primes involves comparing Bernstein parameters at distinct primes through the Emerton–Gee stack. The curve analogue uses the de Rham stack, which is smoother. The number-field compatibility is the residual.

(L_4): No curve analogue. □

Sphericity-Finiteness Preserved Under Restricted Tensor

The "sph-fin" cut in $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$ restricts to categories with finite-type spherical sub-structure, excluding the continuous Eisenstein spectrum and broad classes of non-tempered representations. The condition is preserved under the restricted tensor product.

LEMMA 48.2.4 *(sph-fin preservation under restricted tensor).* Let $\{C_v\}$ be a family of stable presentable ∞-categories with distinguished units u_v at almost every v, and assume each C_v is "sph-fin" in the sense that: (i) C_v has a compact subcategory C_v^ω whose compact objects are finite-type over the local Hecke algebra $\mathcal{H}_v$; (ii) u_v is compact in C_v^ω; (iii) the compact objects generate C_v. Then the restricted tensor product $\otimes'_v C_v$ is likewise sph-fin.

Proof. By Lurie HA 5.3 (higher Deligne centralizers) and HA 4.8 (tensor products of presentable ∞-categories), the tensor product $\otimes_{v\in S} C_v$ over a finite set S inherits compact generation from its finite factors: a family of compact generators is given by tensor products of local compact generators. The distinguished units u_v at $v \notin S$ are compact, so tensoring with them preserves compactness. Taking the filtered colimit over S preserves compact generation (Lurie HA 5.3.2.9 on filtered colimits of compactly generated categories). Hence $\otimes'_v C_v$ is compactly generated, with compact subcategory the filtered colimit of finite tensor products of local compacts. The sph-fin condition is preserved. □

Cross-Place Hecke Commutativity

Commutativity of T_p and T_q at the level of cohomology is automatic; categorical commutativity in the ∞-setting is a coherence datum following from the E_2-monoidal structure on each local Hecke category (assuming F2). Cross-place compatibility requires showing that the global automorphic category decomposes as a restricted tensor product whose factor at each prime is the local Hecke category.

PROPOSITION 48.2.5 *(cross-place Hecke commutativity).* In the restricted tensor product $\otimes'_v C_v$, the local Hecke operators $T_p : C_p \to C_p$ extended by identity on factors at $v \neq p$ (Tate extension) commute: for distinct primes $p \neq q$,

$$(T_p \otimes \mathrm{id}_{\neq p}) \circ (T_q \otimes \mathrm{id}_{\neq q}) \;=\; (T_q \otimes \mathrm{id}_{\neq q}) \circ (T_p \otimes \mathrm{id}_{\neq p})$$

as endofunctors of $\bigotimes'_v C_v$, up to canonical homotopy.

Proof. Each T_p acts on the C_p-factor and by identity on all other factors. The universal property of the tensor product in $\mathrm{Pr}^{\mathrm{L,st}}$ (Lurie HA 4.8.1) gives that endofunctors factoring through disjoint tensor factors commute up to canonical homotopy. Since T_p factors through C_p and T_q through C_q, their extensions to the restricted tensor product commute. □

Non-Transference from Caraiani–Scholze

Caraiani–Scholze arXiv:1511.02418 prove a unitary Shimura variety analogue of $\mathrm{L}_{\mathrm{ACD}}$ for signature $(1, n-1)$ unitary groups $G = U(1, n-1)$ over CM fields. A Jacquet–Langlands transfer from $GL_2/\mathbb{Q}$ to $U(1,1)$ over an imaginary quadratic field $F/\mathbb{Q}$ would reduce the problem to the Caraiani–Scholze case; this reduction fails. Caraiani–Scholze's proof uses three inputs specific to unitary Shimura varieties:

(i) Calegari–Geraghty patching arXiv:1207.4224 for the Galois-deformation side, producing a patched space of automorphic forms whose properties reflect the Emerton–Gee stack.

(ii) The Kottwitz conjecture on cohomology of Shimura varieties in its form for unitary groups (Caraiani–Scholze 2017 §4).

(iii) Ihara-avoidance hypothesis on the existence of adequate Taylor–Wiles primes, required for patching.

None of these transfer to $GL_2/\mathbb{Q}$ in the generality $\mathrm{L}_{\mathrm{ACD}}$ requires.

Observation 48.2.6 *(non-transference of Caraiani–Scholze).* $GL_2/\mathbb{Q}$ has a Shimura variety over $\mathbb{Q}$ in the form of the modular curve $Y(\Gamma(N))$, but the Shimura variety is 1-dimensional, whereas Caraiani–Scholze's Ihara-avoidance argument requires the Shimura variety to be higher-dimensional (specifically $\geq n-1$ where $n = \mathrm{rk}\, G$). For $GL_2/\mathbb{Q}$, the Ihara-avoidance input is essentially degenerate. Caraiani–Scholze's proof cannot be transferred.

The transference fails; but Caraiani–Scholze's proof does suggest the structural shape $\mathrm{L}_{\mathrm{ACD}}$ must take: a patched-spaces argument with local Fargues–Scholze input glued across primes by an "Ihara-avoidance-free" version of the argument.

Reduction to a Single Compatibility

(L_1) is formal in presentable categories. (L_4) supplies the archimedean representation-theoretic boundary datum. (L_2) reduces to the local categorical comparison plus Whittaker-model compatibility; the remaining central compatibility is (L_3): Bernstein-centre diamond gluing. $\mathrm{L}_{\mathrm{ACD}}$ therefore reduces to the single compatibility stated below.

Theorem 48.2.7 *(conditional reduction of* $\mathrm{L}_{\mathrm{ACD}}$*). Conditional statement.* Assuming the local categorical comparison at all finite primes and the archimedean boundary datum, $\mathrm{L}_{\mathrm{ACD}}$ reduces to the following compatibility:

(BC-diamond-glue) *Bernstein-centre diamond gluing.* For each pair of primes $p \neq q$, the local Bernstein centres $\mathcal{Z}_p$ and $\mathcal{Z}_q$ (the centres of the local categorical Hecke algebras on the perfectoid Fargues–Fontaine curves at p and q) admit a common global refinement $\mathcal{Z}_{\{p,q\}}$ such that:

(a) $\mathcal{Z}_{\{p,q\}}$ embeds into $\mathcal{Z}_p \otimes \mathcal{Z}_q$ under the external tensor action on $C_p \otimes C_q$;

(b) the embedding is compatible with restriction to smaller prime sets $S \subsetneq \{p, q\}$;

(c) the inductive limit $\mathcal{Z}_{\mathrm{glob}} := \varinjlim_S \mathcal{Z}_S$ over finite sets S of primes agrees with the global Bernstein centre acting on the global automorphic category.

Proof. Forward direction: assume $\mathrm{L}_{\mathrm{ACD}}$. The global automorphic category $\mathrm{D}([GL_2])^{\text{sph-fin}}$ carries a global Bernstein-centre action. The restricted tensor product structure of $\mathrm{L}_{\mathrm{ACD}}$ expresses this global action as a filtered colimit of finite products of local Bernstein centres. Compatibilities (a)–(c) follow.

Reverse direction: assume (BC-diamond-glue), the local categorical comparisons, and the archimedean boundary datum. Then by Theorem 48.2.1, it suffices to close (L_1), (L_2), (L_3), (L_4). (L_1) closes in §48.3. (L_2) is supplied by the assumed local comparisons, up to local-global compatibility of Whittaker models, which (BC-diamond-glue) supplies via compatibility (b). (L_3) closes from (BC-diamond-glue) directly. (L_4) is the assumed archimedean boundary datum. Assembling, $\mathrm{L}_{\mathrm{ACD}}$ holds. □

Remark 48.2.8 *(domain of (BC-diamond-glue)).* (BC-diamond-glue) is strictly narrower than $\mathrm{L}_{\mathrm{ACD}}$. It is a single compatibility between local Bernstein centres and the global Bernstein centre. Partial change: Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321 ("Coherent Springer theory and the categorical Deligne–Langlands correspondence") constructs the local Bernstein centres as coherent sheaves on the local Emerton–Gee stacks. (BC-diamond-glue) asks that these coherent sheaves glue across primes to a global coherent sheaf on the Selmer-derived global spectral stack $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$, agreeing with the global Bernstein centre action at the level of categorical trace. This is a gluing and centre-comparison problem. The reduction in Theorem 48.2.7 also retains the local categorical comparison, archimedean boundary datum and global identification; it does not construct these maps.

48.3 Subcondition (L_1): Restricted Tensor in ∞-Categories

Definition

Definition 48.3.1 *(restricted tensor product in* $\mathrm{Pr}^{\mathrm{L,st}}$*).* The canonical definition is Definition 50.1.2; the following formula is its older mnemonic form in the ACD notation. Let V be a countable indexing set, $\{C_v\}_{v\in V}$ a family of stable presentable ∞-categories, and let $u_v \in C_v$ be a distinguished unit at almost every v (i.e. at all but finitely many v in a fixed cofinite subset $V^{\mathrm{unr}} \subseteq V$). The *Tate-restricted tensor product* is

$$\bigotimes_{v\in V}{}' C_v \;:=\; \varinjlim_{S \text{ finite},\, V^{\mathrm{unr}}\supseteq V\setminus S} \;\bigotimes_{v\in S} C_v \otimes \bigotimes_{v\in V^{\mathrm{unr}}\setminus S} \mathbb{1}_{u_v},$$

where $\mathbb{1}_{u_v}$ denotes the unit ∞-category generated by u_v (a full subcategory of C_v).

THEOREM 48.3.2 *((L_1) closed).* The restricted tensor product of Definition 48.3.1 is a well-defined stable presentable ∞-category. Specifically:

(i) The filtered colimit $\varinjlim_S$ exists in $\mathrm{Pr}^{\mathrm{L,st}}$.

(ii) The resulting object is stable, presentable, and compactly-generated if each C_v is compactly-generated (Raskin, "D-modules on infinite-dimensional varieties", `samraskin.net/dmod.pdf`; Lurie HA 5.3.2).

(iii) Sphericity-finiteness is preserved (Lemma 48.2.4).

(iv) The restricted tensor product is functorial in the family $\{C_v, u_v\}$ under morphisms that preserve distinguished units.

Proof. **(i) Existence of the filtered colimit.** The ∞-category $\mathrm{Pr}^{\mathrm{L,st}}$ of stable presentable ∞-categories is a (large) ∞-category admitting all small colimits (Lurie HA 4.8.1.15). Filtered colimits exist.

(ii) Presentability and compact generation. Lurie HA 5.3.2.9 asserts that a filtered colimit of compactly-generated stable presentable ∞-categories, under functors preserving compact objects, is compactly generated. The transition maps in the defining filtered colimit are of the form "tensor with $\mathbb{1}_{u_v}$" for newly-included places v, which are left-adjoint (and preserve compact objects because the unit u_v is assumed compact, as in Lemma 48.2.4). Hence the colimit is compactly generated.

(iii) Stability. Filtered colimits of stable ∞-categories in $\mathrm{Pr}^{\mathrm{L,st}}$ are stable (Lurie HA 1.1.4.4: stable ∞-categories are closed under filtered colimits in Pr^{L}).

(iv) Sphericity-finiteness preservation. Lemma 48.2.4.

(v) Functoriality. A morphism of families $\{(C_v, u_v)\} \to \{(C'_v, u'_v)\}$ is a family of left adjoints $F_v : C_v \to C'_v$ sending u_v to u'_v. The induced map $\otimes_{v\in S} F_v : \otimes_{v\in S} C_v \to \otimes_{v\in S} C'_v$ is compatible with unit-extension to larger $S' \supseteq S$ because F_v sends distinguished units to distinguished units. Taking the filtered colimit yields the induced map $\otimes'_v F_v : \otimes'_v C_v \to \otimes'_v C'_v$. The construction is independent of the choice of cofinite unramified subset V^{unr} (any two choices agree on a further cofinite subset, and the filtered colimit is insensitive to such shrinking). □

Remark 48.3.3 *(comparison with Raskin's construction).* Raskin "Chiral principal series categories I", Adv. Math. 388 (2021), 107856, and Raskin "D-modules on infinite-dimensional varieties" (`samraskin.net/dmod.pdf`) construct restricted tensor products of principal-series categories over a smooth curve. The construction uses the same filtered colimit pattern with spherical vectors as distinguished units. The number-field analogue is not a direct transport. The same filtered colimit defines the formal restricted tensor product once the local categories and distinguished units are fixed. The non-trivial content is the identification with the global automorphic category, which is (L_2) and (L_3).

Corollary 48.3.4 *((L_1) holds).* (L_1) is a theorem, closed by Theorem 48.3.2 plus Lemma 48.2.4.

48.4 Subcondition (L_2): Hecke-Functoriality Across Places

Statement and Reduction

Theorem 48.4.1 *((L_2) reduction). Comparison hypothesis.* For each finite set S of primes, the Fargues–Scholze local geometry, after the local categorical comparison (F1.a), supplies comparison functors

$$\Phi_v^{\mathrm{loc}} \;:\; C_v \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG},v}_{GL_2}\big), \qquad v \in S$$

which glue to an equivalence

$$\Phi_S^{\mathrm{loc}} \;:\; \bigotimes_{v\in S} C_v \;\xrightarrow{\sim}\; \mathrm{IndCoh}_{\mathrm{Nilp}}\Big(\prod_{v\in S} \mathcal{X}^{\mathrm{EG},v}_{GL_2}\Big) \tag{48.2}$$

compatible with Hecke operators T_v at distinct primes. The open content is the local categorical comparison plus the (BC-diamond-glue) Whittaker/Bernstein-centre compatibility.

Proof. **Step 1: Local geometry exists.** At each prime p, Fargues–Scholze arXiv:2102.13459 constructs local geometrization, spectral action, and Fargues–Fontaine geometry. It does not by itself identify C_p with $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$. That identification is the local comparison input (F1.a). At the archimedean place, the analogue is Jacquet–Langlands SLN 114 (see §48.6).

Step 2: Hecke-functoriality at each place. Local Fargues–Scholze includes Hecke-functoriality at each prime: the local Hecke algebra $\mathcal{H}_p$ acts on both sides of Φ_p^{loc} once the local comparison is supplied, and Φ_p^{loc} must be $\mathcal{H}_p$-equivariant.

Step 3: Tensor product of equivalences. Lurie HA 4.8.1 states that the tensor product in $\mathrm{Pr}^{\mathrm{L,st}}$ is functorial: a family of equivalences $\Phi_v : C_v \to \mathcal{D}_v$ produces an equivalence $\bigotimes_{v\in S} \Phi_v : \bigotimes_{v\in S} C_v \to \bigotimes_{v\in S} \mathcal{D}_v$. Applied to Φ_v^{loc} (whose existence is (F1.a)), this gives the equivalence Φ_S^{loc}.

Step 4: Tensor compatibility with Hecke. The tensor product of $\mathcal{H}_v$-equivariant functors is $\mathcal{H}_S := \otimes_{v\in S}\mathcal{H}_v$-equivariant in the appropriate sense. Hecke-functoriality across places follows from cross-place commutativity (Proposition 48.2.5).

Step 5: Spectral side decomposition. The spectral side $\mathrm{IndCoh}_{\mathrm{Nilp}}(\prod_{v\in S} \mathcal{X}_{GL_2}^{\mathrm{EG},v})$ decomposes as a tensor product of local factors because $\prod_{v\in S} \mathcal{X}_{GL_2}^{\mathrm{EG},v}$ is a product of derived formal stacks (Gaitsgory–Rozenblyum's AMS DAG monographs give continuity of $\mathrm{IndCoh}_{\mathrm{Nilp}}$ under products of derived stacks). Hence the right-hand side of (48.2) agrees with $\bigotimes_{v\in S} \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG},v})$.

Step 6: Whittaker-model compatibility. The cross-place compatibility requires checking that the Whittaker model on the automorphic side, which factorizes as a tensor product over places, matches the corresponding factorization on the spectral side. This factorization is where (BC-diamond-glue) enters: the Whittaker-model factorization is a compatibility between local Bernstein centres, exactly what (BC-diamond-glue) asserts via compatibility (b) of Theorem 48.2.7.

Thus (L_2) is not closed here. It is reduced to the local categorical comparison (F1.a) plus (BC-diamond-glue). □

Remark 48.4.2 *(finite-prime (L_2) is conditional).* For the subset of conditions involving only finite primes (no archimedean place), the tensor-product formalism is unconditional once the local categorical comparisons are supplied. Fargues–Scholze arXiv:2102.13459, Lurie HA 4.8.1, and Gaitsgory–Rozenblyum supply the local geometry, tensor functoriality, and product-continuity of $\mathrm{IndCoh}_{\mathrm{Nilp}}$. They do not prove the local comparison with the Emerton–Gee stack, nor the Whittaker compatibility encoded by (BC-diamond-glue).

48.5 Subcondition (L_3): Bernstein Centre Compatibility

Statement and Residual Content

THEOREM 48.5.1 *((L_3) is (BC-diamond-glue)).* (L_3) is equivalent to the (BC-diamond-glue) compatibility of Theorem 48.2.7.

Proof. Forward: (L_3) asserts that the local Bernstein-centre actions assemble to a global action on $\otimes'_v C_v$ compatible with restricted tensor. The global Bernstein centre $\mathcal{Z}_{\mathrm{glob}}$ must embed into the colimit $\varinjlim_S \otimes_{v\in S}\mathcal{Z}_v$; this is precisely compatibility (c) of (BC-diamond-glue).

Reverse: given (BC-diamond-glue), conditions (a), (b), (c) supply exactly the data required to construct the global action $\mathcal{Z}_{\mathrm{glob}} \curvearrowright \otimes'_v C_v$ as a filtered colimit of finite-S actions, with the compatibility required by (L_3). □

Transport of a Coherent Springer Object

THEOREM 48.5.2 *(A supplied local transport).* Let $\mathcal{S}_p$ be a coherent Springer object on its specified parameter stack Y_p, with a specified action of the local centre Z_p. Suppose an exact functor $T_p : \mathrm{Coh}(Y_p) \to \mathrm{Coh}(\mathcal{X}_p^{\mathrm{EG}})$ is supplied over compatible coefficients and preserves the required support and centre action. Then $\mathcal{F}_p = T_p\mathcal{S}_p$ is a coherent object with the transported Z_p-action.

Proof. The functor preserves coherence by its declared target, and its action on endomorphisms preserves composition and identities. The specified intertwining identifies the resulting action with the required local one. For a derived action the same assertion uses the supplied homotopy-coherent algebra map. □

Remark 48.5.3 *(The local and global comparison maps).* The coherent Springer construction of Ben-Zvi–Chen–Helm–Nadler is the source object on its own parameter stack. The functor T_p, the coefficient comparison and the arithmetic support condition are additional data; the theorem does not identify the parameter stack with the Emerton–Gee stack. Across primes, a common carrier, compatible transitions and effective coherent descent must be constructed. Agreement with the global arithmetic centre requires an equivariant comparison, beyond an equivalence of underlying categories.

Conjecture 48.5.4 *(BC-diamond-glue, concrete form).* Construct the local transports of Theorem 48.5.2, a common Selmer-derived carrier and compatible transition maps with effective coherent descent, so that the objects $\{\mathcal{F}_v\}_v$ descend to a global coherent sheaf $\mathcal{F}_{\mathrm{glob}}$ whose action on $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$ agrees, under the conjectural global arithmetic AG equivalence, with the action of the global Bernstein centre on $\mathrm{D}([GL_2])^{\text{sph-fin}}$.

Remark 48.5.5 *(domain of the residual).* Conjecture 48.5.4 is the residual content of $\mathrm{L}_{\mathrm{ACD}}$ after the reduction of Theorem 48.2.7. Its domain:

- Gluing of coherent sheaves across a product of stacks: non-formal theorem, standard techniques.
- Agreement with global Bernstein centre under conjectural global AG: non-formal theorem, requires careful adaptation of the geometric-Langlands Bernstein-centre construction (AGKRRV) to the number-field setting.
- Total condition of (BC-diamond-glue): non-formal theorem.

The full $\mathrm{L}_{\mathrm{ACD}}$ comparison additionally requires the local categorical comparisons, archimedean boundary datum and global identification.

48.6 Subcondition (L_4): Archimedean Extension

Statement

Theorem 48.6.1 *((L_4) archimedean boundary datum).* The archimedean factor $C_\infty = \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{R})])$ is modelled by the ind-completed derived category of admissible $(\mathfrak{gl}_2, O(2))$-modules of finite K-type. It carries the trivial K-spherical object as distinguished unit and extends the finite-place restricted tensor product by direct tensoring.

Proof. **Step 1: Well-definedness.** The derived category of admissible $(\mathfrak{g}, K_\infty)$-modules, where $\mathfrak{g} = \mathfrak{gl}_2(\mathbb{R})$ and $K_\infty = O(2) \subseteq GL_2(\mathbb{R})$, has the standard Harish-Chandra description (Jacquet–Langlands SLN 114 §1–3; Vogan 1981 "Representations of Real Reductive Groups"). Its ind-completion is stable and presentable. The sph-fin cut restricts to finite K_∞-type objects.

Step 2: Distinguished unit. The spherical unit at $v = \infty$ is the trivial K_∞-spherical object. Spherical principal series are not unique; they are objects of the category, not the distinguished unit.

Step 3: Tensor product extension. The restricted tensor product of Definition 48.3.1 extends naturally by including $v = \infty$ in the index set V of places: $V = \mathbb{P} \cup \{\infty\}$ with cofinite unramified subset $V^{\mathrm{unr}} = \mathbb{P} \cup \{\infty\} \setminus S_{\mathrm{ram}}$ for the given ramification set S_{ram}. The archimedean factor enters as a tensor factor in each S containing ∞ and by identity-via-distinguished-unit in S excluding ∞.

Step 4: Hecke action at infinity. The archimedean Hecke action is represented by the centre of the universal enveloping algebra $U(\mathfrak{gl}_2(\mathbb{R}))$, commuting with finite-place Hecke action by construction (both act via representation-theoretic restriction to the adelic double coset).

Step 5: Archimedean local factors. Jacquet–Langlands SLN 114 §1–3 classify the archimedean local representations of $GL_2(\mathbb{R})$ and $GL_2(\mathbb{C})$. The sph-fin subcategory is finite-type in each isotypic component; Vogan's classification gives a complete parametrization by Harish-Chandra parameters.

This proves the archimedean boundary datum. It does not construct a number-field spectral equivalence at $v = \infty$. □

Remark 48.6.2 *(archimedean spectral side).* The spectral-side analogue at $v = \infty$ is a proposed Weil-parameter stack for $W_{\mathbb{R}} = \mathbb{C}^\times \rtimes \mathbb{Z}/2$. Vogan and Langlands classify the representations. They do not give an Emerton–Gee stack at infinity, and no local categorical equivalence at infinity is asserted here.

48.7 Curve Analogy: Obstructions and Transfers

The Curve Theorem

THEOREM 48.7.1 *(de Rham geometric Langlands, AGKRRV).* For a smooth complete curve X over an algebraically closed field of characteristic zero and a reductive group G, there is an equivalence

$$\mathrm{D\text{-}mod}(\mathrm{Bun}_G(X)) \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathrm{LocSys}_G^{\mathrm{dR}}(X))$$

satisfying Hecke-functoriality, Bernstein-centre compatibility, and categorical descent over the curve. The proof combines Gaitsgory–Rozenblyum's AMS DAG monographs, Raskin's chiral principal series and D-module foundations, and the AGKRRV mathematical treatments on geometric Langlands.

Obstructions to Transport

THEOREM 48.7.2 *(obstructions to number-field transport).* The de Rham geometric-Langlands proof of Theorem 48.7.1 does not transport directly to the number-field case. The obstructions:

(Obs.1) *No archimedean place.* Geometric Langlands on a curve has no real place. (L_4) has no curve analogue and requires separate treatment (Jacquet–Langlands archimedean).

(Obs.2) *Non-smooth Emerton–Gee stack.* Number-field $\mathcal{X}^{\mathrm{EG}}_{GL_2}$ is formally algebraic but not smooth over $\mathrm{Spec}\,\mathbb{Z}$; the de Rham stack $\mathrm{LocSys}_G^{\mathrm{dR}}(X)$ is smooth in the standard geometric-Langlands range under mild hypotheses. This affects the Bernstein-centre compatibility (L_3).

(Obs.3) *Perfectoid diamonds vs ind-schemes.* Geometric Langlands uses algebraic and ind-algebraic loop spaces. Number-field local geometrisation uses perfectoid diamonds (Scholze arXiv:1709.07343). The gluing formalism differs, and the Bhatt–Lurie prismatic comparison arXiv:2201.06120 is required to bridge the two.

(Obs.4) *Integrality of Galois deformations.* De Rham local systems are geometric; number-field Galois deformations are integral (Emerton–Gee stack). The Bernstein-centre action incorporates integrality in a way the de Rham curve case does not.

COROLLARY 48.7.3 *(what the curve analogy supplies).* Under the de Rham curve proof, the following patterns survive in the number-field setting:

- (L_1) (restricted tensor product well-definedness): **formal pattern**. Raskin's construction is ∞-categorical and does not use curve-specific structure beyond existence of local categories with distinguished units.

- (L_2) (Hecke-functoriality gluing over a finite set of primes): **conditional pattern**. It applies only after the local categorical comparison is supplied. Fargues–Scholze replaces the local de Rham geometric input by diamond geometry and spectral action; the cross-place compatibility argument still needs the local comparison and (BC-diamond-glue).

The following do *not* transport:

- (L_3) (Bernstein-centre compatibility): obstructed by (Obs.2), (Obs.4). Resolution requires (BC-diamond-glue), Conjecture 48.5.4.
- (L_4) (archimedean extension): obstructed by (Obs.1). Resolution requires independent Jacquet–Langlands archimedean construction (§48.6).

48.8 Final Reduction: L_{ACD} to a Single Lemma

Statement

Theorem 48.8.1 *(L_{ACD} residual reduction). Comparison hypothesis.* L_{ACD} holds after the local categorical comparison (F1.a) and the BC-diamond-gluing compatibility lemma (Conjecture 48.5.4) are supplied.

Proof. By Theorem 48.2.1, L_{ACD} contains (L_1), (L_2), (L_3), and (L_4), together with the global identification.

(L_1) is a theorem (Corollary 48.3.4).

(L_2) is conditional: it needs the local categorical comparison (F1.a) and (BC-diamond-glue) for the cross-place Whittaker compatibility (Theorem 48.4.1, Steps 1 and 6).

(L_3) is controlled by the Bernstein-centre gluing datum (Theorem 48.5.1).

(L_4) is the archimedean boundary datum (Theorem 48.6.1).

Hence L_{ACD} reduces, in this chapter, to the conjunction of F1.a, (BC-diamond-glue), and the global identification after the formal construction of (L_1) and the archimedean datum (L_4). □

Dependency on Established Theorems

Proposition 48.8.2 *(dependency table of L_{ACD}).* The conditional reduction of L_{ACD} uses the following established theorems:

(i) Fargues–Scholze arXiv:2102.13459 (local geometrization at each prime).

(ii) Emerton–Gee arXiv:1908.07185 (local Emerton–Gee stack construction; the global target is Selmer-derived here).

(iii) Gaitsgory–Rozenblyum, *A Study in Derived Algebraic Geometry*, AMS Mathematical Surveys and Monographs 221, Vols. I–II ($(\infty, 2)$-category of correspondences, $\mathrm{IndCoh}_{\mathrm{Nilp}}$ continuity).

(iv) Raskin, *Chiral principal series categories I*, Adv. Math. 388 (2021), 107856, and *D-modules on infinite-dimensional varieties* (restricted tensor product machinery for principal-series categories).

(v) Lurie HA 4.8 (tensor products of presentable ∞-categories), 5.3 (compact generation, higher Deligne).

(vi) Scholze arXiv:1709.07343 (étale cohomology of diamonds).

(vii) Bhatt–Scholze arXiv:1905.08229 (prismatic cohomology).

(viii) Bhatt–Lurie arXiv:2201.06120 (absolute prismatic, Nygaard-filtration convention bridge).

(ix) Zhu arXiv:1603.05593 (Witt-vector affine Grassmannian).

(x) Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321 (coherent Springer theory; local Bernstein centres as coherent sheaves).

(xi) Jacquet–Langlands SLN 114 (archimedean local factors).

(xii) Vogan 1981 "Representations of Real Reductive Groups" (archimedean classification).

Together with the local categorical comparison (F1.a), (BC-diamond-glue), and the global identification, these established results constitute the primary literature input for the reduction.

Remark 48.8.3 *(geometric inputs to descent).* The twelve established theorems of Proposition 48.8.2 decompose into the following mathematical topics:

Fargues–Scholze list: (1), (6), (7). Perfectoid / diamond geometry, Fargues–Fontaine curve.

Gaitsgory–Rozenblyum list: (3), (4). DAG and $(\infty, 2)$-categorical correspondences, restricted tensor.

Lurie list: (5). Higher algebra foundations.

Emerton–Gee list: (2). Galois deformation stacks.

Bhatt–Lurie list: (8). Prismatic Nygaard bridge.

Zhu list: (9). Witt-vector Grassmannian.

Coherent Springer theory list: (10). Local Bernstein centres as coherent sheaves.

Jacquet–Langlands + Vogan list: (11), (12). Archimedean local representation theory.

The local categorical comparison, Bernstein-centre gluing, and global restricted-tensor identification remain separate mathematical inputs.

48.9 Consequence: F1 Closure Map

The Full Chain

THEOREM 48.9.1 *(F1 residual chain via* $\mathrm{L}_{\mathrm{ACD}}$*). Comparison hypothesis.* F1 (global arithmetic Arinkin–Gaitsgory, Conjecture 42.1.1) reduces to the local categorical comparison (F1.a) plus (BC-diamond-glue) (Conjecture 48.5.4).

Proof. By Corollary 43.2.3, F1 reduces to F1.a plus $\mathrm{L}_{\mathrm{ACD}}$. By Theorem 48.8.1, $\mathrm{L}_{\mathrm{ACD}}$ reduces to F1.a plus (BC-diamond-glue). The theorem identifies the residual pair {F1.a, (BC-diamond-glue)} as the obstruction visible in this reduction. □

Formal Consequences

COROLLARY 48.9.2 *(consequent form). Comparison hypothesis.* Given the local categorical comparison (F1.a), (BC-diamond-glue), F2, and the corrected arithmetic BZN comparison, the following implications hold under those hypotheses:

- F1 (global arithmetic Arinkin–Gaitsgory).
- $\mathrm{F3.BZN}^{\mathrm{Ar}}$ (arithmetic Ben-Zvi–Nadler, conditional on F1 + F2 plus the full-target/formal-loop comparison).
- The six-window placement theorem (Conjecture 41.1.1) remains conditional on the same residual chain.

Remark 48.9.3 *(comparison of the six windows).* A proof of Conjecture 41.1.1 requires F1 (hence (BC-diamond-glue)), F2 (hence the ∞-categorical Tate restricted tensor lemma F2.c), and F3 (hence $\mathrm{F3.BZN}^{\mathrm{Ar}}$). With (BC-diamond-glue) and the local comparison supplied, F1 becomes a conditional

theorem. With F2.c supplied, F2 becomes a conditional theorem. F3 then requires F3.BZN^{Ar}. The six-window placement remains conditional on these comparison inputs.

Effect on $\mathcal{V}^{\mathrm{prim}}$ Spectral Identification

Corollary 48.9.4 *($\mathcal{V}^{\mathrm{prim}}$ spectral shadow). Comparison hypothesis.* Given the local categorical comparison, (BC-diamond-glue), and the corrected arithmetic BZN full-target comparison, the spectral shadow of $\mathcal{V}^{\mathrm{prim}}$ is

$$\mathcal{V}^{\mathrm{prim}} \rightsquigarrow \mathcal{O}(L\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}).$$

The further passage to $\mathcal{O}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$ requires a constant-loop restriction or a flat-locus truncation. It is not a consequence of Hochschild trace alone.

Proof. $\mathcal{V}^{\mathrm{prim}} = \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$ (Theorem 38.5.1). Under F1, which here means the local comparison together with (BC-diamond-glue), $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}} \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$. Ben-Zvi–Nadler arXiv:0904.1247 computes $\mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})) = \mathcal{O}(L\mathcal{X}) = \mathcal{O}(\mathrm{Map}(S^1,\mathcal{X}))$ for derived stacks $\mathcal{X}$. The constant-loop map $\mathcal{X} \to L\mathcal{X}$ gives a restriction from the loop shadow to $\mathcal{O}(\mathcal{X})$. This restriction is additional data. The categorical trace supplies the loop object. □

48.10 Residual Obstructions

Obstruction Decomposition

After the reduction of Theorem 48.2.7, the residual inputs for $\mathrm{L}_{\mathrm{ACD}}$, and hence for F1, are:

- **Local categorical comparison:** the passage from the pointwise local spectral action to the local categorical equivalence used in L_2.
- **Global restricted-tensor identification:** the comparison between the restricted tensor product and the global automorphic category.
- **(BC-diamond-glue):** Conjecture 48.5.4. The central open residual, non-formal theorem. Domain: gluing of coherent Springer sheaves across a product of local Emerton–Gee stacks, plus agreement with the global Bernstein centre acting on the global automorphic category.

Prior Hypotheses

(BC-diamond-glue) is independent of the remaining open items from the arithmetic branch of Vol IV:

- F2.c (F2 residual, ∞-categorical Tate tensor): independent branch.
- Arithmetic Positselski: independent, on the P1 branch.
- Koszul–Petersson compatibility: independent, on the P3 branch.
- VB* (arithmetic Virasoro positivity): independent, on the RH branch.

(BC-diamond-glue) is central on the F1 branch only after the local comparison and the global identification are fixed.

Primary-Literature Precedents

- Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321: *local* Bernstein centres as coherent sheaves on local Emerton–Gee stacks. This is the state of the art; (BC-diamond-glue) is the global assembly of these local constructions.

- Gan–Savin: partial change on restricted tensor product of local automorphic categories, with specific compatibilities verified for certain Jacquet–Langlands transfers; the global Bernstein-centre compatibility for $GL_2/\mathbb{Q}$ remains open.
- AGKRRV 2020–2024 de Rham geometric Langlands: supplies the curve analogue of the centre-compatibility pattern. It does not prove the number-field (BC-diamond-glue) statement. The surviving pattern is documented in Corollary 48.7.3.

Remaining Descent Inputs

Condition	Mathematical form
$\mathrm{L}_{\mathrm{ACD}}$	Open descent theorem, conditional on the remaining comparisons
(L_1)	Theorem, Corollary 48.3.4
(L_2)	Conditional on a non-formal theorem and the local categorical comparison
(L_3) = (BC-diamond-glue)	Conjectural residual requiring a non-formal theorem
(L_4)	Archimedean boundary datum, without a spectral equivalence

TABLE 48.1: Descent inputs in the reduction of Theorem 48.2.7.

The Bernstein-centre and Whittaker comparisons, the local categorical comparison, and the global identification remain necessary for $\mathrm{L}_{\mathrm{ACD}}$. The stated reductions do not prove full adelic descent without these inputs.

48.11 DESCENT BOUNDARY

(i) $\mathrm{L}_{\mathrm{ACD}}$ decomposes into four disjoint subconditions (L_1)–(L_4) (Theorem 48.2.1).

(ii) (L_1) (restricted tensor well-definedness) closes unconditionally via Lurie HA 4.8 + 5.3, Raskin 2021–2022 (Theorem 48.3.2, Corollary 48.3.4).

(iii) (L_4) (archimedean extension) supplies the representation-theoretic boundary datum via Jacquet–Langlands SLN 114 + Vogan 1981 (Theorem 48.6.1).

(iv) (L_2) (Hecke-functoriality gluing) is conditional: after the local categorical comparisons are supplied it reduces to (BC-diamond-glue), via tensor product formalism + Gaitsgory–Rozenblyum continuity (Theorem 48.4.1).

(v) (L_3) is the Bernstein-centre part of (BC-diamond-glue) (Theorem 48.5.1).

(vi) $\mathrm{L}_{\mathrm{ACD}}$ reduces to local comparison, (BC-diamond-glue), the archimedean boundary datum, and the global identification (Theorem 48.8.1).

(vii) F1 (global arithmetic Arinkin–Gaitsgory) is conditional on the same residual chain (Theorem 48.9.1).

(viii) Given the residual chain, the six-window placement theorem remains conditional on the stated comparison maps. The Hochschild trace of $\mathcal{V}^{\mathrm{prim}}$ sees the loop stack; passage to the Selmer-derived structure sheaf is an extra constant-loop or flat-locus restriction (Corollary 48.9.4).

(ix) The remaining gluing and comparison hypotheses are listed in Table 48.1.

$\mathrm{L}_{\mathrm{ACD}}$ reduces from one large conjecture to a formal tensor construction, local comparison, Bernstein-centre gluing, an archimedean boundary datum, and a global identification. The structural content is a reduction, not an equivalence theorem for F1. The geometric inputs are grouped by their mathematical role (Remark 48.8.3).

The residual (BC-diamond-glue) is a single compatibility check between Ben-Zvi–Chen–Helm–Nadler's local coherent Springer sheaves and the global Bernstein centre on the global automorphic category. It is central on the F1 six-window branch of the arithmetic branch, but it is not the only hypothesis.

48.12 Forward Pointers

- Chapter 43 gives the parent reduction of F1 (Theorem 43.2.1) into sub-items (F1.a)–(F1.d). Theorem 48.2.1 refines that reduction at the adelic-descent layer.
- Chapter 41, Conjecture 41.1.1, requires the (BC-diamond-glue) and F2/F3 comparison hypotheses in Corollary 48.9.2.
- Chapter 44 contains the RH reformulation F-RH; (BC-diamond-glue) sits on the six-window-placement branch (F1–F3 structural branch in Appendix C), not the RH-closure branch (four-input RH branch). (BC-diamond-glue) controls the categorical-trace presentation of $\mathcal{V}^{\mathrm{prim}}$; the RH-closure branch (four-input RH branch) remains on a separate dependency chain.
- Appendix C, Section C.9, records $\mathrm{L}_{\mathrm{ACD}}$ on the F1 branch. After the reduction of Theorem 48.2.7, the Bernstein-centre part is (BC-diamond-glue), with visible requires a non-formal theorem.

Chapter 49

Arithmetic Ben-Zvi–Nadler Identification

The arithmetic Ben-Zvi–Nadler candidate has a sharp obstruction. The procyclic stack $B\widehat{\mathbb{Z}}$ retains only the inertia shadow of the finite-prime topology; it forgets Frobenius, Weil-group, and (φ, Γ) data. The corrected target requires the full Weil/(φ, Γ) parameter stack, with the $B\widehat{\mathbb{Z}}$ construction playing the role of a forgetful procyclic shadow.

49.1 Statement

Conjecture 49.1.1 *(F3.BZN^{Ar}, full target). Conjectural statement. (conditional beyond F1 and F2, i.e. beyond* $\mathrm{L}_{\mathrm{ACD}}$ *and (F2.c) of Theorem 43.2.1 and Theorem 43.3.1).* There should be a canonical equivalence of E_1-algebras in stable presentable ∞-categories, after replacing the inertia-only target by the full Weil/(φ, Γ) parameter stack,

$$\mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \xrightarrow{\sim} \mathcal{O}\big(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}\big)^{\mathrm{flat}},$$

where:

(i) $\mathrm{HH}_\bullet$ is the derived Hochschild trace of the E_2-monoidal ∞-category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$, with the E_2-monoidal structure supplied by F2;

(ii) $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$ is the full derived moduli stack retaining Weil-group and (φ, Γ) data at finite primes; its restriction to $B\widehat{\mathbb{Z}} = B\prod_p \mathbb{Z}_p$ is only a procyclic shadow;

(iii) the flat locus $(\cdot)^{\mathrm{flat}}$ is picked out by the Fargues–Scholze local Langlands compatibility at each prime plus the almost-everywhere-unramified condition at the archimedean place;

(iv) the structure sheaf $\mathcal{O}$ on the right is expected to pull back along the global Emerton–Gee comparison to the full parameter stack, not along the inertia-only shadow of Proposition 49.4.6.

Corollary 49.1.2 *(F3 closure under F1 + F2). Conjectural statement.* Given F1 and F2, F3 (Conjecture 42.3.1) reduces to the corrected arithmetic BZN comparison, the formal-loop compatibility, the flat-locus comparison, and the full Weil/(φ, Γ) target comparison. It is not closed by the inertia-only model.

Proof. This is the honest residual formulation. F1 and F2 supply the global spectral and E_2 inputs. The remaining inputs are the identification of the full Weil/(φ, Γ) parameter stack with the inertia shadow and the profinite formal-loop continuity required by the arithmetic Ben-Zvi–Nadler comparison. □

49.2 Comparison Table

The attempted proof of Conjecture 49.1.1 passes through five independent conditions. The independent comparison identifies which close and which yield residuals.

MKR shadow and the inertia circle. The classifying stack $B\widehat{\mathbb{Z}}$ is the classifying ∞-stack of the profinite abelian group $\widehat{\mathbb{Z}}$; its pro-étale fundamental group is $\pi_1^{\text{ét}}(B\widehat{\mathbb{Z}}) = \widehat{\mathbb{Z}}$. The Mazur–Kapranov–Reznikov (MKR) dictionary identifies $B\widehat{\mathbb{Z}}$ with the arithmetic analogue of S^1 viewed as the inertia circle of a knot complement. Closes (Proposition 49.3.3).

Loop-space identification for the inertia shadow. For an n-geometric derived stack $\mathcal{X}$, the arithmetic free loop space $L^{\text{Ar}}\mathcal{X} := \text{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ is a well-defined derived stack (Toën–Vezzosi DAG framework). For $\mathcal{X} = BGL_2$, one computes $L^{\text{Ar}}BGL_2 = \text{Hom}(\widehat{\mathbb{Z}}, GL_2)/GL_2$ as a derived quotient stack. Closes (Proposition 49.4.4).

Arithmetic transport of the Ben-Zvi–Nadler machine. Ben-Zvi–Nadler prove $\text{HH}_\bullet(\text{IndCoh}(\mathcal{X}/G)) = \mathcal{O}(L(\mathcal{X}/G))^{\text{flat}}$ over $\mathbb{C}$ with S^1 as the topological circle. The proof factors through two ingredients: (i) the Costello–Francis–Lurie identification of the Hochschild trace of a symmetric monoidal ∞-category with factorization homology over S^1; (ii) the flatness assertion cutting out ind-coherent sheaves inside functions on the loop space. Ingredient (i) extends to any framed 1-manifold, hence to $B\widehat{\mathbb{Z}}$; ingredient (ii) is supplied arithmetically by the Fargues–Scholze local equivalence at each prime. Conditional (Theorem 49.5.5).

Dunn additivity and the E_1-structure. The global Iwahori Hecke category is E_2-monoidal by F2. Dunn additivity (Lurie HA 5.1.2.2) supplies the canonical E_1-algebra structure on $\text{HH}_\bullet$ of any E_2-monoidal category, and the arithmetic Ben-Zvi–Nadler map respects this structure via the factorization-homology presentation. Closes under F2 (Proposition 49.6.1).

Full Weil/(φ, Γ) target and the $\mathcal{V}^{\text{prim}}$ pullback. The structure sheaf on the full Weil/(φ, Γ) flat target should pull back along the Emerton–Gee comparison to $\mathcal{V}^{\text{prim}}$ via the spectral-side identification of F1. The forgetful map from the Emerton–Gee stack to the inertia shadow $\text{LocSys}^{\text{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ records only the procyclic restriction; the full Frobenius and (φ, Γ) data are retained only in the complete target. Open (Theorem 49.8.2).

The independent criterion for each condition is recorded in the corresponding subsection below.

49.3 The Arithmetic Inertia Circle $B\widehat{\mathbb{Z}}$

Definition

Definition 49.3.1 *(classifying stack of profinite $\widehat{\mathbb{Z}}$).* Let $\widehat{\mathbb{Z}} = \varprojlim_n \mathbb{Z}/n\mathbb{Z} = \prod_p \mathbb{Z}_p$, the profinite completion of $\mathbb{Z}$. Its classifying ∞-stack $B\widehat{\mathbb{Z}}$ is

$$B\widehat{\mathbb{Z}} \;:=\; * \,/\, \widehat{\mathbb{Z}},$$

the derived quotient of a point by the profinite group $\widehat{\mathbb{Z}}$, formed in the ∞-category of pro-étale derived stacks over $\mathbb{Z}$. Equivalently, $B\widehat{\mathbb{Z}} = \varprojlim_n B(\mathbb{Z}/n\mathbb{Z})$ as a pro-étale limit.

Remark 49.3.2 *(two realisations).* $B\widehat{\mathbb{Z}}$ admits two useful realisations.

(i) *Galois realisation.* $B\widehat{\mathbb{Z}} = B\text{Gal}(\overline{\mathbb{F}}_q/\mathbb{F}_q)$ for any finite field $\mathbb{F}_q$; the absolute Galois group of any finite field is topologically generated by Frobenius and has profinite completion $\widehat{\mathbb{Z}}$.

(ii) *Product realisation.* Under $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$,

$$B\widehat{\mathbb{Z}} \;=\; \prod_p^{\text{proét}} B\mathbb{Z}_p.$$

The pro-étale product is taken in the ∞-category of pro-étale derived stacks (Bhatt–Scholze arXiv:1309.1198); it is well-defined because each $B\mathbb{Z}_p$ is a classifying stack of a profinite group, whose pro-étale cohomology is finitary.

MKR Dictionary and the Arithmetic S^1

Proposition 49.3.3 *(MKR dictionary for $B\widehat{\mathbb{Z}}$). Heuristic.* $B\widehat{\mathbb{Z}}$ is the arithmetic analogue of S^1 under the Mazur–Kapranov–Reznikov (MKR) dictionary:

(i) *Fundamental group.* $\pi_1^{\text{proét}}(B\widehat{\mathbb{Z}}) = \widehat{\mathbb{Z}}$, the profinite completion of $\pi_1(S^1) = \mathbb{Z}$.

(ii) *Higher homotopy.* $\pi_n(B\widehat{\mathbb{Z}}) = 0$ for $n \neq 1$; so $B\widehat{\mathbb{Z}}$ is a pro-$\mathrm{K}(\widehat{\mathbb{Z}}, 1)$, arithmetically the same homotopy type as S^1 profinitely completed.

(iii) *Cup-product structure.* Under étale cohomology $H^*(B\widehat{\mathbb{Z}}; \mathbb{Z}_\ell) = \mathbb{Z}_\ell \oplus \mathbb{Z}_\ell[-1]$ for every ℓ; this matches $H^*(S^1; \mathbb{Z}) = \mathbb{Z} \oplus \mathbb{Z}[-1]$ after pro-ℓ completion.

(iv) *Knot-complement interpretation.* Under Morishita's arXiv:0904.3399 realisation of $\operatorname{Spec} \mathbb{Z}_p$ as a knot complement with inertia circle $B\mathbb{Z}_p$, the product $B\widehat{\mathbb{Z}} = \prod_p B\mathbb{Z}_p$ is the product of all local inertia circles, i.e. the global inertia circle of $\overline{\operatorname{Spec} \mathbb{Z}}$.

Proof. (1) $\widehat{\mathbb{Z}}$ is a profinite abelian group, so $B\widehat{\mathbb{Z}}$ is a $\mathrm{K}(\widehat{\mathbb{Z}}, 1)$-space in the pro-étale topology. Taking the pro-étale fundamental group of a classifying stack of a profinite group returns the group itself (Bhatt–Scholze arXiv:1309.1198 Lem. 7.4.3).

(2) A classifying stack of an abelian group G has $\pi_n = G$ if $n = 1$ and $\pi_n = 0$ otherwise; this is the general fact for classifying stacks of discrete groups, transported to the pro-étale setting via pro-discrete presentation of $\widehat{\mathbb{Z}}$.

(3) $H^*(B\widehat{\mathbb{Z}}; \mathbb{Z}_\ell) = H^*_{\text{cts}}(\widehat{\mathbb{Z}}; \mathbb{Z}_\ell) = \mathbb{Z}_\ell[\epsilon]/(\epsilon^2)$ with ϵ of degree 1 (continuous group cohomology of $\widehat{\mathbb{Z}}$ coefficient in $\mathbb{Z}_\ell$; classical). This matches $H^*(S^1; \mathbb{Z}_\ell) = \mathbb{Z}_\ell[\epsilon]/(\epsilon^2)$.

(4) Morishita's arXiv:0904.3399 identifies the local inertia subgroup of $W_{\mathbb{Q}_p}$ at a prime p with the fundamental group of a small circle linking the "knot" corresponding to p; its classifying stack is $B\mathbb{Z}_p$ (or $BO_p^\times$ in the ramified extension, whose connected component is $B\mathbb{Z}_p$). Product over all primes gives $B\widehat{\mathbb{Z}}$ as the global inertia classifying stack. □

Remark 49.3.4 *(the archimedean place).* The archimedean place ∞ of $\overline{\operatorname{Spec} \mathbb{Z}}$ carries local inertia equal to the fixed-at-∞ subgroup of $W_{\mathbb{R}}$, which is $W_{\mathbb{C}} = \mathbb{C}^\times$; its profinite completion is trivial. Hence $B\widehat{\mathbb{Z}}$ captures only the finite-place inertia, which suffices for the Hochschild trace computation at hand because $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is defined over the finite adeles.

The Procyclic Carrier and Its Arithmetic Interpretation

Procyclic geometry and arithmetic topology. $B\widehat{\mathbb{Z}}$ is defined in the Bhatt–Scholze pro-étale formalism (arXiv:1309.1198). The arithmetic-topology interpretation is discussed by Morishita arXiv:0904.3399, Mazur 2000 Selecta, and Kapranov–Reznikov 1996.

Obstruction 2 (conventions). Pro-étale fundamental group convention: Bhatt–Scholze; matches Morishita's profinite inertia convention.

Obstruction 3 (ambient categories). $B\widehat{\mathbb{Z}}$ is a pro-étale ∞-stack. Derived stacks in the Toën–Vezzosi DAG setting admit pro-étale enhancements (Toën DAG §2.3); so $B\widehat{\mathbb{Z}}$ sits in the same ambient category as the Emerton–Gee stack.

Obstruction 4 (missing hypothesis). None: the definition requires only that $\widehat{\mathbb{Z}}$ be a profinite group, which is classical.

Scope of the analogy. The procyclic carrier alone does not supply an arithmetic trace equivalence.

The MKR dictionary condition closes as a definition of the procyclic shadow; its arithmetic interpretation remains heuristic.

49.4 Arithmetic Free Loop Space

Definition

Definition 49.4.1 *(arithmetic free loop space).* Let $\mathcal{X}$ be an n-geometric derived pro-étale stack over $\mathbb{Z}$ (Toën–Vezzosi, DAG framework). The *arithmetic free loop space of* $\mathcal{X}$ is the internal mapping stack

$$L^{\mathrm{Ar}}\mathcal{X} \;:=\; \mathrm{Map}\big(B\widehat{\mathbb{Z}}, \mathcal{X}\big),$$

the internal Hom in the ∞-category of derived pro-étale stacks.

Remark 49.4.2 *(analogy with complex free loop space).* Over $\mathbb{C}$, the free loop space is $L\mathcal{X} = \mathrm{Map}(S^1, \mathcal{X})$; since $S^1 \simeq B\mathbb{Z}$, this is $\mathrm{Map}(B\mathbb{Z}, \mathcal{X})$. Arithmetically we replace $\mathbb{Z}$ by its profinite completion $\widehat{\mathbb{Z}}$, reflecting the fact that all arithmetic loops (= monodromy actions) are profinite (Grothendieck's étale fundamental group is always profinite).

Remark 49.4.3 *(existence as a derived stack).* That $L^{\mathrm{Ar}}\mathcal{X}$ is a well-defined derived pro-étale stack follows from Toën–Vezzosi DAG V Prop. 4.1 (internal mapping stacks in DAG), applied to the cocartesian closed structure on the ∞-topos of pro-étale derived stacks (Bhatt–Scholze arXiv:1309.1198 §7). Explicitly, the hom $S \mapsto \mathrm{Map}_{\mathrm{proét}}(S \times B\widehat{\mathbb{Z}}, \mathcal{X})$ satisfies pro-étale descent in S by the standard axiom.

Computation for $\mathcal{X} = BGL_2$

PROPOSITION 49.4.4 *($L^{\mathrm{Ar}}BGL_2$).* There is a canonical equivalence of derived pro-étale stacks

$$L^{\mathrm{Ar}}\,BGL_2 \;\simeq\; \mathrm{Hom}^{\mathrm{cts}}\big(\widehat{\mathbb{Z}}, GL_2\big) \;/\; GL_2,$$

where GL_2 acts on $\mathrm{Hom}^{\mathrm{cts}}(\widehat{\mathbb{Z}}, GL_2)$ by conjugation and $\mathrm{Hom}^{\mathrm{cts}}$ denotes continuous group homomorphisms.

Proof. By definition of BG for a group scheme G, a map $B\widehat{\mathbb{Z}} \to BGL_2$ of classifying stacks of a discrete and a group-scheme object is a continuous group homomorphism $\widehat{\mathbb{Z}} \to GL_2$ up to GL_2-conjugation (which acts on the target by inner automorphism, corresponding to gauge transformations of the loop-space description). In derived pro-étale geometry this upgrades to the derived quotient $\mathrm{Hom}^{\mathrm{cts}}(\widehat{\mathbb{Z}}, GL_2)/GL_2$, where the action is by conjugation.

Explicitly, $\mathrm{Map}(B\widehat{\mathbb{Z}}, BGL_2)$ is the ∞-groupoid whose objects are GL_2-torsors on $B\widehat{\mathbb{Z}}$. Such a torsor is equivalent to a representation $\widehat{\mathbb{Z}} \to GL_2$ of the fundamental group (= $\widehat{\mathbb{Z}}$ by Proposition 49.3.3 (1)) modulo GL_2-equivalence. □

COROLLARY 49.4.5 *(identification with arithmetic GL_2-local systems on $B\widehat{\mathbb{Z}}$).*

$$L^{\mathrm{Ar}}\,BGL_2 \;=\; \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}\big(B\widehat{\mathbb{Z}}\big) \;=\; \Big\{(\rho_p)_p \in \prod_p \mathrm{Hom}(\mathbb{Z}_p, GL_2) \;/\; \mathrm{conj}\Big\},$$

an arithmetic analogue of the classical character variety.

Proof. By Proposition 49.4.4 and Remark 49.3.2 (2), $\mathrm{Hom}^{\mathrm{cts}}(\widehat{\mathbb{Z}}, GL_2) = \mathrm{Hom}^{\mathrm{cts}}(\prod_p \mathbb{Z}_p, GL_2)$. Since GL_2 is algebraic (hence its topology is discrete on the points-functor but ℓ-adic on ℓ-adic points), a continuous homomorphism from $\prod_p \mathbb{Z}_p$ factors uniquely through a finite product for any finite-image representation, and in general decomposes as $(\rho_p)_p$ with almost all ρ_p unramified (i.e. trivial on $\mathcal{O}_p^\times$ under the local reciprocity map); this is the adelic restricted-product structure on $\widehat{\mathbb{Z}}$. □

The Selmer Inertia-Shadow Morphism

Proposition 49.4.6 *(Selmer target to inertia shadow).* There is an expected forgetful morphism of pro-étale derived stacks

$$\iota^{\mathrm{Sel}} : \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}} \longrightarrow \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$$

which, at each prime p, should be the composition of the Emerton–Gee stack's universal Galois representation (φ,Γ)-module $\to GL_2$-rep of the inertia subgroup of $W_{\mathbb{Q}_p}$, followed by restriction to $\mathbb{Z}_p \subset W_{\mathbb{Q}_p}$ (the wild-tame inertia quotient composed with reciprocity).

Proof. At each prime p, the Emerton–Gee stack $\mathcal{X}^{\mathrm{EG},p}_{GL_2}$ parametrises (φ,Γ)-modules of rank 2 over the period ring of $\mathbb{Q}_p$. Each such module determines, via local reciprocity, a representation $W_{\mathbb{Q}_p} \to GL_2$ of the Weil group; its restriction to the inertia subgroup $I_p \subset W_{\mathbb{Q}_p}$, composed with the natural map $I_p \twoheadrightarrow \mathbb{Z}_p$ (quotient by wild inertia), is a representation $\mathbb{Z}_p \to GL_2$, hence a point of $\mathrm{Hom}^{\mathrm{cts}}(\mathbb{Z}_p, GL_2)/GL_2$.

Globally, the assembly factors through the Selmer-derived stack: the local inertia-shadow maps must be compatible with one global representation, fixed determinant, and the chosen local Selmer conditions. It is not a product or filtered colimit of local maps. □

The Flat Locus

Definition 49.4.7 *(provisional flat locus).* The *provisional flat locus* $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})^{\mathrm{flat}} \subset \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ is the procyclic shadow of the full Fargues–Scholze or Emerton–Gee flat parameter space; the full space retains Frobenius, Weil, and (φ,Γ) data beyond what the procyclic shadow records. The provisional locus is cut out by:

(i) *Fargues–Scholze local compatibility.* At each prime p, $\rho_p : \mathbb{Z}_p \to GL_2$ extends to a representation of $W_{\mathbb{Q}_p}$ coming from a continuous (φ,Γ)-module (Fargues–Scholze arXiv:2102.13459 Thm. I.9).

(ii) *Almost-everywhere unramified condition.* For all but finitely many primes p, ρ_p is unramified (i.e. trivial on the maximal pro-p subgroup of $\mathbb{Z}_p$).

Remark 49.4.8 *(flat in the arithmetic sense).* The adjective "flat" in this context does not refer to flatness of modules; it refers to the arithmetic analogue of *flat connections* in the complex Ben-Zvi–Nadler setting. Over $\mathbb{C}$, the flat locus of $\mathrm{LocSys}_G(X)$ for a complex variety X picks out representations of $\pi_1(X)$ that are compatible with the algebraic D-module structure, i.e. come from flat connections. Arithmetically, the analogue is: representations of the fundamental group (= $\widehat{\mathbb{Z}}$) that come from (φ,Γ)-module data, which is the correct analogue of a "flat connection in the arithmetic topology".

Proposition 49.4.9 *(image of the Selmer inertia-shadow morphism).* Conjectural statement. The full Selmer comparison morphism is expected to factor through the flat full-parameter locus. The forgetful inertial shadow ι^{Sel} of Proposition 49.4.6 factors through the flat locus

$$\iota^{\mathrm{Sel}} : \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}} \longrightarrow \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})^{\mathrm{flat}}$$

as a map of pro-étale derived stacks. Whether this inertia-only restriction is a closed immersion is an open question: on points, the Colmez–Fontaine theorem shows the full (φ, Γ) data carries strictly more information than the procyclic restriction.

Proof. Factorization through the flat locus: by construction, each (φ, Γ)-module gives rise to a $W_{\mathbb{Q}_p}$-representation (Fontaine's theorem, reviewed in Emerton–Gee arXiv:1908.07185 §1.2); restriction to inertia supplies a $\mathbb{Z}_p$-representation extending compatibly, which is the Fargues–Scholze local compatibility condition (1). The almost-everywhere-unramified condition (2) is imposed in the Selmer datum by requiring unramified local conditions outside the finite set S.

Closed immersion residual. Locally at each prime, the full (φ, Γ) or Weil parameter retains Frobenius data beyond the inertia restriction. The map $\iota^{\mathrm{EG},p}$ is surjective onto the locally-admissible $\mathbb{Z}_p$-representations (those coming from (φ, Γ)-modules) by Fargues–Scholze Thm. I.9.6, and is injective on $\mathbb{C}$-points by the standard fact that a (φ, Γ)-module is determined by its Weil–Deligne or (φ, Γ) data up to finite data (Colmez–Fontaine 2000). The inertia restriction forgets Frobenius and unramified data; the closed-immersion property accordingly belongs to the full Weil/(φ, Γ) target. □

Loop-Space Carriers and Comparison Maps

Geometric carriers. Toën's derived mapping stacks and Bhatt–Scholze's pro-étale geometry (arXiv:1309.1198) provide the mapping-space settings. Emerton–Gee arXiv:1908.07185 and Fargues–Scholze arXiv:2102.13459 supply arithmetic deformation and spectral-action data; identifying these with a loop-space model requires the comparison morphism.

Obstruction 2 (conventions). (φ, Γ)-module convention: Fontaine. Local reciprocity convention: Artin arithmetic normalisation sends a uniformizer to arithmetic Frobenius; geometric Frobenius is its inverse and acts by p^{-1} on the Tate line. These are the Emerton–Gee conventions; they match Fargues–Scholze after the standard twist.

Obstruction 3 (ambient categories). $L^{\mathrm{Ar}} BGL_2$ and $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ both live in pro-étale derived stacks; the morphism ι^{Sel} is in the same ambient ∞-category as the target.

Obstruction 4 (missing hypothesis). The almost-everywhere-unramified condition is essential; without it the product $\prod_p \mathrm{Hom}(\mathbb{Z}_p, GL_2)/GL_2$ is not locally of finite type. This is an explicit hypothesis in Definition 49.4.7. *hypothesis explicit.*

Obstruction 5 (false functoriality). The Emerton–Gee morphism is functorial in the chain $GL_2 \to GL_2$-rep $\to \mathbb{Z}_p$-rep $\to \widehat{\mathbb{Z}}$-rep, compatible with conjugation and with the inductive limit over finite sets of primes.

Obstruction 6 (unproved equivalence). The closed-immersion property requires the full Weil/(φ, Γ) target: $B\widehat{\mathbb{Z}}$ records only the procyclic shadow, omitting Frobenius and unramified data retained by the Colmez–Fontaine datum. **Residual: full target comparison.**

The loop-space condition closes for the procyclic mapping-stack computation. The Emerton–Gee comparison to the full arithmetic target remains open.

49.5 The Hochschild-Trace Theorem (Arithmetic)

Classical Ben-Zvi–Nadler

Theorem 49.5.1 *(Ben-Zvi–Nadler 2009, Theorem 1.1).* For a complex reductive group G, there is an equivalence of E_1-algebras

$$\mathrm{HH}_\bullet\big(\mathrm{D}(G/G)\big) \;\simeq\; \mathcal{O}\big(\mathrm{LocSys}_G(S^1)\big)^{\mathrm{flat}},$$

where G/G is the adjoint quotient, $\mathrm{LocSys}_G(S^1) = G/G$ as a derived stack, and the flat locus consists of flat G-connections (= all connections on S^1, i.e. the whole space).

Remark 49.5.2 *(structure of the classical proof).* Ben-Zvi–Nadler's proof has two ingredients.

(i) *Costello–Francis–Lurie.* For a symmetric monoidal ∞-category $\mathcal{C}$, $\mathrm{HH}_\bullet(\mathcal{C}) = \int_{S^1} \mathcal{C}$, factorization homology of $\mathcal{C}$ over S^1 (Costello 2004; Francis arXiv:1206.5522; Lurie HA 5.5.3).

(ii) *Loop-space identification.* For $\mathcal{C} = \mathrm{D}(\mathcal{X})$ the ∞-category of quasi-coherent sheaves on a derived stack $\mathcal{X}$, factorization homology over S^1 equals functions on the free loop space $\mathcal{O}(L\mathcal{X})$, with a flatness cut supplied by the requirement that functions come from quasi-coherent sheaves rather than arbitrary pro-coherent data.

Both ingredients admit arithmetic extensions; the content of the arithmetic Ben-Zvi–Nadler theorem is that these extensions match.

Arithmetic Extension of Costello–Francis–Lurie

Theorem 49.5.3 *(arithmetic factorization homology).* Conjectural statement. For an E_2-monoidal stable presentable ∞-category $\mathcal{C}$ in the ∞-category of pro-étale derived stacks, there is a canonical equivalence

$$\mathrm{HH}_\bullet(\mathcal{C}) \;\simeq\; \int_{B\widehat{\mathbb{Z}}} \mathcal{C}$$

as E_1-algebras, where the right-hand side is factorization homology of $\mathcal{C}$ over the pro-étale classifying stack $B\widehat{\mathbb{Z}}$ equipped with its cyclotomic/profinite orientation datum.

Proof. Factorization homology $\int_M \mathcal{C}$ is defined (Francis arXiv:1206.5522) as the left Kan extension along the inclusion of framed disks into framed manifolds, applied to $\mathcal{C}$ viewed as an E_n-algebra. The framed 1-manifold case requires an E_1-algebra structure on $\mathcal{C}$, which is supplied by the E_2-monoidal structure via Dunn additivity.

The Costello–Francis–Lurie theorem (Lurie HA 5.5.3.11) computes $\mathrm{HH}_\bullet(\mathcal{C}) = \int_{S^1} \mathcal{C}$ for a symmetric monoidal stable ∞-category $\mathcal{C}$, with S^1 the standard topological circle. For the arithmetic extension, S^1 is replaced by $B\widehat{\mathbb{Z}}$, which is a cyclotomically oriented pro-étale classifying stack (Proposition 49.3.3: $B\widehat{\mathbb{Z}}$ has the same homotopy type as S^1 pro-ℓ-completed). The framing is provided by the natural orientation on $\widehat{\mathbb{Z}}$ as a profinite abelian group. Frobenius acts through the Weil quotient and is recorded separately by the full $\mathrm{Weil}/(\varphi, \Gamma)$ target; it is not identified with an inertia generator.

The computation

$$\int_{B\widehat{\mathbb{Z}}} \mathcal{C} \;=\; \varinjlim_{n} \int_{B(\mathbb{Z}/n\mathbb{Z})} \mathcal{C}$$

follows from the pro-étale limit presentation $B\widehat{\mathbb{Z}} = \varprojlim_n B(\mathbb{Z}/n\mathbb{Z})$ (Definition 49.3.1) combined with the fact that factorization homology converts pro-étale limits of framed manifolds into colimits of factorization homology (by the left-Kan-extension definition).

Each $\int_{B(\mathbb{Z}/n\mathbb{Z})} C$ is the $\mathbb{Z}/n\mathbb{Z}$-Hochschild trace of C (Lurie HA 5.5.3 applied to the finite cyclic group); equivalently, the $\mathbb{Z}/n\mathbb{Z}$-coinvariants of the cyclic object computing $\mathrm{HH}_\bullet(C)$. The limit over n under divisibility recovers $\mathrm{HH}_\bullet(C)$ itself, because the cyclic object's $\mathbb{Z}$-coinvariants are $\mathrm{HH}_\bullet$ (classical) and pro-completion over n does not alter the value on finite-type categories. □

Remark 49.5.4 *(The trace and completion comparison).* Factorization homology supplies a trace construction on its declared coefficient category; pro-étale completion changes the carrier and its limiting diagrams. The arithmetic comparison must specify the transition maps and prove that the trace commutes with the required completion. The factorization-homology and pro-étale frameworks alone do not supply that interchange.

Arithmetic Loop-Space Identification

THEOREM 49.5.5 *(arithmetic loop-space identification, core HH identity).* Conjectural statement. Let $\mathcal{X}$ be a derived pro-étale formal algebraic stack, Noetherian, with $C = \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ the ∞-category of ind-coherent sheaves with nilpotent singular support. Then

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;\simeq\; \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}\big)^{\mathrm{flat}}$$

as E_1-algebras, where $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ and the flat locus on the right is cut out by the condition that functions extend to global sections of the pro-ind-coherent structure sheaf.

Proof. We combine Theorem 49.5.3 with an arithmetic version of Ben-Zvi–Nadler's ind-coherent-sheaves/free-loop-space identification.

Step 1: HH to factorization homology. $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ is an E_2-monoidal stable presentable ∞-category (by the convolution structure on ind-coherent sheaves on derived stacks; Gaitsgory–Rozenblyum Vol. II Ch. IV). By Theorem 49.5.3,

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;=\; \int_{B\widehat{\mathbb{Z}}} \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}).$$

Step 2: Factorization homology to loop-space functions. Ben-Zvi–Francis–Nadler arXiv:0805.0157 (integral transforms and categorical trace) establish

$$\int_M \mathrm{IndCoh}(\mathcal{X}) \;=\; \mathcal{O}\big(\mathrm{Map}(M, \mathcal{X})\big)$$

for M a framed compact 1-manifold and $\mathcal{X}$ a derived stack in the complex setting. The proof goes through a *spatial-loop-space* computation: factorization homology of ind-coherent sheaves on $\mathcal{X}$ over M is functions on the mapping stack $\mathrm{Map}(M, \mathcal{X})$, via the pull-push along the correspondence $\mathcal{X} \leftarrow \mathrm{Map}(M, \mathcal{X}) \to \mathrm{Map}(M, \mathcal{X})$ using IndCoh-functoriality. This proof uses only derived-geometry inputs: Toën–Vezzosi's DAG, Gaitsgory–Rozenblyum's Vol. II integral-transform calculus, and Lurie's $(\infty, 2)$-category of correspondences. None of these are specific to the complex setting; all admit pro-étale extensions.

Applied to $M = B\widehat{\mathbb{Z}}$ with the arithmetic DAG framework, this yields

$$\int_{B\widehat{\mathbb{Z}}} \mathrm{IndCoh}(\mathcal{X}) \;=\; \mathcal{O}\big(\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})\big) \;=\; \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}\big).$$

Step 3: Nilpotent singular support and flatness cut. The restriction to nilpotent singular support on the source side translates, under the pull-push, into a flatness constraint on the target side: functions on the loop space must extend to the pro-ind-coherent structure sheaf, i.e. admit a lift from the mapping stack to its nilpotent-singular-support refinement. Over $\mathbb{C}$ this is precisely the Ben-Zvi–Nadler flat-connection locus; arithmetically it is the condition that the loop-space function is pulled back from an object of $\mathrm{IndCoh}_{\mathrm{Nilp}}$, which is a closed subcondition by Arinkin–Gaitsgory arXiv:1201.6343 for singular support applied to pro-étale derived stacks.

Step 4: E_1-algebra structure compatibility. The E_1-algebra structure on $\mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}))$ comes from Dunn additivity applied to the E_2-monoidal structure (Lurie HA 5.1.2.2). On the right-hand side, the E_1-algebra structure on $\mathcal{O}(L^{\mathrm{Ar}}\mathcal{X})$ comes from the natural pairing of loops (composition of paths in $B\widehat{\mathbb{Z}}$) lifted to functions. The equivalence (49.5.5) is compatible with these E_1-structures because the factorization-homology model encodes the E_1-structure via the 1-dimensional factorization structure on $B\widehat{\mathbb{Z}}$. □

Remark 49.5.6 *(prismatic-Nygaard convention bridge).* The bridge between the pro-étale topology on $B\widehat{\mathbb{Z}}$ and the de Rham-style loop-space functions on $\mathcal{X}^{\mathrm{EG}}$ uses the Bhatt–Lurie prismatic-Nygaard filtration arXiv:2201.06120, which aligns pro-étale and de Rham conventions at the level of the arithmetic cotangent complex. The role is identical to its role in (F1) Obstruction 2 (Section 43.2).

Source Comparison: Arithmetic Transport of Ben-Zvi–Nadler

Trace and geometric transport. Factorization homology (Francis, arXiv:1206.5522), the Hochschild trace (Lurie, *Higher Algebra*, Section 5.5.3), and integral transforms (Ben-Zvi–Francis–Nadler, arXiv:0805.0157) give their stated categorical constructions. Arithmetic transport additionally needs the coefficient, singular-support and completion maps to the chosen Emerton–Gee or full Weil target.

Obstruction 2 (conventions). Factorization-homology convention: Francis (left-Kan-extension from framed disks). Singular-support convention: Arinkin–Gaitsgory. Pro-étale convention: Bhatt–Scholze. Prismatic-Nygaard bridge: Bhatt–Lurie. Their compatibility is part of the specified arithmetic comparison.

Obstruction 3 (ambient categories). E_2-monoidal stable presentable ∞-categories in pro-étale derived geometry. Factorization homology, mapping stacks, and IndCoh all live in this ambient $(\infty, 2)$-category (Gaitsgory–Rozenblyum).

Obstruction 4 (missing hypothesis). Noetherianness and derived formal algebraic stack structure on $\mathcal{X}$ are required to apply Arinkin–Gaitsgory singular support. The local Emerton–Gee stacks supply the local formal input (Emerton–Gee arXiv:1908.07185 Thm B.0.1), but the corrected global target is Selmer-derived. Its Noetherian and singular-support properties are additional conditional hypotheses.

Obstruction 5 (false functoriality). The arithmetic Ben-Zvi–Nadler map is constructed as an E_1-algebra map via the factorization-homology presentation, preserving all relevant structure.

Obstruction 6 (unproved equivalence). Step 2 invokes Ben-Zvi–Francis–Nadler arXiv:0805.0157 in the pro-étale setting; the pro-étale extension is not explicitly written in the 2009 paper but is a formal

consequence of the setup, since all inputs (DAG, correspondences, integral transforms) are topology-agnostic. This formal extension is not in the literature and must be proved as the R1.formal.b continuity theorem. **Residual: profinite formal-loop continuity.**

The arithmetic transport condition is conditional. The pro-étale lift of Ben-Zvi–Francis–Nadler and the compatibility with formal Noetherian Emerton–Gee stacks are residual inputs.

49.6 Dunn Additivity and E_1-Structure

PROPOSITION 49.6.1 *(Dunn additivity for the global Hecke category). (conditional on F2).* Given F2 (the perfectoid E_2-enhancement; see Theorem 43.3.1), the global Iwahori Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is E_2-monoidal, and its Hochschild trace $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$ carries a canonical E_1-algebra structure obtained by Dunn additivity from the E_2-structure.

Proof. Dunn additivity (Lurie HA 5.1.2.2): for an E_2-monoidal stable presentable ∞-category C, $\mathrm{HH}_\bullet(C)$ is an E_1-algebra in stable presentable ∞-categories, with the E_1-structure induced by the E_2-monoidal convolution on C. The E_2-monoidal structure on $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is supplied by F2: the perfectoid BD Grassmannian with its two-dimensional factorization structure induces an E_2-monoidal structure on each local Hecke category (Theorem 43.3.1 (F2.a), (F2.b)), and the ∞-categorical Tate restricted tensor product (F2.c) assembles these into a global E_2-monoidal category.

Applied to $C = \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$, Dunn additivity gives the E_1-algebra structure on $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}})$. □

Remark 49.6.2 *(domain of F2-conditionality).* The conditionality on F2 is narrow: it enters only through the E_2-structure on the global Hecke category, which is precisely what F2 supplies. Without F2, the Hochschild trace is still defined (as a stable ∞-category) but its natural E_1-algebra structure requires the E_2-enhancement to avoid an ad hoc choice.

49.7 Main Theorem

THEOREM 49.7.1 *(F3.BZN^{Ar}, conditional on F1 and F2).* Conjectural statement. *(conditional on F1, F2, and the full-target/formal-loop comparison).* There should be a canonical equivalence of E_1-algebras

$$\Psi^{\mathrm{BZN,Ar}} : \mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \xrightarrow{\sim} \mathcal{O}\big(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}\big)^{\mathrm{flat}}.$$

Proof. The following is a conditional strategy; each step names its hypothesis explicitly.

Step 1: F1 identifies the Hecke category with $\mathrm{IndCoh}_{\mathrm{Nilp}}$ **of the Selmer-derived stack.** If F1 is proved after the local comparison and adelic descent residuals, it gives

$$\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}} \simeq \mathrm{D}([GL_2])^{\text{sph-fin}} \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}\big).$$

Here the first equivalence is the standard identification of the global Iwahori Hecke category with the sph-finite automorphic category (Bezrukavnikov arXiv:1209.0403 for local, lifted globally via restricted tensor product); the second is F1 itself.

Step 2: F2 supplies the E_2**-structure.** If F2 is proved after the local mixed-characteristic E_2 input and (F2.c): $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is E_2-monoidal, with the equivalence of Step 1 respecting the E_2-structure (both sides are E_2-monoidal and the equivalence is E_2-monoidal by functoriality of F1).

Step 3: Apply the arithmetic HH identity. If Theorem 49.5.5 is proved for $\mathcal{X} = \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ with the required formal-Noetherian hypotheses, it yields

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})\big) \;\simeq\; \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}\big)^{\mathrm{flat}}.$$

Step 4: Full Weil/(φ,Γ) target comparison. The required comparison involves a morphism from the procyclic loop space to the full Weil/(φ,Γ) target. $\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$ is the procyclic shadow of the arithmetic loop problem; the target $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ records only the inertia restriction, while the full Weil group data lives in $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$. The required morphism is:

$$L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}} \longrightarrow \mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2},$$

whose pullback on flat functions must identify $\mathcal{O}(L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})^{\mathrm{flat}}$ with $\mathcal{O}(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2})^{\mathrm{flat}}$. This is the full-target/formal-loop comparison named in the statement.

If Steps 1–4 are all supplied, concatenation gives:

$$\begin{aligned}\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) &\overset{\mathrm{F1}}{\simeq} \mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}))\\ &\overset{\text{arith BZN}}{\simeq} \mathcal{O}(L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})^{\mathrm{flat}}\\ &\simeq \mathcal{O}(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2})^{\mathrm{flat}}.\end{aligned}$$

Each equivalence preserves the E_1-algebra structure (the first by F1 functoriality, the second by Theorem 49.5.5, the third by the still-open full-target/formal-loop comparison). The composition would be $\Psi^{\mathrm{BZN,Ar}}$.

The proof therefore leaves exactly the residuals listed in the statement: F1, F2, formal-loop continuity, and full-target pullback. □

Remark 49.7.2 *(Procyclic definition and conditional comparison).* The procyclic shadow is defined independently of F2. Given the E_2-structure required by F2, Dunn additivity gives the stated operadic consequence. The arithmetic Ben-Zvi–Nadler machinery, specifically Theorem 49.5.3, Theorem 49.5.5, Proposition 49.4.6, Proposition 49.4.9, remains conjectural until the full Weil/(φ,Γ) target and formal-loop continuity are established.

49.8 Consequence: F3 Closure under F1 + F2

Theorem 49.8.1 *(F3 theorem under F1 + F2).* Conjectural statement. Assume F1 (equivalently, $\mathrm{L}_{\mathrm{ACD}}$) and F2 (equivalently, (F2.c)). Then F3 (arithmetic Ben-Zvi–Nadler, Conjecture 42.3.1) has as its remaining input the corrected BZN comparison against the full Weil/(φ,Γ) target.

Proof. F3 asserts the E_1-algebra equivalence $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \xrightarrow{\sim} \mathcal{V}^{\mathrm{prim}}$. The displayed conjecture Theorem 49.7.1 would give the Hochschild side as functions on the full Weil/(φ,Γ) flat target. F1 would then identify the Emerton–Gee structure sheaf with $\mathcal{V}^{\mathrm{prim}}$. The corrected BZN comparison and the full-target pullback are the remaining inputs; their supply closes F3. □

THEOREM 49.8.2 *(identification of structure sheaf pullback with $\mathcal{V}^{\mathrm{prim}}$). (conditional on F1 and the full-target comparison).* The pullback of the structure sheaf on the full Weil/(φ, Γ) flat target along the Emerton–Gee comparison is expected to equal $\mathcal{V}^{\mathrm{prim}}$:

$$\iota^{\mathrm{EG},*}\mathcal{O} \;=\; \mathcal{V}^{\mathrm{prim}}.$$

Proof. By F1 (Conjecture 42.1.1), the spectral-side reading identifies $\mathcal{V}^{\mathrm{prim}}$ with the structure sheaf of the Emerton–Gee stack. The full-target comparison requires that the map from Emerton–Gee to the Weil/(φ, Γ) flat target has the required pullback on structure sheaves; the inertia-only map to $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ records only the procyclic restriction, and the full Weil group data must enter through the complete target. □

Dunn Additivity and Full-Target Pullback

Dunn additivity and E_1-structure.

Operadic input. Lurie HA 5.1.2 supplies Dunn additivity. Its use here requires the stated E_2-monoidal structure; it does not construct the perfectoid geometric input of F2.

Obstruction 2 (conventions). E_n-operad convention: Lurie HA (little cubes). E_2-monoidal category convention matches Fresse's operadic conventions via the Dunn–Lurie theorem.

Obstruction 3 (ambient categories). E_2-monoidal stable presentable ∞-categories in pro-étale derived geometry. Lurie HA applies unchanged in this ambient category.

Obstruction 4 (missing hypothesis). Stability and presentability of $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ are supplied by Bezrukavnikov's mixed derived category at each prime (stable, presentable) plus the ∞-categorical Tate restricted tensor product preserving these properties (part of (F2.c)).

Obstruction 5 (false functoriality). Dunn additivity is a natural transformation of $(\infty, 2)$-functors, functorial in C.

Scope. The operadic conclusion uses the stated categorical structures.

The Dunn additivity condition closes under F2.

Full Weil/(φ, Γ) target and $\mathcal{V}^{\mathrm{prim}}$ pullback.

Pullback input. Pullback along closed immersions: Emerton–Gee arXiv:1908.07185 (construction of the global stack) and standard ind-coherent-sheaf pullback functoriality (Gaitsgory–Rozenblyum). F1 supplies the spectral-side reading of $\mathcal{V}^{\mathrm{prim}}$.

Obstruction 2 (conventions). Structure-sheaf pullback convention matches the standard adjunction pullback ι^* left adjoint to pushforward ι_*; in the ind-coherent setting (Gaitsgory–Rozenblyum) this is a shift-compatible convention.

Obstruction 3 (ambient categories). Ind-coherent sheaves on ind-formal algebraic stacks, Noetherian, with nilpotent singular support (Arinkin–Gaitsgory). Emerton–Gee stack satisfies all three constraints.

Obstruction 4 (missing hypothesis). The identification of $\mathcal{V}^{\mathrm{prim}}$ with the Emerton–Gee structure sheaf requires F1 (spectral-side reading). *hypothesis explicit as F1.*

Obstruction 5 (false functoriality). The pullback $\iota^{\mathrm{EG},*}$ is the standard functoriality, which preserves structure sheaves (trivially: $\iota^* \mathcal{O}_Y = \mathcal{O}_X$ for any morphism $\iota\colon X \to Y$).

Obstruction 6 (unproved equivalence). The identification of $\mathcal{V}^{\mathrm{prim}}$ with the Emerton–Gee structure sheaf is part of F1's content (spectral-side reading of the arithmetic Langlands equivalence sends the trivial automorphic side object to the structure sheaf). Classical for local Fargues–Scholze; F1 globalises. *Conditional on F1.*

The full-target pullback condition closes under F1.

49.9 Trace Constructions and Arithmetic Comparison Data

The comparison path for Theorem 49.7.1.

Factorization Homology and Categorical Traces

The derivation of Theorem 49.7.1 above uses:

- Francis arXiv:1206.5522 (factorization homology);
- Lurie HA 5.5.3 (Hochschild trace);
- Ben-Zvi–Francis–Nadler arXiv:0805.0157 (integral transforms);
- Emerton–Gee arXiv:1908.07185;
- Fargues–Scholze arXiv:2102.13459 (local equivalence);
- Bhatt–Scholze arXiv:1309.1198 (pro-étale);
- Toën DAG framework.

Arithmetic Topology and Hodge-Theoretic Comparisons

Related arithmetic constructions include:

- Mazur 2000 Selecta, Morishita arXiv:0904.3399 (MKR dictionary);
- Kapranov 1996 (arithmetic topology);
- Antieau–Nikolaus (TR, THH, arithmetic traces);
- Teleman 2020 (HKR in arithmetic);
- Bhatt–Morrow–Scholze Inv. Math. 218 (prismatic Nygaard);
- Scholze 2018 Forum Math. Pi 6 (p-adic Hodge theory);
- Costello 2007 PAMQ (A-model Hochschild trace).

Distinct Carriers and Required Maps

Remark 49.9.1 *(comparison of trace carriers).* The arithmetic-topology dictionary of Mazur–Kapranov–Reznikov–Morishita provides a topological analogy. Topological Hochschild, cyclic and restriction homology use equivariant spectra, while categorical traces and loop-space functions lie in their specified

derived categories. The constructions of Antieau–Nikolaus and Nikolaus–Scholze, Teleman's cohomological calculations, and the prismatic Nygaard comparison of Bhatt–Morrow–Scholze concern these different carriers. Using them together requires maps preserving the relevant coefficients, actions, filtrations and completion. A single-prime Hodge comparison such as that discussed in Remark 49.5.6 does not construct the global arithmetic Ben-Zvi–Nadler equivalence for the full Weil/(φ, Γ) target.

Comparison Sketch

Remark 49.9.2 *(the comparison path).* A non-formal comparison theorem would proceed as follows.

(i) *Teleman–Antieau–Nikolaus computation of* $\mathrm{HH}_\bullet$ *of the global Iwahori Hecke category via THH*$_\bullet$ of the Emerton–Gee stack regarded as a prismatic-Nygaard-polarised derived scheme. This path goes through the trace-methods framework of Nikolaus–Scholze, producing an E_1-algebra in genuine S^1-equivariant spectra, whose underlying object matches the factorization-homology model of Theorem 49.5.3.

(ii) *MKR-dictionary match of the arithmetic loop space.* From the topological analogy, the arithmetic free loop space The full-target arithmetic loop object for $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$ corresponds to the loop space of the 3-manifold analogue of the Emerton–Gee stack; Morishita's dictionary (arXiv:0904.3399 Ch. 3) reads off the correct moduli of local-system pairs.

(iii) *Comparison of Bhatt–Morrow–Scholze prismatic-Nygaard trace with the* E_1*-algebra* $\mathcal{O}(\mathrm{LocSys}^{\mathrm{Ar}})^{\mathrm{flat}}$. Both sides give an E_1-algebra in S^1-equivariant spectra; the match is a prismatic-Nygaard compatibility, encoded as the Bhatt–Lurie filtration of arXiv:2201.06120.

These local descriptions concern the stated carriers. Comparing them with the arithmetic trace of Theorem 49.7.1 requires maps preserving the cyclic action, products and filtrations; the descriptions alone do not supply those maps.

49.10 Residual Conditions

The independent comparison leaves F3 with genuine residual conditions. Besides F1 and F2, the proof needs the corrected arithmetic BZN comparison against the full Weil/(φ, Γ) target, the profinite formal-loop continuity theorem, and the flat-locus pullback comparison. Thus F3.BZN^{Ar} remains a residual of Section 43.9.

Remark 49.10.1 *(residual F3 ingredients).* The open ingredients are:

- the local categorical comparison (F1.a) and $\mathrm{L}_{\mathrm{ACD}}$ (F1's adelic categorical descent);
- the mixed-characteristic local E_2 Hecke enhancement and (F2.c) (∞-categorical Tate restricted tensor product);
- profinite formal-loop continuity for $\mathrm{Map}(B\widehat{\mathbb{Z}}, -)$;
- the full Weil/(φ, Γ) target comparison and flat-locus pullback;
- arithmetic Positselski (from P1's Step 3);
- Koszul–Petersson compatibility (from P3).

The first four are number-field adaptations of function-field geometric Langlands and arithmetic loop-space technology. The last two are bar-cobar-structural conditions internal to the arithmetic Heisenberg.

Domain: Archimedean Place

Remark 49.10.2 *(archimedean contribution).* Theorem 49.7.1 treats only the finite-place inertia (Remark 49.3.4). The archimedean contribution to $\mathcal{V}^{\mathrm{prim}}$ is the complex Heisenberg Fock on the archimedean fibre (Theorem 43.7.1 archimedean-place discussion), whose Hochschild trace is classical Ben-Zvi–Nadler over $\mathbb{C}$. The arithmetic-to-classical reduction at the archimedean place is exactly the classical Ben-Zvi–Nadler theorem Theorem 49.5.1, which is a theorem of 2009. No new work is needed for the archimedean fibre.

Domain: Non-GL_2 Groups

Remark 49.10.3 *(extension to GL_n).* The machinery extends to $G = GL_n$ for any $n \geq 1$, since:

- The definition of $B\widehat{\mathbb{Z}}$ and arithmetic free loop space is group-independent.
- Local Emerton–Gee stacks are defined for all n in Emerton–Gee arXiv:1908.07185; the global spectral target must still be Selmer-derived.
- Fargues–Scholze local geometrization and spectral action are available for GL_n (arXiv:2102.13459 Thm. I.9); the categorical comparison remains a separate input.

The only GL_2-specific input is F1 ($\mathrm{L}_{\mathrm{ACD}}$ is currently formulated for $GL_2/\mathbb{Q}$), which is a number-theoretic arithmetic-Langlands conjecture. With F1 upgraded to GL_n, Theorem 49.7.1 extends directly. The rank-2 structure is not used essentially.

49.11 Ben-Zvi–Nadler Boundary

(i) The arithmetic inertia circle $B\widehat{\mathbb{Z}}$ is well-defined as a pro-étale derived stack, has pro-étale fundamental group $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$, and is the arithmetic analogue of S^1 under the MKR dictionary (Proposition 49.3.3).

(ii) The arithmetic free loop space $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ is a derived pro-étale stack for any n-geometric derived pro-étale stack $\mathcal{X}$ (Definition 49.4.1, Remark 49.4.3). For $\mathcal{X} = BGL_2$, $L^{\mathrm{Ar}}BGL_2 = \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ (Proposition 49.4.4, Corollary 49.4.5).

(iii) The Emerton–Gee stack has an expected comparison to the full Weil/(φ, Γ) flat target; its restriction to $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ is a forgetful procyclic shadow; whether the restriction is a closed immersion is an open question (Proposition 49.4.6, Proposition 49.4.9).

(iv) Arithmetic factorization homology is conjectured to give $\mathrm{HH}_\bullet(C) = \int_{B\widehat{\mathbb{Z}}} C$ for any E_2-monoidal stable presentable ∞-category C in pro-étale derived geometry (Theorem 49.5.3).

(v) The core arithmetic HH identity Theorem 49.5.5 gives $\mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})) = \mathcal{O}(L^{\mathrm{Ar}}\mathcal{X})^{\mathrm{flat}}$ for any Noetherian derived formal algebraic pro-étale stack $\mathcal{X}$; this remains conditional for formal Noetherian pro-étale stacks and requires the R1.formal.b/R1.formal.c inputs.

(vi) Dunn additivity gives the E_1-algebra structure on the Hochschild trace (Proposition 49.6.1), conditional on F2.

(vii) The main comparison Theorem 49.7.1 is conjectural and must target $\mathrm{LocSys}^{W,\varphi^\Gamma}_{GL_2}$, not the inertia-only shadow.

(viii) F3 remains conditional after F1 and F2 (Theorem 49.8.1); the residual is the corrected BZN comparison, formal-loop compatibility, and full-target pullback.

(ix) The arithmetic-topology dictionary, topological Hochschild invariants, cohomological calculations and prismatic Nygaard comparisons involve distinct carriers. Their use in the main theorem requires the specified structure-preserving maps (Remark 49.9.1, Remark 49.9.2).

(x) The machinery extends to GL_n for arbitrary $n \geq 1$ with only F1 as the group-specific input (Remark 49.10.3).

The six-window presentation of $\mathcal{V}^{\mathrm{prim}}$ (Chapter 41) remains conditional. F1 and F2 reduce F3 to a sharper residual: construct the corrected arithmetic BZN equivalence over the full Weil/(φ, Γ) target and prove the profinite formal-loop and flat-locus comparisons.

Chapter 50

The ∞-Categorical Tate Restricted Tensor Product

The restricted-tensor assertion F2.c is a formal assembly theorem. Its inputs are stable presentable categories with specified operadic structures and the actual pointing maps of Setup 50.1.1(D2). Finite tensor products of these maps form an operadic diagram. HA 3.2.3.1 constructs its filtered colimit on the underlying categorical colimit. No arithmetic input is used in that construction.

Applying it to arithmetic Iwahori categories still requires the local E_2-structures and the specified pointing maps. Neither an invariant vector nor a central idempotent alone supplies those maps. The assembly theorem does not construct geometric collision comparisons or an identification with an independently defined global Hecke category.

50.1 Statement of (F2.c)

Setup and Definition

Fix a small one-coloured ∞-operad $\mathcal{O}^{\otimes}$ (the chief cases are $\mathcal{O} = E_n$ for $n \geq 1$). Fix an indexing set V of *places*: in the target application $V = |\overline{C}|$ is the set of places of $\overline{\mathrm{Spec}\,\mathbb{Z}}$, but the statement is place-agnostic.

Write $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ for the ∞-category of stable presentable ∞-categories and colimit-preserving functors. Its tensor product represents functors preserving colimits in each input. The tensor unit is Sp, the ∞-category of spectra, and $\mathbb{S} \in \mathrm{Sp}$ is the sphere spectrum. In particular, an empty tensor of categories means Sp.

Setup 50.1.1 *(F2.c data).*

(D1) For each $v \in V$, a stable presentable ∞-category $C_v \in \mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ equipped with an $\mathcal{O}$-monoidal structure compatible with colimits in each variable: $C_v^{\otimes} \to \mathcal{O}^{\otimes}$ exhibits C_v as an $\mathcal{O}$-algebra in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$.

(D2) A cofinite subset $V^{\mathrm{sph}} \subseteq V$ and, for each $v \in V^{\mathrm{sph}}$, a specified morphism

$$\eta_v : \mathrm{Sp} \longrightarrow C_v \quad \text{in} \quad \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}).$$

Write $u_v = \eta_v(\mathbb{S})$. The morphism includes compatibility with every operation, including nullary operations, and all their coherences. Throughout this chapter, pointed spherical data means these maps, not merely their values on $\mathbb{S}$.

In the unital E_n cases, $n \geq 1$, necessarily $u_v \simeq \mathbb{1}_{C_v}$. A non-unit central idempotent under $\mathbb{1}_{C_v}$ does not give such a map into C_v. A construction using it would require a different unital target or a different notion of morphism.

Write $\mathrm{Fin}(V)$ for the filtered poset of finite subsets of V ordered by inclusion, and $\mathrm{Fin}^{\mathrm{sph}}(V)$ for the cofinal subposet consisting of finite $S \subseteq V$ with $V \setminus S \subseteq V^{\mathrm{sph}}$.

Definition 50.1.2 *(Tate restricted tensor product).* Under Setup 50.1.1, the *Tate restricted tensor product* of $\{C_v\}_v$ with pointed spherical data $\{(\eta_v, u_v)\}_{v\in V^{\mathrm{sph}}}$ is the colimit

$$\bigotimes_{v\in V}{}'(C_v, u_v) \;:=\; \varinjlim_{S\in \mathrm{Fin}^{\mathrm{sph}}(V)} \Big(\bigotimes_{v\in S} C_v\Big) \tag{50.1}$$

in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. The transition morphism for $S \subseteq S'$ uses the pointing at each $v \in S' \setminus S$:

$$\iota_{S\subseteq S'} \;:\; \bigotimes_{v\in S} C_v \xrightarrow{\mathrm{id}\otimes \bigotimes_{v\in S'\setminus S}\eta_v} \bigotimes_{v\in S'} C_v, \qquad X \mapsto X \otimes \Big(\bigotimes_{v\in S'\setminus S} u_v\Big). \tag{50.2}$$

The right-hand side uses the Lurie tensor product in Pr^{L} of HA 4.8.1. It restricts to a symmetric monoidal structure on $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ by HA 4.8.2.18.

THEOREM 50.1.3 *(F2.c: ∞-categorical Tate restricted $\mathcal{O}$-tensor).* Fix a small coherent ∞-operad $\mathcal{O}^{\otimes}$. This includes E_n for $n \geq 1$ and E_∞. Under Setup 50.1.1, the restricted tensor product (50.1) carries a canonical $\mathcal{O}$-monoidal structure such that:

(M1) For each $S \in \mathrm{Fin}^{\mathrm{sph}}(V)$, the canonical map

$$\iota_S \;:\; \bigotimes_{v\in S} C_v \;\longrightarrow\; \bigotimes_{v\in V}{}'(C_v, u_v)$$

is an $\mathcal{O}$-monoidal functor.

(M2) If $V \setminus \{v\} \subseteq V^{\mathrm{sph}}$, the canonical functor $C_v \to \otimes'_{w\in V}(C_w, u_w)$ is $\mathcal{O}$-monoidal. For a general v, the same construction requires specified $\mathcal{O}$-algebra maps $\mathrm{Sp} \to C_w$ at the finitely many remaining places $w \in V \setminus (V^{\mathrm{sph}} \cup \{v\})$.

(M3) Fix the full diagram of finite tensor products and specified pointing maps, and fix its underlying colimit cocone in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. The space of lifts of this entire cocone, including all higher coherences, to a colimit cocone in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ is contractible.

Applied with $\mathcal{O} = E_2$ and $C_v = \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,v}$ and the pointing maps of (D2), this proves the formal transport step (F2.c) in Theorem 43.3.1. Both the local Iwahori E_2-structures and any identification $|0\rangle_v \simeq \eta_v(\mathbb{S})$ remain required inputs.

Tensor Products and Factorization Homology

The tensor-product construction of Theorem 50.1.3 uses Lurie HA 4.8 and the integral E_n-operads discussed by Fresse. Dunn additivity (HA 5.1.2.4; Dunn 1988), Ayala–Francis factorization homology, and Ginot's account of factorization algebras provide related descriptions of the monoidal structures (Section 50.12). Applying these descriptions requires the same units, coefficient category and colimit conventions.

50.2 Obstructions and Their Resolutions

Six questions isolate the ingredients of Theorem 50.1.3: operadic insertion, filtered colimits, discrete factorization, additivity, cocone uniqueness and the cofinite pointing condition.

The Pointing Required for Unit Insertion

Obstruction 50.2.1 *(operadic insertion).* Does a distinguished object u_v, or a central idempotent under the unit, suffice to make insertion an $\mathcal{O}$-monoidal functor?

Correction 50.2.2 *(actual pointing maps).* The required datum is the morphism η_v in Setup 50.1.1(D2). Tensoring these morphisms with identities gives the insertion functors, including their nullary and higher compatibilities. For unital E_n, a strong E_n-monoidal functor preserves the unit, so its value on $\mathbb{S}$ cannot be a non-unit central idempotent. For a nonzero field k, the object $(k, 0)$ of $\mathcal{D}(k \times k)$ is compact, central and idempotent under the unit (k, k). Insertion of $(k, 0)$ from Sp is not unital monoidal. Lemma 50.4.1 uses the specified maps, not an implication from central idempotence.

$\mathcal{O}$-Algebra Structure under Filtered Colimits

Obstruction 50.2.3 *(filtered colimit of $\mathcal{O}$-algebras).* (50.1) is a filtered colimit in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. Does the $\mathcal{O}$-algebra structure propagate through such a colimit?

Correction 50.2.4 *(colimit preservation).* Lurie HA 3.2.3.1, applied to the ∞-operad $\mathcal{O}^{\otimes}$ and the symmetric monoidal ∞-category $(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}, \otimes)$, which admits filtered colimits preserved by tensoring in each variable: the forgetful functor $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}) \to \mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ preserves filtered colimits. Hence the colimit $\varinjlim_S (\otimes_{v \in S} \mathcal{C}_v)$ taken in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ coincides with the colimit in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$, and the $\mathcal{O}$-algebra structure is preserved. Detailed in Proposition 50.5.1.

Factorization for Disjoint Subsets of V

Obstruction 50.2.5 *(factorization axiom).* Does the finite tensor diagram underlying (50.1) respect disjoint unions of place labels, and what geometric data does this supply?

Correction 50.2.6 *(discreteness of V).* The associator identifies the tensor for $S \sqcup T$ with the tensor of the two separate values whenever $S \cap T = \varnothing$. Spherical-unit insertions respect these identifications on the inclusions for which they are defined. This is the discrete factorization of Corollary 30.2.2. It specifies no position diagonal or normal coefficient. A comparison with a geometric factorization system must supply those data separately.

Dunn Additivity and the Restricted Tensor Product

Obstruction 50.2.7 *(Dunn additivity compatibility).* For $\mathcal{O} = E_{n_1}$ and $\mathcal{O}' = E_{n_2}$ with $n_1 + n_2 = n$, Dunn additivity (HA 5.1.2.4) gives $E_{n_1} \otimes E_{n_2} \simeq E_{n_1+n_2}$, with the tensor product of ∞-operads. The restricted tensor product of E_{n_1}-categories composed with the restricted tensor product of E_{n_2}-categories should give the restricted tensor product of $E_{n_1+n_2}$-categories. Does Theorem 50.1.3 respect this composition?

Correction 50.2.8 *(operad-variable functoriality).* Dunn additivity concerns the operad E_n itself (HA 5.1.2.4). For an operad product $\mathcal{O} \otimes \mathcal{O}'$, the restricted-tensor construction agrees with its iterated form. Both supplied structures and their interchange coherences must be retained. The corresponding algebra equivalence identifies the finite tensor diagrams and their filtered colimits. Proposition 50.7.6 gives the comparison for the little-cubes operads.

Cofinality Invariance of the $\mathcal{O}$-Structure

Obstruction 50.2.9 *(uniqueness modulo cofinal filtration).* The proof of Theorem 50.1.3(M3) claims uniqueness of the $\mathcal{O}$-monoidal structure up to contractible choice. Does this uniqueness hold unconditionally, or only modulo the choice of cofinal filtration $\mathrm{Fin}^{\mathrm{sph}}(V)$?

Correction 50.2.10 *(cofinality invariance).* A cofinal replacement of the filtered indexing category does not change the colimit of its operadic diagram. The resulting equivalence is the one compatible with the complete colimit cocones. Colimit cocones are initial objects in the appropriate cocone category, so their space of choices is contractible. This uses the universal property of colimits, not an ∞-topos structure on Cat_∞. See Proposition 50.9.1.

Ramified Places without a Spherical Unit

Obstruction 50.2.11 *(ramified archimedean places).* Setup 50.1.1 asks for a distinguished spherical unit u_v at *almost all* places $v \in V$. At a finite number of ramified places (for $GL_2/\mathbb{Q}$ typically the archimedean place and a finite set of primes where the Iwahori level is nontrivial), no spherical unit need exist. Does Theorem 50.1.3 still apply?

Correction 50.2.12 *(cofinite spherical locus).* Every $S \in \mathrm{Fin}^{\mathrm{sph}}(V)$ contains the finite complement $V \setminus V^{\mathrm{sph}}$. Thus every newly added place has a specified pointing map, and the finite-stage diagram is defined without choosing pointing maps at the remaining places. This does not supply every singleton map: the precise condition is (M2). An archimedean invariant vector does not by itself verify (D2). An actual operadic pointing is still required before that place can be inserted.

50.3 ∞-Operadic Preliminaries

The proof of Theorem 50.1.3 draws on three ingredients from Lurie HA and Fresse, recorded here with their precise references. Numbering follows the 2017 version of Lurie's *Higher Algebra*.

Symmetric Monoidal Structure on $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$

THEOREM 50.3.1 *(HA 4.8.1.15, HA 4.8.2.18).* The ∞-category Pr^{L} of presentable ∞-categories and colimit-preserving functors carries a canonical symmetric monoidal structure. Its tensor product is characterized by the universal property

$$\mathrm{Fun}^{\mathrm{L}}(\mathcal{C} \otimes \mathcal{D}, \mathcal{E}) \;\simeq\; \mathrm{Fun}^{\mathrm{L,L}}(\mathcal{C} \times \mathcal{D}, \mathcal{E})$$

(colimit-preserving functors of tensor products = bi-colimit-preserving functors of products). The full subcategory $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ of stable presentable ∞-categories is closed under this tensor product and carries a canonical symmetric monoidal structure with unit Sp (the ∞-category of spectra).

COROLLARY 50.3.2 *(HA 4.8.1.24 and HA 4.8.2.18).* The ∞-category $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ admits small colimits, and the tensor product ⊗ preserves colimits separately in each variable. In particular, ⊗ preserves filtered colimits in each variable.

Algebras over an ∞-Operad in a Presentable Symmetric Monoidal ∞-Category

THEOREM 50.3.3 *(HA 3.2.3.1 and 3.2.3.5).* For a small coherent ∞-operad $\mathcal{O}^{\otimes}$ and a presentable symmetric monoidal ∞-category $\mathcal{E}^{\otimes}$ with $\otimes_{\mathcal{E}}$ preserving colimits separately in each variable:

(i) $\mathrm{Alg}_{\mathcal{O}}(\mathcal{E})$ is presentable;
(ii) the forgetful functor $\mathrm{Alg}_{\mathcal{O}}(\mathcal{E}) \to \mathcal{E}$ preserves sifted colimits (and in particular filtered colimits).

Stability of $\mathcal{E}$ does not imply stability of its algebra category. For example, for a nonzero field k, the initial object of $\mathrm{Alg}_{E_1}(\mathcal{D}(k))$ is k and its terminal object is the zero algebra. They are not equivalent, so this category is not pointed and cannot be stable.

For the restricted tensor product, we need only filtered colimits. Corollary 50.3.2 supplies these in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$, compatibly with tensor products. Proposition 50.3.7 then constructs the colimit of the algebra diagram on its underlying colimit. This application uses no presentability assertion about $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ itself.

E_n-Operad and Integral Structure

Theorem 50.3.4 *(Fresse 2017* Homotopy of Operads *I.4.1; Lurie HA 5.1.0.4).* For each $n \geq 0$, let $E_n^{\otimes}$ be the little n-cubes ∞-operad. Its k-ary operations are parametrized by the space $\mathrm{Conf}_k(\mathbb{R}^n)$ of configurations of k ordered little n-cubes in the unit n-cube. This ∞-operad is coherent in the sense of HA 3.3.1.1. The standard inclusion $E_n^{\otimes} \to E_{n+1}^{\otimes}$ induces restriction from E_{n+1}-algebras to E_n-algebras. The relation with iterated algebra structures is the Dunn additivity equivalence below, not a forgetful morphism $E_{n+1} \to E_n$.

Theorem 50.3.5 *(Dunn additivity; HA 5.1.2.4; Dunn 1988 JPAA 50).* For any $n_1, n_2 \geq 0$,

$$E_{n_1}^{\otimes} \otimes E_{n_2}^{\otimes} \;\simeq\; E_{n_1+n_2}^{\otimes}$$

as ∞-operads, where $\otimes$ is the tensor product of ∞-operads (HA 2.2.5.6). In particular, an $E_{n_1+n_2}$-algebra in $\mathcal{E}$ is the same datum as an E_{n_1}-algebra in E_{n_2}-algebras in $\mathcal{E}$.

Compatibility of a Specified Pointing

Theorem 50.3.6 *(operadic pointing compatibility).* Let $\eta : \mathrm{Sp} \to C$ be a morphism in $\mathrm{Alg}_O(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. For every O-operation, its compatibility with η, together with all substitution coherences, is part of this morphism. For unital E_n, $n \geq 1$, its nullary compatibility gives $\eta(\mathbb{S}) \simeq \mathbb{1}_C$.

Proof. A morphism of operadic algebras commutes with the operation maps and their coherences. The nullary operation of the canonical unital E_n-algebra Sp is the identity $\mathrm{Sp} \to \mathrm{Sp}$. That of C is its unit functor. Compatibility identifies η with that unit functor and gives the stated equivalence on $\mathbb{S}$. □

This is the pointing compatibility used in Lemma 50.4.1. It asserts no mapping-space identity involving the identity functor as an object of C.

Filtered Colimits of ∞-Operadic Algebras

Proposition 50.3.7 *(HA 3.2.3.1).* Let $O^{\otimes}$ be a small one-coloured coherent ∞-operad, and let $\mathcal{E}^{\otimes}$ be a symmetric monoidal ∞-category admitting small filtered colimits. Suppose $\otimes_{\mathcal{E}}$ preserves these colimits in each variable. Then the forgetful functor

$$U_O \;:\; \mathrm{Alg}_O(\mathcal{E}) \;\longrightarrow\; \mathcal{E}$$

preserves and creates filtered colimits. Concretely: a filtered diagram $F : I \to \mathrm{Alg}_O(\mathcal{E})$ has colimit whose underlying object in $\mathcal{E}$ is $\varinjlim_i U_O F(i)$, with O-algebra structure induced levelwise.

This is the mechanism of colimit-preservation (§50.5).

50.4 Unital Inclusion Functors

Inserting a spherical unit at a new place gives an O-monoidal functor; the following lemma makes this precise.

LEMMA 50.4.1 *(unit insertion is $\mathcal{O}$-monoidal).* Let $\mathcal{O}^{\otimes}$ be a coherent ∞-operad, and let $C_1, \dots, C_k$ and $C_{k+1}, \dots, C_m$ be $\mathcal{O}$-algebras in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ for some $k \le m$. For $i > k$ choose a spherical unit $u_i \in C_i$ in the sense of Setup 50.1.1(D2). Then the functor

$$\iota_{\{1,\dots,k\}\subseteq\{1,\dots,m\}} \;:\; \bigotimes_{i=1}^{k} C_i \longrightarrow \bigotimes_{i=1}^{m} C_i$$

defined by inserting u_i at position i for $i > k$ is an $\mathcal{O}$-monoidal functor.

Proof. The symmetric monoidal tensor product on $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ is induced by the ambient tensor product. The insertion is the morphism

$$\bigotimes_{i\le k} C_i \simeq \Big(\bigotimes_{i\le k} C_i\Big) \otimes \mathrm{Sp}^{\otimes(m-k)} \xrightarrow{\mathrm{id}\otimes\bigotimes_{i>k}\eta_i} \bigotimes_{i\le m} C_i.$$

Every η_i is a specified morphism of $\mathcal{O}$-algebras, so this is also such a morphism. In particular, writing A and B for the source and target, respectively, each operation $c \in \mathcal{O}(r)$ satisfies

$$\iota \circ \mu_c^{A} \simeq \mu_c^{B} \circ \iota^{\otimes r}.$$

For $r = 0$ this is unit compatibility. The higher compatibilities are inherited from the supplied morphisms and the symmetric monoidal structure, rather than chosen independently for each operation. Tensor associativity supplies the compatible composites for every chain of finite subsets. □

COROLLARY 50.4.2 *(restriction of ι).* Assume the hypotheses of Lemma 50.4.1. For every sub-triangle $\{1,\dots,k\} \subseteq \{1,\dots,k'\} \subseteq \{1,\dots,m\}$ the composite $\iota_{\{1,\dots,k\}\subseteq\{1,\dots,m\}}$ equals $\iota_{\{1,\dots,k'\}\subseteq\{1,\dots,m\}} \circ \iota_{\{1,\dots,k\}\subseteq\{1,\dots,k'\}}$ as $\mathcal{O}$-monoidal functors under the comparison supplied by tensor associativity and the fixed pointing maps. These comparisons are coherent for longer chains.

Proof. Both sides are tensor products of the same identities and supplied maps η_i at the same positions. The associativity and unit coherences of the symmetric monoidal algebra category identify these composites, compatibly with longer chains. This is the specified coherent comparison, not an assertion that arbitrary homotopies between the underlying functors form a contractible space. □

Remark 50.4.3 *(two cells of the full diagram system).* Lemma 50.4.1 together with Corollary 50.4.2 upgrades the system $\{\iota_{S\subseteq S'}\}_{S\subseteq S'}$ to a diagram

$$\Phi_{\{C_v,u_v\}} \;:\; \mathrm{Fin}^{\mathrm{sph}}(V) \longrightarrow \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$$

covariant in the filtered poset ordered by inclusion. Its map for $S \subseteq S'$ inserts the specified spherical units in $S' \setminus S$. This is the diagram on which Proposition 50.5.1 will take colimits.

50.5 COLIMIT PRESERVATION

PROPOSITION 50.5.1 *($\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ of $\mathcal{O}$-categories is cocomplete under filtered colimits).* Let $\mathcal{O}^{\otimes}$ be a small one-coloured coherent ∞-operad. For every small filtered ∞-category I and every functor $\Phi : I \to \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$, the colimit $\varinjlim_i \Phi(i)$ exists in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$, and its underlying presentable stable ∞-category

is $\varinjlim_i (U_{\mathcal{O}}\Phi(i))$ in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. Every $\mathcal{O}$-operation on the colimit is computed levelwise: given $c \in \mathcal{O}(r)$, the operation

$$\mu_c^{(\mathrm{colim})} \;:\; \prod_{j=1}^{r}\Big(\varinjlim_i \Phi(i)\Big) \;\longrightarrow\; \varinjlim_i \Phi(i)$$

is the filtered colimit of the family $\{\mu_c^{(\Phi(i))}\}_i$.

Proof. Put $C_i = U_{\mathcal{O}}\Phi(i)$ and $C = \varinjlim_i C_i$ in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. Corollary 50.3.2 gives this colimit and preservation by tensoring. Hence Proposition 50.3.7, with $\mathcal{E} = \mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$, gives an algebra colimit whose underlying object is C.

The operations can be seen directly. For $r > 0$, the diagonal $I \to I^r$ is cofinal because I is filtered. Therefore

$$C^{\otimes r} \simeq \varinjlim_{(i_1,\dots,i_r)\in I^r} C_{i_1}\otimes\cdots\otimes C_{i_r} \simeq \varinjlim_{i\in I} C_i^{\otimes r}.$$

For $c \in \mathcal{O}(r)$, take the colimit of $\mu_c^{(i)} : C_i^{\otimes r} \to C_i$. The resulting map is the displayed operation on C, viewed as a functor preserving colimits in each input. Nullary operations pass through the coherent cocone from Sp; the nerve of a filtered category is contractible. Operadic composition and its homotopies pass through these same colimit comparisons. Thus the construction retains the full algebra structure, as asserted by HA 3.2.3.1. □

Corollary 50.5.2 *(restricted tensor product as colimit in* $\mathrm{Alg}_{\mathcal{O}}$*).* The diagram $\Phi_{\{C_v,u_v\}} : \mathrm{Fin}^{\mathrm{sph}}(V) \to \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ of Remark 50.4.3 admits a colimit in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$, whose underlying presentable stable ∞-category is $\otimes'_{v\in V}(C_v, u_v)$ of Definition 50.1.2.

Proof. $\mathrm{Fin}^{\mathrm{sph}}(V)$ is a filtered ∞-poset (union of finite subsets is again finite; the empty set, or any initial element of $\mathrm{Fin}^{\mathrm{sph}}(V)$, gives non-emptiness). Apply Proposition 50.5.1. □

50.6 Proof of the Main Theorem

Proof of Theorem 50.1.3. **Step 1 (construction of the diagram).** Given the data of Setup 50.1.1, construct the diagram

$$\Phi \;:\; \mathrm{Fin}^{\mathrm{sph}}(V) \;\longrightarrow\; \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}), \qquad \Phi(S) \;:=\; \bigotimes_{v\in S} C_v$$

with transition maps $\iota_{S\subseteq S'}$ of (50.2). By Lemma 50.4.1, each $\iota_{S\subseteq S'}$ is an $\mathcal{O}$-monoidal functor. For every chain of inclusions, each composite tensors with the same supplied maps η_v at the same positions. Coherence of the tensor product gives all composition homotopies and their compatibilities; the triangular identity is Corollary 50.4.2. Thus Φ is a functor from the filtered ∞-poset $\mathrm{Fin}^{\mathrm{sph}}(V)$ into $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$.

Step 2 (existence of the $\mathcal{O}$-structured colimit). By Corollary 50.5.2, the colimit $\varinjlim_S \Phi(S)$ exists in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$, and its underlying object in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ is $\otimes'_{v\in V}(C_v, u_v)$ by Definition 50.1.2. This supplies the $\mathcal{O}$-monoidal structure promised in Theorem 50.1.3.

Step 3 (property (M1): each ι_S is $\mathcal{O}$-monoidal). The canonical map $\iota_S : \Phi(S) \to \varinjlim_{S'} \Phi(S')$ is a morphism in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ by the universal property of the colimit applied inside the ∞-category of $\mathcal{O}$-algebras. Hence ι_S is $\mathcal{O}$-monoidal. This is (M1).

Step 4 (property (M2): a single-place map). If $V \setminus \{v\} \subseteq V^{\mathrm{sph}}$, the singleton $\{v\}$ belongs to $\mathrm{Fin}^{\mathrm{sph}}(V)$, so Step 3 applies directly. Otherwise put $E = V \setminus V^{\mathrm{sph}}$ and choose the additional maps in (M2). They give an $\mathcal{O}$-algebra map

$$C_v \longrightarrow \bigotimes_{w \in E \cup \{v\}} C_w \xrightarrow{\iota_{E\cup\{v\}}} \bigotimes'_{w \in V} (C_w, u_w).$$

The first arrow tensors with the chosen maps at $E \setminus \{v\}$; the second is supplied by (M1). Passing to a larger admissible finite set inserts only the original spherical-unit maps, so tensor coherence and the colimit cocone identify the composites. The resulting functor depends on the extra choices. Full faithfulness is not part of (M2).

Step 5 (property (M3): uniqueness up to contractible space of choices). By Step 2, the structured colimit is initial among cocones under Φ in $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. Here compatibility with (ι_S) includes the whole coherent cocone. Let another such structure be given on the fixed underlying colimit. Initiality supplies a contractible space of maps to its cocone. After forgetting the algebra structure, each is the equivalence determined by the two colimit cocones. The forgetful functor detects equivalences, so the structured map is itself an equivalence. Consequently every compatible structured cocone is initial, and the space of them is contractible. This proves (M3).

Steps 1–5 together prove Theorem 50.1.3. □

Remark 50.6.1 *(categorical content).* The proof displays the ∞-categorical Tate restricted tensor product as a filtered colimit in the ∞-category $\mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. This is the ∞-categorical analogue of the classical Tate restricted direct product of locally compact abelian groups:

$$\prod'_{v \in V} G_v \;:=\; \varinjlim_{S \text{ finite}} \prod_{v \in S} G_v \times \prod_{v \notin S} K_v$$

with $K_v \subseteq G_v$ compact-open, via filtered union over finite ramification sets. Here a transition uses the inclusions $K_v \hookrightarrow G_v$ at the newly unrestricted places; the categorical tensor instead inserts the specified objects u_v. The common filtered indexing does not identify these different transition maps or their colimits.

50.7 Discrete Factorization and Geometric Comparison

Finite tensor products carry coherent decomposition maps for disjoint sets of place labels. We construct these maps together with the allowed unit insertions. A comparison with geometric factorization must also specify the coefficients and maps at colliding positions.

Factorization on Finite Sets of Places

Setup 50.7.1 *(finite subsets and multisets of V).* For the set V, let $\mathrm{Fin}_+(V)$ be its nonempty finite subsets. The set of nonempty finite multisets is instead $\coprod_{n\geq 1} V^n/\mathfrak{S}_n$. Forgetting multiplicities maps the latter onto the former. The diagram below is indexed by finite subsets, including the empty set, with explicitly specified arrows; no transition between symmetric powers is needed.

Definition 50.7.2 *(Discrete factorization with specified unit insertions).* Let $\mathrm{Fin}^{u}(V)$ have all finite subsets as objects, with an arrow $S \to T$ when $S \subseteq T$ and $T \setminus S \subseteq V^{\mathrm{sph}}$. Thus only places with a specified spherical-unit map may be inserted. A discrete factorization datum in the category of $\mathcal{O}$-algebras in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ is a diagram

$$\mathcal{A} \;:\; \mathrm{Fin}^{u}(V) \;\longrightarrow\; \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$$

satisfying the factorization axiom: for every pair of disjoint finite subsets $S_1, S_2 \subset V$,

$$\mathcal{A}(S_1 \sqcup S_2) \;\simeq\; \mathcal{A}(S_1) \otimes \mathcal{A}(S_2)$$

as O-algebras, coherently associative and symmetric, and natural in the allowed inclusions of disjoint subsets.

Theorem 50.7.3 *(Finite tensors give discrete factorization).* Under Setup 50.1.1, the finite tensors define a discrete factorization datum in the sense of Definition 50.7.2. Its restriction to $\mathrm{Fin}^{\mathrm{sph}}(V)$ is the diagram $\Phi_{\{C_v, u_v\}}$ of Remark 50.4.3. Its value on $S = \{v_1, \dots, v_k\}$ is $\bigotimes_{i=1}^{k} C_{v_i}$, and on a disjoint union $S_1 \sqcup S_2$ is $\mathcal{A}(S_1) \otimes \mathcal{A}(S_2)$ by associativity of the tensor product.

Proof. For each allowed inclusion, insert the maps η_v at the new places. Composing two inclusions inserts the same maps at the same places, giving the diagram. Associativity of the finite tensor identifies the value on a disjoint union with the tensor of its two values. Tensor coherence proves all refinements and permutations of this identification. On $\mathrm{Fin}^{\mathrm{sph}}(V)$, these maps are precisely the transitions defining Φ. □

Corollary 50.7.4 *(Filtered assembly of the finite tensors).* Under the hypotheses of Theorem 50.1.3,

$$\bigotimes_{v \in V}{}' (C_v, u_v) \;=\; \varinjlim_{S \in \mathrm{Fin}^{\mathrm{sph}}(V)} \Phi(S).$$

The colimit assembles the discrete factorization datum of Theorem 50.7.3 along its spherical-unit insertions. Identifying it with sections or homology of a geometric Ran object requires a separate comparison.

Remark 50.7.5 *(Position geometry is additional).* The discrete construction proves the disjoint tensor identities and their unit-insertion coherences. It does not compute the coefficient on a position diagonal. The formal-disc and derived closed-point models of Proposition 2.8.1 retain different normal data at a finite place. A geometric arithmetic realization must select and compare its local models, including the archimedean one in Remark 30.6.2.

Compatibility with Dunn Additivity

The restricted tensor product commutes with Dunn additivity (Theorem 50.3.5) in the following precise sense.

Proposition 50.7.6 *(Dunn additivity commutes with restricted tensor product).* Fix $n_1, n_2 \geq 0$. Let $\{C_v\}_{v \in V}$ be a family of $E_{n_1+n_2}$-monoidal stable presentable ∞-categories with the pointing maps of Setup 50.1.1(D2) for $E_{n_1+n_2}$. Then the restricted tensor product $\bigotimes'_v (C_v, u_v)$ constructed via Theorem 50.1.3 with $O = E_{n_1+n_2}$ coincides, as an $E_{n_1+n_2}$-monoidal ∞-category, with the iterated construction:

(a) View each C_v as an E_{n_1}-algebra in E_{n_2}-monoidal stable presentable ∞-categories (via Theorem 50.3.5).

(b) Apply Theorem 50.1.3 with $O = E_{n_2}$ to the underlying family to get $\bigotimes'_v C_v$ as an E_{n_2}-category;

(c) View the result as an E_{n_1}-algebra in E_{n_2}-categories, by functoriality of the restricted tensor product.

Via Theorem 50.3.5, this is an $E_{n_1+n_2}$-monoidal structure. It agrees with the $E_{n_1+n_2}$-structure of Theorem 50.1.3 applied directly.

Proof. Both constructions yield filtered colimits in the same ∞-category. The key is that the tensor product of ∞-operads $E_{n_1} \otimes E_{n_2}$ (Theorem 50.3.5) encodes the two supplied structures together with their interchange coherences. The colimit over S preserves these operations and coherences (Proposition 50.5.1). The induced $E_{n_1+n_2}$-structure on the colimit equals the $E_{n_1+n_2}$-structure of the direct construction. Formally: the forgetful functor $\mathrm{Alg}_{E_{n_1+n_2}} \simeq \mathrm{Alg}_{E_{n_1} \otimes E_{n_2}} \to \mathrm{Alg}_{E_{n_2}}$ commutes with filtered colimits (Proposition 50.3.7), so both iterated colimit computations agree. □

COROLLARY 50.7.7 *(special case: $E_1 \otimes E_1 = E_2$).* Suppose each C_v is E_1-monoidal in E_1-monoidal presentable stable ∞-categories (equivalently, E_2-monoidal by Theorem 50.3.5). Suppose the supplied pointings are maps for that entire structure. Then the restricted tensor product is E_2-monoidal. It is computed either by direct E_2-application of Theorem 50.1.3 or by nested E_1-applications.

Remark 50.7.8 *(role for F2).* In the F2 application, suppose $C_v = \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,v}$ has the required E_2-structure and pointing maps. Dunn additivity gives a factorization as an E_1-algebra in E_1-categories. The compatibility of Proposition 50.7.6 confirms that the global E_2-structure on $\bigotimes'_v \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,v}$ is well-defined either via direct E_2-restricted-tensor or via nested E_1-restricted-tensors.

50.8 APPLICATION TO THE IWAHORI HECKE CATEGORY

The Conditional Local Data

Setup 50.8.1 *(Iwahori Hecke family).* Fix $V = \mathbb{P} \cup \{\infty\}$. Suppose a stable presentable model $C_v = \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,v}$, its colimit-compatible E_2-monoidal structure, and the actual pointing maps of Setup 50.1.1(D2) have been specified. Write $|0\rangle_v = \eta_v(\mathbb{S})$ where the pointing is supplied. These are inputs. A class of a double coset or a fixed vector does not by itself construct such a categorical pointing.

LEMMA 50.8.2 *(the archimedean unit identification required for insertion).* Suppose C_∞ has the specified stable presentable E_2-monoidal structure. Its unit functor $\eta_\infty : \mathrm{Sp} \to C_\infty$ is an E_2-algebra morphism. To use a chosen object $|0\rangle_\infty$ as its value on $\mathbb{S}$, a unit identification $|0\rangle_\infty \simeq \mathbb{1}_{C_\infty}$ is required. Existence of an $O(2)$-fixed vector alone does not supply this identification.

Proof. The unit functor sends a spectrum E to its canonical spectral action on $\mathbb{1}_{C_\infty}$. Applying an operation commutes with the spectral action in each input, by colimit preservation. The unit identities then identify its value with the smash product of the input spectra acting on $\mathbb{1}_{C_\infty}$. The operadic coherences give the same identifications under substitution, including the nullary operation. Thus the functor is E_2-monoidal, and its value on $\mathbb{S}$ is the unit. This identifies the extra datum needed for a chosen object to serve as that value. □

The Conditional Assembly Corollary

COROLLARY 50.8.3 *(restricted-tensor E_2 transfer).* Under Setup 50.8.1, define

$$\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}} := \bigotimes'_{v \in V} (C_v, |0\rangle_v).$$

This object has the E_2-monoidal structure and admissible finite-stage maps of Theorem 50.1.3. A singleton map is available under exactly its condition (M2), including any additional pointing maps required there. Uniqueness is relative to the complete specified colimit cocone. The displayed formula is a definition, not a comparison with a separately constructed global arithmetic Hecke category.

Proof. The hypotheses give the diagram in $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. Apply Theorem 50.1.3, including its singleton and cocone qualifications. The proof supplies neither the local E_2-structures nor pointing maps whose existence has not been assumed. □

Remark 50.8.4 *(local operations and geometric comparison remain inputs).* Discrete place labels do not construct the local E_2-operations, nor do they identify operations at geometric collision strata. Dunn additivity compares supplied operadic structures. It does not supply missing local structures from the discreteness of the place set. These requirements remain separate from F2.c.

Remark 50.8.5 *(archimedean pointing).* The archimedean factor may be included in every admissible finite stage without a pointing. Inserting that factor, or forming a singleton map that must insert it, requires the actual E_2-algebra map into that factor. A spherical vector in a representation or in a Fock-space presentation is not a proof of this categorical datum.

50.9 Uniqueness of the E_n Structure

Proposition 50.9.1 *(uniqueness for a fixed cocone).* Fix the full diagram $\Phi : \mathrm{Fin}^{\mathrm{sph}}(V) \to \mathrm{Alg}_{O}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$ and an underlying colimit cocone with vertex $C = \operatorname{colim} U\Phi$. The space of lifts of this whole cocone to a colimit cocone of O-algebras is contractible. The lift of Theorem 50.1.3 is one such lift.

Proof. HA 3.2.3.1, in the form of Proposition 50.3.7, creates the filtered colimit and detects a colimit cocone on underlying objects. Thus every lift of the fixed underlying colimit cocone is a structured colimit cocone. Any two structured colimit cocones have a contractible space of equivalences respecting the complete cocone. Forgetting the structure gives the corresponding equivalences of underlying colimit cocones, whose space is also contractible. Taking the fiber over the fixed underlying cocone proves the assertion. Merely specifying individual arrows or commuting triangles would not specify that complete cocone. □

Corollary 50.9.2 *(compatibility of available singleton maps).* If $V \setminus \{v\} \subseteq V^{\mathrm{sph}}$, the singleton map $\iota_v : C_v \to C$ is O-monoidal. For a general v, the same assertion holds after the additional pointing maps required by (M2) have been specified. In either case ι_v intertwines the local and global operations, with the coherences of its specified operadic cocone. No full faithfulness or identification of C_v with its image is asserted.

Proof. In the first case $\{v\}$ is an admissible finite stage, so (M1) applies. In the second case insert the additionally supplied pointings to reach an admissible stage and apply (M1). For example, for two places with categories Sp and $\mathrm{Mod}_{H\mathbb{Q}}$ and their unit maps, the singleton map from Sp is rationalization. It is not fully faithful: for any prime p, the nonzero spectrum $H\mathbb{F}_p$ maps to zero. It is nevertheless symmetric monoidal. Thus recovery of a local category from its image cannot follow from uniqueness. □

50.10 Base Change and Functoriality

The restricted tensor product is functorial in the family $\{C_v\}$ and covariant under base change.

Proposition 50.10.1 *(functoriality in the pointed family).* Let two families over the same set V satisfy Setup 50.1.1, and let $f_v : C_v \to C'_v$ be O-algebra morphisms. At every place where both pointings

are supplied, require a specified equivalence $f_v\eta_v \simeq \eta'_v$ as morphisms of O-algebras. Then these pointed morphisms induce an O-algebra map

$$\bigotimes_v{}' f_v : \bigotimes_v{}'(C_v, u_v) \longrightarrow \bigotimes_v{}'(C'_v, u'_v).$$

This construction is ∞-functorial in the pointed family. An equivalence of the objects $f_v(u_v)$ and u'_v without compatibility with the specified operadic pointings is not the hypothesis for a general O.

Proof. Use the common cofinal index consisting of finite subsets containing $(V \setminus V^{\mathrm{sph}}) \cup (V \setminus V'^{\mathrm{sph}})$. The finite tensor products $\bigotimes_{v\in S} f_v$, together with the given pointed equivalences, form a natural transformation of the complete operadic diagrams. Taking its colimit gives the asserted map. Functoriality follows from the functoriality of tensor products and of the colimit functor on diagram categories. □

PROPOSITION 50.10.2 *(base change along a colimit-preserving symmetric monoidal functor).* Let $F^{\otimes} : (\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}, \otimes) \to (\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}, \otimes)$ be a symmetric monoidal colimit-preserving functor. For a family as in Setup 50.1.1, define its transported pointing and distinguished object by

$$\eta_v^F : \mathrm{Sp} \simeq F(\mathrm{Sp}) \xrightarrow{F(\eta_v)} F(C_v), \qquad u_v^F = \eta_v^F(\mathbb{S}).$$

Then

$$F\big(\bigotimes_v{}'(C_v, u_v)\big) \;\simeq\; \bigotimes_v{}'(FC_v, u_v^F)$$

as O-monoidal ∞-categories.

Proof. F preserves both filtered colimits (colimit-preservation) and tensor products (symmetric monoidality). Both operations are separately applied to the colimit diagram Φ; their commutativity gives the equivalence. Formally:

$$F\big(\varinjlim_S \bigotimes_{v\in S} C_v\big) \;\simeq\; \varinjlim_S F\big(\bigotimes_{v\in S} C_v\big) \;\simeq\; \varinjlim_S \bigotimes_{v\in S} FC_v$$

by symmetric monoidality of F, and the transition maps $F\iota_{S\subseteq S'} = \iota^{(F)}_{S\subseteq S'}$ by functoriality of F applied to the pointed spherical maps η_v. □

Remark 50.10.3 *(scope of categorical base change).* Proposition 50.10.2 applies to a specified functor on stable presentable categories and to its transported pointing maps. It supplies an arithmetic change of base only after those categorical data have been constructed. The bar–cobar base-change comparisons in Volume I concern their own coefficient systems and hypotheses. Relating the two constructions requires a map between their carriers that preserves the relevant operations. Formal commutation with tensor products and colimits alone does not identify them.

50.11 EXAMPLES

Example 1: Module Categories and the Spectral Tensor Product

Example 50.11.1 *(the tensor colimit of module categories).* Let R_v be discrete commutative rings, put $A_v = HR_v$, and give $C_v = \mathrm{Mod}_{A_v}$ its usual symmetric monoidal structure and unit pointing. Define

$$A_{\mathrm{tens}} = \operatorname*{colim}_{S\in \mathrm{Fin}(V)} \bigotimes_{v\in S,\,\mathbb{S}} A_v \quad \text{in} \quad \mathrm{CAlg}(\mathrm{Sp}),$$

with unit insertions as transition maps and empty tensor $\mathbb{S}$. Then

$$\bigotimes_{v\in V}{}'(\mathrm{Mod}_{A_v}, A_v) \simeq \mathrm{Mod}_{A_{\mathrm{tens}}}$$

as symmetric monoidal stable presentable categories. This is a spectral tensor-colimit formula. It is not an identification with a profinite completion or with a classical adelic restricted product.

Proof. The module-category tensor equivalence identifies each finite stage with modules over $\bigotimes_{v\in S,\mathbb{S}} A_v$, and identifies the transition functors with extension of scalars. The module-category functor preserves filtered colimits (HA 4.8.5.13), with tensor compatibility given by HA 4.8.5.16. These identifications preserve the symmetric monoidal structures and unit maps, so passage to the filtered colimit gives the formula.

For example, if $V = \mathbb{P}$ and $R_p = \mathbb{Z}_p$, every prime ℓ becomes invertible in A_{tens}: add any factor $H\mathbb{Z}_p$ with $p \neq \ell$. Thus the output is rational, whereas $H\widehat{\mathbb{Z}}$ is not. In particular this construction does not recover $\mathrm{Mod}_{H\widehat{\mathbb{Z}}}$. The classical finite adeles also use integral subrings at the unramified places. That restricted-product diagram is not the diagram above with $A_p = H\mathbb{Q}_p$. □

Example 2: Conditional Function-Field Application

Example 50.11.2 *(function-field assembly).* Let $V = |X|$ for a smooth projective curve over $\mathbb{F}_q$. A family of stable presentable E_2-monoidal local categories with actual pointing maps satisfying (D2) has the restricted E_2-tensor product of Theorem 50.1.3. To apply this to chosen Hecke categories, their local E_2-structures and those maps must first be supplied. A comparison with Beilinson–Drinfeld factorization requires its geometric coefficients, collision maps and higher coherences separately. Discretizing $|X|$ does not provide that comparison or its missing operations.

Remark 50.11.3 *(no automatic comparison between arithmetic bases).* The filtered-colimit theorem applies over either indexing set once its categorical inputs are supplied. It gives no function-field-to-arithmetic comparison functor. Such a comparison must specify the functor, its pointing compatibility, and any required geometric factorization data.

Example 3: Conditional Arithmetic Iwahori Assembly

Example 50.11.4 *(arithmetic Iwahori application).* Under Setup 50.8.1, Corollary 50.8.3 gives an E_2-structure on the categorical restricted tensor product. The notation $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ in that corollary denotes this defined object. An independently defined global arithmetic Hecke category requires a separate comparison. So does a restricted tensor product of representations. Neither comparison follows from filtered colimits.

50.12 The Finite Labeled-Disk Description

Setup 50.12.1 *(finite labeled coefficients).* Take $\mathcal{O} = E_n$, $n \geq 1$, and the data of Setup 50.1.1. For a finite set S, write $M_S = \coprod_{v\in S} \mathbb{R}^n_v$, retaining each place label. Assign coefficient C_v to its own labeled component. The finite labeled-disk value is

$$F^{\mathrm{lab}}(M_S) := \bigotimes_{v\in S} C_v.$$

This is a family of coefficients, not the single constant coefficient $\bigotimes_{v\in S} C_v$ on every disk. For admissible inclusions insert the specified maps η_v. Only this finite labeled diagram and its filtered colimit are being defined. No presentability assertion about $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ itself is used.

THEOREM 50.12.2 *(comparison with the finite labeled-disk diagram).* The diagram F^{lab} on $\mathrm{Fin}^{\mathrm{sph}}(V)$, with its specified insertions, is the finite tensor diagram Φ used in Theorem 50.1.3. Hence

$$\operatorname*{colim}_{S \in \mathrm{Fin}^{\mathrm{sph}}(V)} F^{\mathrm{lab}}(M_S) \simeq \bigotimes_{v \in V}{}' (C_v, u_v)$$

as E_n-algebras in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$, compatibly with the complete colimit cocones.

Proof. At each finite stage the values are identical. On each inclusion the morphisms are the same tensor products of identities and supplied η_v. Their higher compatibilities come from the same symmetric monoidal structure and the same pointing maps. Thus this is the same operadic diagram, and taking its filtered colimit gives the assertion. □

For comparison, ordinary factorization homology on framed disks with a single coefficient algebra A, when defined, satisfies

$$\int_{\coprod_{v \in S} \mathbb{R}^n} A \simeq A^{\otimes |S|}.$$

The disk overcategory has a terminal object. Applying the symmetric monoidal disk algebra gives the displayed tensor power. See Ayala–Francis, *A factorization homology primer*, Definitions 3.5 and 3.7.

Putting $A = \otimes_{v \in S} C_v$ in this formula therefore does not give $\otimes_{v \in S} C_v$. Nor is an integral with a single coefficient $A_V = \otimes'_v C_v$ over all the disks a replacement for the labeled diagram. The usual factorization homology construction is a left Kan extension of a disk algebra. Disk normalization and disjoint-union compatibility alone do not characterize its values on general manifolds.

Remark 50.12.3 *(scope of the description).* The labeled-disk description uses exactly the same finite diagram and colimit argument as the restricted tensor theorem. It is not a second independent proof, an Ext comparison, or a construction of geometric collision operations. A comparison with a factorization algebra on a geometric space requires its coefficient system and comparison morphisms separately.

50.13 REMARKS ON OPERADIC COHERENCE

Hypotheses Used by the Filtered-Colimit Argument

The application of HA 3.2.3.1 uses a small operad and filtered colimits in the ambient symmetric monoidal category. Tensoring must preserve those colimits in each variable. It requires neither operadic coherence in the sense of HA 3.3.1.1 nor presentability of the ambient category. The coherence assumption retained in some statements above is an extra hypothesis, not a premise needed for this argument. The separate presentability result HA 3.2.3.5 is not being applied to $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ itself. The preservation of higher operation coherences follows from taking the colimit of the supplied operadic diagram, not from recognizing operations in its cohomology.

Alternative Pointing Maps

Remark 50.13.1 *(non-spherical insertion).* A replacement pointing must be an actual morphism $\widetilde{\eta}_v : \mathrm{Sp} \to C_v$ in $\mathrm{Alg}_O(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$, with $\widetilde{u}_v = \widetilde{\eta}_v(\mathbb{S})$. Specified equivalences between pointing maps, in that mapping space, induce equivalences of the diagrams and their colimits. Equivalence of the underlying central objects alone is not the general operadic compatibility required. In the unital E_n cases every such pointing sends $\mathbb{S}$ to the actual monoidal unit. Thus a non-unit central object is not an alternative pointing of this kind.

Iterated Restricted Tensor Products

Proposition 50.13.2 *(iterated restricted tensor products).* Let $V = V_1 \sqcup V_2$ be a partition, with spherical data restricting to each V_i. Then

$$\bigotimes_{v \in V}{}'(C_v, u_v) \;\simeq\; \Big(\bigotimes_{v \in V_1}{}'(C_v, u_v)\Big) \otimes \Big(\bigotimes_{v \in V_2}{}'(C_v, u_v)\Big)$$

as O-monoidal ∞-categories.

Proof. Intersection with V_1 and V_2 identifies the indexing poset with $\mathrm{Fin}^{\mathrm{sph}}(V_1) \times \mathrm{Fin}^{\mathrm{sph}}(V_2)$. At each pair of finite stages, tensor associativity identifies the two values and their pointing maps. Separate preservation of filtered colimits by tensor products, from Corollary 50.3.2, identifies the underlying colimits. The same comparison preserves every operation in the supplied diagrams, so it is an equivalence of O-algebras. □

50.14 Completeness of F2.c and Residual Local Input

Theorem 50.14.1 *(F2.c assembly for supplied local Iwahori data).* F2.c proves the restricted-tensor assembly step for local Iwahori categories satisfying Setup 50.8.1, including the specified E_2-algebra pointings. Its uniqueness is relative to the complete colimit cocone. It does not construct any of these local inputs.

Proof. Apply Corollary 50.8.3 with its full hypotheses, which in turn is the E_2 specialization of Theorem 50.1.3. □

Remark 50.14.2 *(scope of the F2 conclusion).* F2.c is the formal assembly theorem. An arithmetic application requires the local E_2-enhancement F2.b and all pointing data of (D2). These remain hypotheses wherever they have not been constructed. Identifying the defined tensor colimit with an independently specified global geometric object remains a separate comparison.

Corollary 50.14.3 *(F3 after formal F2.c assembly).* Assume the full local E_2 and pointing hypotheses. Then F2.c supplies the formal restricted-tensor construction in the reduction of $F3$. The local input F2.b and any unverified pointing or global comparison requirements remain. F2.c also leaves the other hypotheses of Theorem 43.4.1 unchanged.

Proof. Substitute Theorem 50.14.1 only for its formal assembly conclusion in the cited reduction. That theorem assumes the local pointed operadic diagram and makes no independent arithmetic comparison. □

50.15 Tate Tensor Boundary

The categorical restricted tensor product is the filtered colimit of the finite tensor diagram of supplied O-algebras and actual operadic pointing maps. HA 3.2.3.1 applies because the ambient categorical tensor product preserves filtered colimits separately. Presentability of $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ itself is not needed.

The whole colimit cocone has a contractible space of structured lifts. This does not assert full faithfulness of singleton maps, and a singleton map requires the precise pointing condition (M2). The construction is functorial in pointed families. It commutes with the stated symmetric monoidal base changes and iterated tensor products, and respects Dunn additivity for supplied structures.

The finite labeled-disk description is the same diagram, not an independent derivation. The module-category example computes a spectral tensor colimit, not a profinite or adelic restricted product. Neither example supplies geometric collision maps.

F2.c is therefore a proved formal assembly theorem under its full hypotheses. The local arithmetic E_2-structures, pointing maps and any independent global comparison remain required inputs. The arithmetic comparison in F3 is likewise not absorbed by this categorical construction.

Chapter 51

Arithmetic Comparisons and Residual Structure

The six comparison problems of Chapter 43 are $\mathrm{L}_{\mathrm{ACD}}$ (adelic categorical descent), F2.c (∞-categorical Tate restricted tensor product), $\mathrm{F3.BZN}^{\mathrm{Ar}}$ (arithmetic Ben-Zvi–Nadler identification), arithmetic Positselski (co-contra equivalence over Λ), Koszul–Petersson compatibility, and VB* (arithmetic Virasoro positivity). Each comparison has a specified domain and additional conditions for extension beyond it. In the positivity problem, three different objects must be distinguished: a scalar Li coefficient, a transform of a zero-divisor operator, and a polynomial in a Fock energy operator. A positive scalar trace does not identify these operators or make each of their quadratic forms nonnegative.

51.1 First Residual Decomposition

F2.c: ∞-Categorical Tate Restricted Tensor Product

The formal restricted-tensor construction is proved in Theorem 50.1.3. Its inputs include actual operadic maps $\eta_v : \mathrm{Sp} \to \mathcal{C}_v$ on a cofinite set of places. These maps form the transition functors between finite tensors. The colimit is taken over that diagram, without an infinite tensor of unspecified unit-comparison arrows.

Definition 51.2.1 states the pointing used here, and Theorem 51.2.3 records the formal E_2 consequence. The specialization in Theorem 73.3.1 has the same inputs. A non-unit central idempotent does not replace them. The remaining arithmetic problem is to construct the local structures, their pointings and any independently required global geometric comparison.

$\mathrm{L}_{\mathrm{ACD}}$*: Adelic Categorical Descent*

$\mathrm{L}_{\mathrm{ACD}}$ in Chapter 43 asserts that the adelic categorical descent from local automorphic categories to the global automorphic category holds; but four subconditions are conflated into the single statement: (i) dg-categorical proof that the restricted tensor product with distinguished units preserves the colimit structure; (ii) proof that local Hecke-functoriality together with cross-prime commutativity implies global Hecke-functoriality on the colimit; (iii) sph-finite preservation under the colimit; (iv) strong approximation for the simply connected derived group, together with the determinant idele-class quotient for $GL_2/\mathbb{Q}$. Subcondition (iv) is a theorem after this separation: Kneser supplies the simply connected strong-approximation input for SL_2, while Tate's idelic formalism supplies the determinant quotient. The conditions (i)–(iii) depend on F2.c and are conjectural. Thus $\mathrm{L}_{\mathrm{ACD}}$ splits into the four subconditions $\mathrm{L}_{\mathrm{ACD}}.1$–$\mathrm{L}_{\mathrm{ACD}}.4$; see Theorem 51.2.4.

F3.BZN^{Ar}: Arithmetic Ben-Zvi–Nadler Identification

$\mathrm{F3.BZN}^{\mathrm{Ar}}$ proposes that the arithmetic analogue of the Ben-Zvi–Nadler Hochschild-trace identification holds. Three independent obstructions separate the complex-analytic source theorem from its arithmetic extension. (R1) Ben-Zvi–Nadler's proof over $\mathbb{C}$ uses holomorphic factorization on $S^1 = B\mathbb{Z}$; the arithmetic analogue requires locally-constant-with-Adams factorization on $B\widehat{\mathbb{Z}}$, and the survival of the

Hochschild-trace pairing under this qualitative change is not established via Gaitsgory–Rozenblyum DAG Vol. II for formal-Noetherian targets. (R2) The arithmetic free loop space requires a fixed descent topology; the rigid-analytic topology on the Emerton–Gee stack (arXiv:1908.07185 §2) is the canonical choice. (R3) The Mazur–Kapranov–Reznikov dictionary (primes as knots, $\overline{\mathrm{Spec}\,\mathbb{Z}}$ as 3-manifold) is a heuristic motivation; the technical content runs through the Emerton–Gee rigid-analytic construction. The arithmetic statement uses R2's topology, treats R3 as motivation, and isolates R1's formal-Noetherian extension as the open subcondition; see Theorem 51.2.5.

Arithmetic Co–Contra Comparison

An arithmetic co–contra correspondence must specify a coalgebra over $\Lambda = \mathbb{Z}_p[[\Gamma]]$, its continuous dual, and the categories and resolutions to be compared. The abelian nature of Γ does not identify an oscillator module with a cyclotomic Iwasawa module. Nor does the vanishing of a module's μ-invariant imply conilpotence of a coalgebra. Question 51.2.7 retains the comparison with these coefficient requirements.

Koszul–Petersson Compatibility: Sub-Claim Structure

The Koszul–Petersson compatibility asserted in Chapter 43 is the identity $\langle\cdot,\cdot\rangle^{\mathrm{Pet}} = \langle\cdot,\cdot\rangle^{\mathrm{Koszul}} \circ (\mathrm{id} \otimes \text{BC-inv.})$ where BC-inv. denotes the Bost–Connes involution on the dual. The assertion conflates seven independent sub-claims: (K1) definition of the arithmetic Koszul pairing via adic transfer of Vol I's derived-centre pairing; (K2) Hecke-equivariant embedding $\mathcal{V}^{\mathrm{prim}} \hookrightarrow L^2([GL_2])^{\text{sph-fin}}$; (K3) specification of the Bost–Connes anti-involution as the KMS_1 Tomita–Takesaki modular conjugation after the modular half-density normalisation; (K4) archimedean normalisation; (K5) reconciliation of the Bost–Connes KMS_1 pairing with the local Whittaker/Kirillov pairing at each finite prime p, up to the declared spherical norm factor $m_p(1 + p^{-1})L_p(1, \mathrm{Ad})$; (K6) agreement of adelic Tamagawa measure with the restricted tensor product of local Haar measures; (K7) confirmation that the sph-finite cut is the natural locus for the identification. The explicit model calculations fix the conjugations and local norms. Their transport to the arithmetic carrier still requires (K2), the arithmetic identifications in (K3)–(K5), and the adelic comparison in (K6). A local functional equation does not construct these maps. The Heisenberg self-duality and Bost–Connes self-duality are each properties of their respective objects; the sub-claim structure exhibits that their pairing requires a separate comparison. See Theorem 51.2.9.

VB: Arithmetic Virasoro Positivity and Spectral Hypotheses*

Scalar positivity $\lambda_n \geq 0$ and operator positivity $T_n \succeq 0$ are different assertions. Operator positivity means that $\langle T_n v, v\rangle \geq 0$ for every vector in the specified quadratic-form domain. It cannot be recovered from the sign of one trace. This distinction already occurs for bounded self-adjoint matrices, independently of any issue of moment determinacy.

For example, on $\mathbb{C}^2$ with its usual Hermitian inner product, set $A = \mathrm{diag}(0, 2)$, let I be the identity, and put $S_n = A^n - (A - I)^n$ for $n \geq 1$. Direct diagonal multiplication gives

$$S_n = \mathrm{diag}\big((-1)^{n+1}, 2^n - 1\big), \qquad \mathrm{Tr}(S_n) = \begin{cases} 2^n - 2, & n \text{ even}, \\ 2^n, & n \text{ odd}. \end{cases}$$

Every displayed trace is strictly positive, whereas $S_2 = \mathrm{diag}(-1, 3)$ has quadratic form -1 on the first coordinate vector. Here A is bounded, nonnegative and self-adjoint, and the ordinary trace is positive and faithful. Its moment measure is $\delta_0 + \delta_2$, where δ_a denotes unit mass at a. This measure is determinate:

any positive measure with the same moments has integral of $x^2(x-2)^2$ equal to zero, hence is supported on $\{0, 2\}$; its zeroth and first moments then determine both masses. Thus even compact spectral support and moment determinacy do not turn the scalar inequalities into operator positivity. No identification of these traces with the arithmetic Li coefficients is being made.

For these particular polynomials there is an exact operator criterion. Let A be self-adjoint on a Hilbert space $\mathcal{H}$, with spectral projections E_A, and use the common spectral domain

$$\mathcal{D}_{\mathrm{sp}} = \bigcup_{R>0} E_A([-R, R])\mathcal{H}.$$

Every power of A preserves this dense domain. Spectral truncations converge in the graph norm of every polynomial in A, so it is a common core. Interpret $p_n(A)$, where $p_n(x) = x^n - (x-1)^n$, first on $\mathcal{D}_{\mathrm{sp}}$ and then by its closed spectral-calculus realization. Then

$$p_n(A) \succeq 0 \quad \text{for all } n \geq 1 \quad \Longleftrightarrow \quad A \succeq \tfrac{1}{2} I.$$

Necessity follows from $p_2(A) = 2A - I$. For sufficiency, odd powers are strictly increasing on $\mathbb{R}$, so $p_n(x) > 0$ for odd n. If n is even and $x \geq \frac{1}{2}$, then $|x| \geq |x-1|$, hence $p_n(x) \geq 0$. The spectral calculus gives the asserted positivity. For an unbounded operator, a statement made only on a smaller common domain also needs a specified form core and closure. The scalar traces supply neither that domain nor the spectral lower bound.

The arithmetic Hilbert–Pólya hypothesis H-P^{Ar} (Hypothesis 44.3.2) supplies a separate spectral object: $\Theta_\xi = \frac{1}{2} I + i H_{\mathrm{HP}}$, with a self-adjoint ordinate operator, specified domain, determinant divisor and regularised trace. It does not identify H_{HP} with a Virasoro zero-mode L_0^{Ar}. Its Li transforms are

$$\mathcal{L}_n = I - (I - \Theta_\xi^{-1})^n, \qquad \lambda_n = \mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n),$$

under the determinant and trace hypotheses of Proposition 44.3.8. If the self-adjoint ordinate operator and the determinant-divisor identity are both assumed, zero-placement already follows from the spectrum of Θ_ξ. The scalar Li route uses the determinant and trace identities separately. The forward implication of Theorem 44.3.10 is therefore positive HP–Li trace $\Rightarrow$ Li positivity $\Rightarrow$ zero-placement. The operator and trace positivity requirements can be separated explicitly. Under the self-adjoint H-P^{Ar} hypothesis, put $U = I - \Theta_\xi^{-1}$. At a real spectral ordinate t, its scalar value is $(-1/2 + it)/(1/2 + it)$, of modulus one. Thus U is unitary, and

$$\mathrm{Re}\, \mathcal{L}_n := \frac{\mathcal{L}_n + \mathcal{L}_n^*}{2} = \frac{(I - U^n)^*(I - U^n)}{2} \succeq 0.$$

The unsymmetrized $\mathcal{L}_n$ need not be self-adjoint. To pass from this real-part positivity to $\lambda_n \geq 0$, the regularised trace must be defined, compatible with adjoints and nonnegative on the relevant real-part cone, with the required continuity or Li/Weil approximation. These are additional trace hypotheses in the positive-trace route of Corollary 44.3.9; regularisation alone supplies no positivity property.

To deduce this implication from VB*, one would also need a comparison from the primary Fock operators and their positive forms to these Li transforms and the regularised trace, preserving the relevant positivity cone. No such comparison is supplied by the moment argument. Conversely, zero-placement alone does not construct the primary Virasoro operators, their common invariant domain, self-adjoint extensions, or this comparison. On the standard Fock space the zero-energy vacuum prevents positivity of every Virasoro polynomial. The precise positive spectral sector and the remaining arithmetic comparison are described below.

51.2 SHARP SUBCONDITIONS

Pointed E_n-monoidal Category

Definition 51.2.1 *(pointed E_n-monoidal category).* A *pointed E_n-monoidal stable presentable ∞-category* for $n \geq 1$ consists of an E_n-algebra C in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ and a specified morphism

$$\eta : \mathrm{Sp} \longrightarrow C \quad \text{in} \quad \mathrm{Alg}_{E_n}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}).$$

Write $u = \eta(\mathbb{S})$, where $\mathbb{S}$ is the sphere. The notation (C, u, η) retains this relation. Compatibility with the nullary operation gives $u \simeq \mathbb{1}_C$. Thus η is a functor with all operadic compatibilities, not an arbitrary arrow $\mathbb{1}_C \to u$ inside C.

Remark 51.2.2 *(why pointed).* The classical restricted direct product specifies local subgroups and their inclusions. The categorical tensor construction instead specifies transition functors by tensoring with the maps η_v. Their nullary and higher compatibilities make these functors operadic morphisms. A chosen object or central idempotent alone does not do so. The maps into the colimit need not be fully faithful.

With these pointings, the formal F2.c assertion is the following theorem.

THEOREM 51.2.3 *(F2.c with specified pointings).* Let C_v be stable presentable E_2-monoidal categories whose tensor products preserve colimits separately. On a cofinite subset $V^{\mathrm{sph}} \subseteq V$, supply pointings as in Definition 51.2.1. Put $E = V \setminus V^{\mathrm{sph}}$. Then

$$\bigotimes_v{}' (C_v, u_v) := \operatorname*{colim}_{\substack{S \subseteq V \text{ finite} \\ E \subseteq S}} \bigotimes_{v \in S} C_v$$

is an E_2-algebra in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$.

Transitions insert the supplied maps η_v. The finite-stage maps are E_2-monoidal, with uniqueness relative to the complete underlying colimit cocone. Singleton maps require the condition or additional pointings in (M2) of Theorem 50.1.3.

Proof. Tensoring the actual E_2-algebra maps with identities gives the finite-stage diagram in $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. Its indexing poset is filtered. The categorical tensor product preserves filtered colimits separately, so HA 3.2.3.1 constructs its colimit on the underlying categorical colimit. Theorem 50.1.3 gives the cocone and singleton assertions with precisely these hypotheses. □

$\mathrm{L}_{\mathrm{ACD}}$ *Split into Four Named Subconditions*

THEOREM 51.2.4 *($\mathrm{L}_{\mathrm{ACD}}$ split).* $\mathrm{L}_{\mathrm{ACD}}$ is equivalent to the conjunction of:

($\mathrm{L}_{\mathrm{ACD}}$.1) *Dg-categorical colimit commutation.* The restricted tensor product of dg-categories with pointed units commutes with the sph-finite truncation. **Form: conjectural**. Formal assembly is supplied by Theorem 51.2.3, but it does not prove compatibility with the specified sph-finite truncation.

($\mathrm{L}_{\mathrm{ACD}}$.2) *Cross-prime Hecke coherence.* For distinct primes $p \neq q$, the local Hecke operators T_p and T_q commute on the restricted tensor product of local automorphic categories, with associativity and unit coherences. **Form: conjectural**; follows from local Hecke-functoriality (Fargues–Scholze) plus a symmetric-monoidal coherence check.

($\mathrm{L}_{\mathrm{ACD}}$.3) *Sph-finite preservation.* The sph-finite subcategory $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$ is preserved under the restricted-tensor colimit: the colimit of sph-finite categories embeds in the sph-finite subcategory of the colimit. **Form: conjectural**; plausibly automatic given ($\mathrm{L}_{\mathrm{ACD}}$.1).

(L_{ACD}.4) *Strong approximation and determinant quotient.* The simply connected group $SL_2/\mathbb{Q}$ satisfies strong approximation away from a nonempty set of places (Kneser 1966; Platonov–Rapinchuk 1994). The passage from SL_2 to GL_2 keeps the determinant idele-class quotient $\mathbb{A}_{\mathbb{Q}}^{\times}/\mathbb{Q}^{\times}$, which is the Tate line rather than a strong-approximation consequence. **Form: theorem.**

Under this split, L_{ACD} follows from (L_{ACD}.1) + (L_{ACD}.2) + (L_{ACD}.3); (L_{ACD}.4) is theorem.

F3.BZN^{Ar} Split into Three Sub-Obstructions

Theorem 51.2.5 *(Conditional arithmetic trace comparison).* Fix the coefficient category, trace construction and completions. Assume the following comparison data, with compatible circle actions and the operations required in F3:

(R1) For the specified spectral category C_X, an actual equivalence from its chosen Hochschild trace complex to $\Gamma(LX, \mathcal{O}_{LX})$. Here the geometric loop object is the derived self-intersection of the diagonal. An arithmetic or profinite loop object requires its own comparison.

(R2) The specified global Selmer-derived target X, with its coefficient, formal and singular-support conditions, and the categorical equivalence transporting the arithmetic trace to that of C_X.

(R3) An actual equivalence from this loop-function complex to the full Weil/(φ, Γ) target, preserving the stated completion and operations. The inertia object $\mathrm{Map}(B\widehat{\mathbb{Z}}, X)$ alone does not supply this equivalence.

Then composition gives the F3 trace comparison on the specified carrier. These are sufficient data; no formal-stack trace theorem is inferred from a categorical framework alone.

Proof. Transport the trace along the categorical equivalence in (R2), then apply (R1) and (R3). Their compatibility preserves the specified circle action, completion and operations. □

Proposition 51.2.6 *(The affine loop calculation).* Let k be a field and A a smooth finitely generated commutative k-algebra. For the small k-linear category $\mathrm{Perf}(A)$ and ordinary derived loops of $X = \mathrm{Spec}\, A$,

$$\mathrm{HH}_k(\mathrm{Perf}(A)) \simeq A \otimes^{\mathbf{L}}_{A\otimes_k A} A \simeq \Gamma(X \times^{\mathbf{R}}_{X\times_k X} X, \mathcal{O}).$$

Proof. The perfect generator A identifies the categorical trace with the trace of the diagonal A-bimodule. Resolve that bimodule by the two-sided bar resolution over $A \otimes_k A$; tensoring with A gives the Hochschild chain complex and the first formula. The derived affine fibre-product rule gives the second. The cyclic bar construction supplies the circle action. Extending this calculation to a formal completion or a nilpotent-support ind-coherent category requires the actual continuity and support comparison in (R1); smoothness of an arbitrary stack is not such a comparison. □

Arithmetic Positselski with Abelian Domain Restriction

Question 51.2.7 *(an integral co–contra comparison).* Let C be a specified complete coalgebra over $\Lambda = \mathbb{Z}_p[[\Gamma]]$. Construct its co-derived category of continuous comodules and the contra-derived category of contramodules over its specified continuous dual. Determine hypotheses on the coefficient modules, resolutions, conilpotent filtration, and inverse limits that give an equivalence

$$\mathrm{D}^{\mathrm{co}}(C\text{-comod}_\Lambda) \simeq \mathrm{D}^{\mathrm{ctr}}(C^\vee_{\mathrm{cont}}\text{-contramod}_\Lambda).$$

If additional chiral operations are imposed, construct their compatibility with this ordinary coefficient comparison.

A field-coefficient equivalence cannot be transferred by an unspecified unital map $k \to \mathbb{Z}_p[[\Gamma]]$. For $\Gamma \simeq \mathbb{Z}_p$, the target is $\mathbb{Z}_p[[T]]$, which has characteristic zero and in which p is not invertible. A field of positive characteristic cannot map to it unitally. A field of characteristic zero contains $1/p$, whose image would invert p. Thus there is no such field map. Reduction to $\mathbb{F}_p$ and extension to $\mathbb{Q}_p$ are different operations, and an integral comparison must control both when it uses them.

Question 51.2.8 *(the arithmetic Heisenberg coefficient object).* Construct the coalgebra, coefficient module, topology, and Γ-action for the proposed arithmetic Heisenberg realization. If an Iwasawa vanishing theorem is used, identify the resulting module with one in that theorem's domain and transport its μ-invariant. Prove separately the hypotheses of Question 51.2.7.

Ferrero–Washington concerns the Iwasawa modules attached to abelian number fields. A trivial Γ-action on an oscillator lattice does not give the required identification. A co–contra equivalence still leaves the P1 evaluation and defect identity to construct. The converse in Theorem 43.5.1 also requires defect detection.

Koszul–Petersson Compatibility Split into Seven Sub-Claims

THEOREM 51.2.9 *(Sufficient pairing comparison data).* The following data give Koszul–Petersson compatibility on the specified cuspidal core:

(K1) A defined arithmetic bilinear Koszul pairing on the chosen completed carrier and a continuous antilinear involution J, with Hermitian form $H(v, w) = B(v, Jw)$.

(K2) An actual Hecke-equivariant arithmetic placement into the chosen automorphic Hilbert space, with a dense comparison core.

(K3) Compatibility with local conjugations. On the prime Gibbs cyclic carrier at $\beta = 1$, $J(\mu_{p^k}\Omega) = p^{k/2}\mu^*_{p^k}\Omega$. This Hilbert–Schmidt carrier is distinct from the weighted occupation model; their arithmetic placement is supplied data.

(K4) The archimedean comparison. For the declared K_0-Whittaker function, its norm squared is $\pi/4$, giving an isometry of the normalized vacuum line. The full Fock comparison and transport of Segal coefficient conjugation must also be supplied.

(K5) The finite-place comparison with the declared multiplicative Haar measure. For normalized unramified tempered parameters, the spherical Whittaker norm is

$$C_p = m_p(1 + p^{-1})L_p(1, \mathrm{Ad}), \qquad m_p = \mathrm{vol}(\mathbb{Z}_p^\times).$$

The normalized line has unit norm; the weighted occupation/radial and diagonal Hilbert–Schmidt isometries are those of Chapter 56. Identifying the actual arithmetic pairing with them is an additional comparison.

(K6) Compatible normalized reference vectors, completed restricted tensor products, and an adelic placement preserving pairings and the specified global measure. Any continued scalar normalization must be finite and nonzero and applied to both forms.

(K7) The chosen cuspidal domain and its completed embedding are specified. No equality on the Eisenstein continuous spectrum is inferred from these spherical or discrete calculations.

Under these data the transported Hermitian Koszul form equals the Petersson form on the comparison core and hence on its Hilbert completion wherever both forms are continuous.

Proof. The local model identities are proved in Chapters 47 and 56. Under the assumed arithmetic intertwiners they are identities of the arithmetic local forms. Their products agree on normalized finite tensors by (K6); linearity and continuity extend equality to the stated completion. The antilinear map in (K1) converts the bilinear pairing to the required sesquilinear form. This is a conditional transport theorem, not a construction of (K2) or (K6). □

VB: Vacuum Obstruction and Positive Spectral Sectors*

The spectral comparison separates the following inputs:

- H-P^{Ar}, with the operator, domain, determinant and trace data of Hypothesis 44.3.2; these are additional to P1, P2 and P3.
- Positive HP–Li trace, which implies Li positivity and zero-placement by Corollary 44.3.9 and Theorem 44.3.10, under their stated hypotheses.
- An arithmetic comparison from a specified positive energy sector to this trace condition, with the operations preserved on that sector stated explicitly.

The conformal-energy normalization is decisive for the operator inequalities. Write L_0^{Vir} for the standard Fock energy and $T_n^{\mathrm{Vir}} = p_n(L_0^{\mathrm{Vir}})$, with $p_n(x) = x^n - (x-1)^n$ as above. The vacuum is a primary vector; the word "primary" does not exclude its energy-zero contribution.

Proposition 51.2.10 *(vacuum obstruction and maximal positive spectral sector).* In the normalization of Lemma 45.6.1, the nonzero vacuum Ω satisfies $L_0^{\mathrm{Vir}}\Omega = 0$. Consequently

$$T_n^{\mathrm{Vir}}\Omega = (-1)^{n+1}\Omega, \qquad \langle T_{2k}^{\mathrm{Vir}}\Omega, \Omega\rangle = -\|\Omega\|^2 < 0 \quad (k \geq 1).$$

Thus positivity of every T_n^{Vir} fails on the vacuum-containing Fock space, independently of any hypothesis on Θ_ξ.

For a specified self-adjoint energy operator A on $\mathcal{H}$, with spectral projections E_A, put

$$\mathcal{H}_+ = E_A([1/2, \infty))\mathcal{H}, \qquad \mathcal{D}_+ = \bigcup_{R \geq 1/2} E_A([1/2, R])\mathcal{H}.$$

Then $\mathcal{H}_+$ is the largest closed reducing subspace on which every closed spectral-calculus operator $p_n(A)$ is nonnegative, and $\mathcal{D}_+$ is a common spectral core for their restrictions. Here reducing means that the orthogonal projection onto the subspace commutes with every spectral projection of A.

Proof. On the vacuum, substitution of the eigenvalue zero gives $p_n(0) = (-1)^{n+1}$, proving the obstruction. On $[1/2, \infty)$, the polynomial sign calculation above gives $p_n \geq 0$. Spectral calculus therefore proves positivity on $\mathcal{H}_+$, and bounded spectral truncations give the stated common core. Conversely, on any closed reducing subspace with this positivity property, $p_2(A) = 2A - I \succeq 0$. Its spectral support lies in $[1/2, \infty)$, so the subspace is contained in $\mathcal{H}_+$. This proves maximality without a zero-placement hypothesis. □

For the standard free-boson Fock space, the energies are the nonnegative integers and the zero-energy space is the vacuum line. Hence $\mathcal{H}_+ = \Omega^\perp$. The non-vacuum positivity of Corollary 45.6.4 therefore extends to the closed polynomial realizations on this subspace. This is a statement about the archimedean Fock factor; it does not identify the full arithmetic energy operator or its domain.

Reducing the energy operator is weaker than preserving a Virasoro representation. In the $c = 2$ vacuum representation, write L_m for the Virasoro modes, so $L_0 = L_0^{\mathrm{Vir}}$ and $L_m\Omega = 0$ for $m > 0$. The Virasoro relation gives

$$L_2 L_{-2}\Omega = [L_2, L_{-2}]\Omega = (4L_0 + c/2)\Omega = \Omega.$$

In particular $L_{-2}\Omega \neq 0$; it has energy two because $[L_0, L_{-2}] = 2L_{-2}$. Thus a non-vacuum vector has a Virasoro image in the vacuum line. The vacuum complement is not a Virasoro subrepresentation. A shift $L_0 \mapsto L_0 + aI$ with all other modes fixed is not an alternative normalization of the same representation: $[L_1, L_{-1}] = 2L_0$ forces $a = 0$.

Remark 51.2.11 *(arithmetic sector and trace comparison).* An arithmetic positivity construction must specify a Hilbert sector, its self-adjoint conformal-energy operator and common core, establish $A \succeq I/2$ there, and state which arithmetic and Virasoro operations preserve that sector. The spectral projection alone supplies a reducing sector for A, not those additional operations. A different arithmetic representation must be constructed if the intended operations require more than the non-vacuum Fock sector. To imply HP–Li positivity, such a construction must also provide a comparison with the Li transforms of Θ_ξ and the regularised trace that preserves the required positive forms and domains. These are separate construction requirements, not consequences of RH or of moment determinacy.

51.3 First Logical Core

The six residuals from Chapter 43 have the following logical form.

F1 reduces from the monolithic $\mathrm{L_{ACD}}$ to the conjunction $\mathrm{L_{ACD}}.1 + .2 + .3$; subcondition $\mathrm{L_{ACD}}.4$ is the product of strong approximation for $SL_2/\mathbb{Q}$ and the determinant idele-class quotient for $GL_2/\mathbb{Q}$; the first is a theorem of Kneser (1966) and Platonov–Rapinchuk (1994).

F2.c is Theorem 51.2.3, with actual operadic pointings. Its arithmetic use still requires the local E_2-structures, those pointing maps and the comparison with any independently defined global category.

F3 follows from the compatible R1, R2 and R3 comparison data of Theorem 51.2.5. The finite-type trace model proved here is the affine Perf(A) calculation of Proposition 51.2.6. The formal trace, global target and full Weil/(φ, Γ) equivalences remain actual comparison inputs.

P1 (Theorem 43.5.1) requires the arithmetic central-defect identity, Mellin evaluation, and defect detection. Question 51.2.8 asks separately for the coefficient object needed to apply an Iwasawa vanishing theorem.

P2 is theorem and unchanged.

P3 follows from the seven specified comparison data in Theorem 51.2.9. The local model norms and conjugations are explicit; the arithmetic placement and completed adelic pairing comparison remain to be constructed.

For zero-placement, the available implication is positive HP–Li trace $\Rightarrow$ Li positivity $\Rightarrow$ RH (Theorem 44.3.10), with the determinant and trace identities of H-P^{Ar}. A derivation from VB* requires the additional positive comparison described above.

The relevant comparison theories are Positselski (2011) and Ferrero–Washington (1979) for the arithmetic Positselski abelian domain; Flath (1979), Weil (1967), and Godement–Jacquet (1972) for the Koszul–Petersson sub-claims; and Gaitsgory–Rozenblyum DAG Vol. II for F3.BZN^{Ar}. The spectral comparison must also distinguish scalar traces from operator quadratic forms.

51.4 Second Residual Decomposition

The categorical comparisons require higher coherence data in addition to their scalar identities. The spectral comparison also requires a separation between a zero-divisor operator and a primary Virasoro representation, as in Chapter 35.

F2.c: E_2-Algebra Structure on the Unit Map

The pointing is a morphism $\eta : \mathrm{Sp} \to C$ in $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$. It is not an object of $\mathrm{Alg}_{E_2}(C)_{\mathbb{1}/}$. Tensoring these functors forms the finite-stage diagram, including nullary and higher compatibilities. Uniqueness of its structured colimit is relative to the full underlying colimit cocone.

Dunn additivity $E_2 \otimes E_2 \simeq E_4$ compares two supplied E_2-structures with their interchange coherences to an E_4-structure. A single E_2-structure does not supply that additional data. The inclusion $E_2 \to E_4$ induces restriction from E_4-algebras to E_2-algebras. Neither this restriction nor the filtered-colimit theorem constructs a higher structure on an arbitrary E_2-category.

$\mathrm{L}_{\mathrm{ACD}}$*: Archimedean Stratum and Hecke-at-Infinity*

The first-comparison split into $\mathrm{L}_{\mathrm{ACD}}$.1–.4 covers only finite places. At $v = \infty$, the spherical condition is K_∞-finiteness / admissibility in the sense of Harish-Chandra (1966), not Iwahori-fixedness; the empty-S base case collapses to $D(BK_\infty)$, not to the trivial category. The completed Tate character $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$ forces any honest $\mathrm{L}_{\mathrm{ACD}}$ to include a parallel archimedean factor. The new subcondition is:

($\mathrm{L}_{\mathrm{ACD}}$.0) *Archimedean stratum.* At $v = \infty$, the local factor is $D((\mathfrak{g}, K_\infty)\text{-mod}^{\text{sph-fin}})$ with admissibility (Harish-Chandra) replacing Iwahori-fixedness; $\mathrm{L}_{\mathrm{ACD}}$.2 extends to include $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance commuting with the finite-prime Hecke operators T_p; the empty-S base is $\mathrm{Rep}(K_\infty)$ with $\eta : \mathbb{1} \to \mathrm{triv}_{K_\infty}$. **Form: conjectural.**

F3.BZN^{Ar}*: Formal-Noetherian Extension, Non-Semisimple Correction, and Loop-Space Convention*

The first-comparison subconditions R1–R3 require four refinements.

(D1) The finite-type model proved in Proposition 51.2.6 uses $\mathrm{Perf}(A)$, a smooth affine k-scheme and ordinary derived loops. Denote this precise model by R1.fin-type. The arithmetic R1.formal requirement is an actual comparison for the chosen completed, support-restricted category on the Selmer-derived target. It must supply continuity under completion and the loop-object comparison; neither the phrase "formal Noetherian" nor smoothness of an unspecified stack supplies them.

(D2) R2 requires an ind-level cotangent-complex calculation on the global Selmer-derived target. The local smoothness input of Emerton–Gee §2 does not by itself supply the global comparison or its descent compatibility.

(D3) New subcondition R4: the Iwahori Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ at wild primes $p \in \{2, 3\}$ is not semisimple; the Hochschild trace picks up $\mathrm{Ext}^{\mathrm{I}}$-contributions invisible to the Ben-Zvi–Nadler semisimple template (Etingof–Ostrik 2004). **Form: conjectural.**

(D4) R3 requires a derived-internal-Hom convention for profinite classifying stacks and comparison maps among the cofiltered-limit, derived internal-Hom and direct ind-constructions after the specified formal-Noetherian completion. Their agreement is part of the required comparison.

Arithmetic Positselski: Five Supplementary Subconditions

The coefficient comparison of Question 51.2.7 must be supplemented by further operations in the arithmetic theory. (C1) requires factorization-coalgebra coherence at each place. (C2) requires $d^2 = 0$

for the three-piece arithmetic differential $d^{\mathrm{Ar}} = d_{\mathrm{Iw}} + d_{\mathrm{Gersten}} + d_{\mathrm{bar}}^{\mathrm{local}}$ (the candidate cancellation input is Parshin reciprocity). (C3) requires Euler-product convergence for the infinite-product structure, with an actual convergence theorem. (C4) requires a comparison at the archimedean place. (C5) requires naturality of the co-contra equivalence in morphisms of abelian Λ-coalgebras.

C5 is required for any functorial use of a constructed co–contra comparison. P1 additionally needs the explicit evaluation in Theorem 43.5.1. Naturality alone supplies neither its central-defect identity nor its detection condition.

Koszul–Petersson Compatibility: Five Higher-Structural Sub-Claims

The scalar-level decomposition K1–K7 of the first comparison (Theorem 51.2.9) conceals five higher-structural conditions: (K1a) the categorical-to-Hilbert descent functor $F = \mathrm{RHom}(\mathbb{1}, -)$ is not exhibited; (K3a) Galois-KMS$_1$ equivariance requires the Connes–Marcolli (2004) passage from the Bost–Connes Galois symmetry to the half-density normalised Tomita–Takesaki conjugation; (K5a) defect-pairing commutativity at ramified primes is a potential anomaly in the Kim arithmetic Chern–Simons defect setup: the open question is whether the Kim arithmetic-CS defect structure is anomaly-free at primes where Hecke characters ramify; (K6a) the actual adelic measure comparison must be compatible with any finite nonzero continued $L(1, \mathrm{Ad}\pi)$ normalization applied to both pairings; (K7a) dimensional-reduction coherence ($3d$ adelic $\to$ $2d$ archimedean $\to$ $1d$ prime-knot) is stated without proof. K5a asks for the ramified defect-pairing calculation and its compatibility with the specified arithmetic comparison maps.

VB: Zero-Divisor Operators and Primary Virasoro Representations*

H-P^{Ar} (Hypothesis 44.3.2) concerns the self-adjoint ordinate operator H_{HP} and the normal operator $\Theta_\xi = \frac{1}{2}I + iH_{\mathrm{HP}}$. A primary Virasoro representation is a separate construction. Chapter 35 identifies three obstructions on the full Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$: (i) only the modes $m \geq -1$ act as global finite sums on the restricted tensor product; (ii) the central term $c_{\mathrm{full}} = \sum_p c^{(p)}$ diverges; (iii) the scalar $r_\zeta = 2$ is a determinant-rank residue, not a trace or a global central charge. Restricting to the primary subspace does not by itself construct closed Virasoro operators or identify them with the spectral operator. The relevant distinctions in Chapter 44 are:

- Remark 44.3.4 separates H_{HP} from conformal modes and keeps $\mathcal{V}^{\mathrm{prim}}$ as a Hochschild trace class.
- Conjecture 44.3.5 asks for closed operators L_m^{PV} on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ satisfying the Virasoro relations with central charge 2. Its equality with $r_\zeta = 2$ is additional compatibility data.
- Remark 44.3.6 distinguishes the Fock energy L_0^{Vir}, Bost–Connes Hamiltonian N_{BC}, ordinate operator H_{HP}, and zero-divisor operator Θ_ξ. Self-adjointness of H_{HP} means that its spectral ordinates are real; $\Theta_\xi - \frac{1}{2}I = iH_{\mathrm{HP}}$ is skew-adjoint.
- Remark 44.3.7 uses $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$. The gamma poles cancel the trivial zeros and $s(s-1)$ removes the Tate poles. This normalization is distinct from restricting a Fock representation to a primary subspace.

The primary-Virasoro construction and the Weyl-asymptotic comparison remain separate questions. The latter asks whether the Riemann–von Mangoldt density $N(T) \sim (T/2\pi)(\log(T/2\pi) - 1)$ arises in a specified Berry–Keating xp, Connes adelic, or Meyer–Schwartz operator model.

51.5 Resulting Logical Core

The subcondition structure is as follows.

For F2.c, the pointing in Definition 51.2.1 is a morphism $\mathrm{Sp} \to \mathcal{C}$ of E_2-algebras in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. It includes nullary compatibility. The colimit structure has a contractible space of choices relative to the entire underlying colimit cocone, as in Theorem 51.2.3.

For $\mathrm{L}_{\mathrm{ACD}}$: new subcondition $\mathrm{L}_{\mathrm{ACD}}.0$ (archimedean stratum, as above); $\mathrm{L}_{\mathrm{ACD}}.2$ is extended to include $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance.

For F3.$\mathrm{BZN}^{\mathrm{Ar}}$: R1 splits into R1.fin-type (the stated smooth affine $\mathrm{Perf}(A)$ calculation) and R1.formal (the required completed, support-compatible trace comparison); R4 is the non-semisimple Hecke condition at wild primes $p \in \{2, 3\}$.

For arithmetic co–contra comparison, C1–C5 specify further operations and naturality. The P1 application also requires the central-defect identity, Mellin evaluation, and detection condition.

For Koszul–Petersson: five higher-structural sub-claims K1a–K7a are required; K5a asks whether the ramified defect pairing in the Kim arithmetic Chern–Simons construction is anomaly-free.

For VB^*, the primary-Virasoro construction (Conjecture 44.3.5), its common operator domain, and its comparison with Θ_ξ remain additional data. The Weyl-asymptotic problem concerns the spectral realization rather than a Virasoro central-charge computation.

The P1 criterion requires its arithmetic evaluation and defect detection (Theorem 43.5.1). P2 retains its stated domain. P3 requires the arithmetic placement, pairings, completions, and adelic maps of K1–K7 and their higher conditions. The local model calculations do not supply these comparisons.

The F1–F3 comparisons include $\mathrm{L}_{\mathrm{ACD}}.0$, R4, and R1.formal. The positive HP–Li trace implication in Theorem 44.3.10 requires H-P^{Ar} from Hypothesis 44.3.2. The primary Virasoro comparison remains Conjecture 44.3.5.

The sufficient trace route to RH uses the determinant and trace identities of H-P^{Ar} and HP–Li positivity, on the specified arithmetic Hermitian domain. Arithmetic Positselski (C1–C5), Koszul–Petersson compatibility (K1–K7, K1a–K7a), primary-Virasoro reconstruction and Weyl asymptotics are distinct comparison problems; their labels do not identify their carriers. A route through operator positivity must first specify its sector and preserved operations, and then supply the positive trace comparison. Proposition 51.2.10 rules out the all-Fock assertion under the vacuum normalization and constructs the maximal reducing positivity sector of a given self-adjoint energy operator. Its comparison with arithmetic operations and the HP–Li trace is the remaining problem of Remark 51.2.11.

The finite trace calculation and the operator dictionary have different roles. The calculation excludes a general scalar-trace-to-operator positivity argument. The dictionary states which arithmetic operators and maps a proof must actually construct. Neither removes the primary-Virasoro or spectral-realization problems.

The remaining open subconditions are primary-Virasoro reconciliation, the non-semisimple Hecke condition R4, the defect-pairing anomaly K5a, and Weyl-asymptotic class.

Chapter 52

$\mathrm{L}_{\mathrm{ACD}}$ Subconditions: Archimedean Stratum, Colimit Commutation, Cross-Prime Hecke, Sph-Finite Preservation

The modular decomposition of $\mathrm{L}_{\mathrm{ACD}}$ *(Theorem 48.2.1, Theorem 51.2.4) produces five subconditions:* $\mathrm{L}_{\mathrm{ACD}}.0$ *(archimedean stratum admissibility, isolated by the archimedean-factor analysis of Section 51.4),* $\mathrm{L}_{\mathrm{ACD}}.1$ *(dg-categorical colimit commutation),* $\mathrm{L}_{\mathrm{ACD}}.2$ *(cross-prime Hecke coherence including* $U(\mathfrak{gl}_2)^{K_\infty}$*-equivariance),* $\mathrm{L}_{\mathrm{ACD}}.3$ *(sph-finite preservation), and* $\mathrm{L}_{\mathrm{ACD}}.4$ *(strong approximation for* $SL_2/\mathbb{Q}$ *together with the determinant idele-class quotient for* $GL_2/\mathbb{Q}$*). Kneser 1966 and Platonov–Rapinchuk 1994 supply the simply connected part; Tate's idele formalism supplies the determinant line. This chapter separates the formal subconditions from the remaining comparison data: Harish-Chandra 1966 admissibility, Jacquet–Langlands SLN 114 archimedean theory, Vogan 1981 classification, Wallach 1988/1992 real-reductive-groups spectrum theory, Bernstein–Zelevinsky 1976 induced representations, and Lurie HA §5.1, §4.8 and Fresse 2017* E_n *operadic machinery; the Fargues–Scholze list is not invoked for the formal steps. The* ∞*-categorical Bernstein lift and the Bernstein-centre diamond-gluing compatibility remain open inputs.*

52.1 Subconditions and Independent Sources

The Subcondition List

The modular decomposition (Theorem 48.2.1) splits $\mathrm{L}_{\mathrm{ACD}}$ into (L_1)–(L_4); Theorem 51.2.4 relabels these as $\mathrm{L}_{\mathrm{ACD}}.1$–$\mathrm{L}_{\mathrm{ACD}}.4$:

- $\mathrm{L}_{\mathrm{ACD}}.1$ (colimit commutation);
- $\mathrm{L}_{\mathrm{ACD}}.2$ (cross-prime Hecke coherence);
- $\mathrm{L}_{\mathrm{ACD}}.3$ (sph-finite preservation);
- $\mathrm{L}_{\mathrm{ACD}}.4$ (strong approximation for SL_2 plus determinant idele-class quotient for GL_2).

The archimedean-factor analysis of Section 51.4 identifies a fifth subcondition $\mathrm{L}_{\mathrm{ACD}}.0$ (archimedean stratum admissibility) and tightens $\mathrm{L}_{\mathrm{ACD}}.2$ to include $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance.

The local list of subconditions considered here is:

$\mathrm{L}_{\mathrm{ACD}}.0$: archimedean stratum with Harish-Chandra admissibility replacing Iwahori-fixedness;

$\mathrm{L}_{\mathrm{ACD}}.1$: colimit commutes with sph-finite truncation in $\mathrm{Pr}^{\mathrm{L,st}}$;

$\mathrm{L}_{\mathrm{ACD}}.2$: cross-prime Hecke coherence including $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance;

$\mathrm{L}_{\mathrm{ACD}}.3$: sph-finite preservation under restricted-tensor colimit;

$\mathrm{L}_{\mathrm{ACD}}.4$: strong approximation for $SL_2/\mathbb{Q}$, with the determinant quotient retained for $GL_2/\mathbb{Q}$.

Independent Sources

The formal parts of $L_{ACD}.0$–$L_{ACD}.3$ are treated here via an independent list; the Fargues–Scholze geometrization construction is not invoked for those formal steps.

Primary sources used:

Harish-Chandra 1966 "Discrete series for semisimple Lie groups II", Acta Math. 116. Admissible representations of reductive Lie groups; the category of $(\mathfrak{g}, K)$-modules.

Jacquet–Langlands 1970 *Automorphic Forms on $GL(2)$*, SLN 114. Archimedean local theory for $GL_2(\mathbb{R})$ and $GL_2(\mathbb{C})$.

Vogan 1981 *Representations of Real Reductive Lie Groups*, change in Math. 15. Langlands–Vogan classification at $\mathbb{R}$.

Wallach 1988/1992 *Real Reductive Groups I, II*, Pure & Applied Math., Academic Press. Admissible spectrum theory.

Bernstein–Zelevinsky 1976 "Induced representations of reductive $\mathfrak{p}$-adic groups I", Ann. Sci. ENS. Bernstein decomposition of p-adic Hecke categories.

Lurie HA *Higher Algebra*, 2017 draft. §5.1 (E_n monoidal coherence), §4.8 (colimits in Pr^{L}).

Fresse 2017 *Homotopy of Operads and Grothendieck–Teichmüller Groups, Vol. II*. Integral E_n operadic machinery.

Secondary sources: Beilinson–Bernstein 1993 (localization; D-modules on G/B, archimedean localization), Nadler 2009 (microlocal sheaves on real flag varieties), Borel 1976 (admissible representations of semi-simple groups over local fields), Kneser 1966 (strong approximation for simply-connected groups), Platonov–Rapinchuk 1994 *Algebraic Groups and Number Theory*, Moeglin–Waldspurger 2016 (twisted trace formula).

Raskin 2021 JAMS supplies the geometric precedent for (L_1). For (L_2), the local input is Fargues–Scholze, while the function-field comparison remains an analogy. Gaitsgory–Rozenblyum supplies the $\mathrm{IndCoh}_{\mathrm{Nilp}}$ continuity input.

The categorical colimit argument uses Lurie HA §5.1 and §4.8, with the stated pointed-E_n hypotheses. The archimedean admissibility input uses Harish-Chandra, Vogan, and Wallach. Bernstein–Zelevinsky and Lurie HA §5.1.2 supply the local Hecke and symmetric-monoidal constructions. For $L_{ACD}.0$, $L_{ACD}.1$, and $L_{ACD}.3$, the geometric source set consists of Raskin, Fargues–Scholze, and Gaitsgory–Rozenblyum. The categorical and representation-theoretic set consists of Lurie, Harish-Chandra, Vogan, Wallach, and Bernstein–Zelevinsky. These sources concern different parts of the construction. A comparison requires the actual maps and compatibilities of Chapter 1; the separation of references does not provide them. Raskin's geometric descent result does not establish archimedean admissibility, and Wallach's representation theory does not construct colimits in $\mathrm{Pr}^{\mathrm{L,st}}$. The ∞-categorical lift required for Bernstein–Zelevinsky compatibility remains a separate lift datum.

52.2 Overview of Subcondition Closures

The formal subconditions $L_{ACD}.0$–$L_{ACD}.3$ are analysed in the four sections that follow; the compatibility with the completed Tate character $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$ functional equation occupies Section 52.8.

$L_{ACD}.0$: *archimedean stratum*

At the archimedean place, the local category $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{R})])$ is not defined by Iwahori-fixed vectors (as at finite primes) but by $(\mathfrak{g}, K_\infty)$-admissibility: the empty-S base case of the restricted tensor product

is $\mathrm{Rep}(K_\infty)$, not Vec, and any construction of the restricted tensor product $\bigotimes'_{v\in|\overline{C}|} C_v$ must carry a parallel archimedean factor.

The resolution is Harish-Chandra admissibility. The archimedean local category is $\mathrm{D}((\mathfrak{g}, K_\infty)\text{-mod}^{\text{sph-fin}})$ with admissibility replacing Iwahori-fixedness. Jacquet–Langlands SLN 114 §1–3 and Vogan 1981 classify the admissible $(\mathfrak{g}, K_\infty)$-modules for $GL_2(\mathbb{R})$; the sph-fin cut selects the modules finite over the archimedean Hecke algebra (the convolution algebra of bi-K_∞-finite distributions). The detailed construction and proof appear in Section 52.3.

$\mathrm{L}_{\mathrm{ACD}}$.1*: colimit commutation*

The filtered colimit defining $\bigotimes'_v C_v$ and the sph-fin subcategory inclusion $C_v^{\text{sph-fin}} \hookrightarrow C_v$ are a priori unrelated operations; it is not immediate that they commute.

F2.c tightened (Theorem 50.1.3) supplies the universal property needed: the restricted tensor product of pointed E_n-monoidal categories carries a canonical E_n-monoidal structure, unique up to a contractible space of choices, compatible with the insertion functors ι_S. Sph-finite truncation is defined by compact generation (Lemma 48.2.4), and Lurie HA 5.3.2.9 gives that filtered colimits of compactly generated categories along compact-generator-preserving functors are compactly generated. Hence the colimit commutes with the sph-fin inclusion. The proof appears in Section 52.4.

$\mathrm{L}_{\mathrm{ACD}}$.2*: cross-prime Hecke coherence*

For distinct primes $p \neq q$, the local Hecke operators T_p and T_q act on disjoint tensor factors of the restricted tensor product. The question is whether they commute up to coherent associators and unit coherences, and whether this extends to $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance at the archimedean place.

Lurie HA 5.1.2.4 (Dunn additivity) and HA 5.1.2.26 (centrality of the unit in an E_n-monoidal category) supply the coherence: endofunctors of a tensor product acting on disjoint tensor factors commute up to a contractible space of coherence data. Extension to the archimedean place is immediate from the disjointness of C_∞ and each C_p as tensor factors. The proof appears in Section 52.5.

$\mathrm{L}_{\mathrm{ACD}}$.3*: sph-finite preservation*

Sph-finite truncation composes with the colimit to give the sph-finite truncation of the colimit (not merely an approximation), because this is the content of $\mathrm{L}_{\mathrm{ACD}}$.1: if the colimit commutes with sph-fin, then the sph-fin subcategory of the colimit equals the colimit of sph-fin subcategories. Lemma 48.2.4 handles the compact generation step. The proof appears in Section 52.6.

Archimedean character and the completed ξ-function

The archimedean factor $\Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2)$ is the archimedean local L-factor of the trivial representation; Tate 1950 §4.3 computes it as the Mellin transform of the Gaussian. Thus the trace comparison, if it is constructed, must send the archimedean unit to the Gaussian Tate vector. The restricted tensor product is compared with $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$, not with $\zeta(s)$ alone. The necessary Tate calculation appears in Section 52.8; the categorical trace comparison is a separate input.

52.3 $\mathrm{L}_{\mathrm{ACD}}$.0: Archimedean Stratum Closure

Statement and Construction

Definition 52.3.1 *(archimedean admissible $(\mathfrak{g}, K_\infty)$-module).* Let $\mathfrak{g} = \mathfrak{gl}_2(\mathbb{R})$ and $K_\infty = O(2) \subseteq GL_2(\mathbb{R})$. A $(\mathfrak{g}, K_\infty)$-*module* is a real vector space V with a $\mathfrak{g}$-module structure and a compatible

K_∞-action such that: (i) the K_∞-action is locally finite; (ii) the differentiated K_∞-action agrees with the restriction of the $\mathfrak{g}$-action to $\mathrm{Lie}(K_\infty) = \mathfrak{k}$. The module is *admissible* if also: (iii) each K_∞-isotype $V(\sigma)$ for $\sigma \in \widehat{K_\infty}$ is finite-dimensional (Harish-Chandra 1966 §3).

Definition 52.3.2 *(archimedean sph-finite category).* The archimedean sph-finite category is

$$\mathcal{C}_\infty \;:=\; \mathrm{D}^{\text{sph-fin}}\big((\mathfrak{g}, K_\infty)\text{-mod}^{\text{adm}}\big)$$

the stable presentable ∞-category of admissible $(\mathfrak{g}, K_\infty)$-modules of finite type over the archimedean Hecke algebra $\mathcal{H}_\infty = \mathrm{End}_{(\mathfrak{g},K_\infty)}(V_{K_\infty}^{\mathrm{fin}})$, where $V_{K_\infty}^{\mathrm{fin}}$ ranges over admissible $(\mathfrak{g}, K_\infty)$-modules.

Theorem 52.3.3 *(L_{ACD}.0 closed).* The archimedean category $\mathcal{C}_\infty$ of Definition 52.3.2 is:

(i) a well-defined stable presentable ∞-category;

(ii) equipped with a distinguished unit $u_\infty \in \mathcal{C}_\infty$ (the K_∞-spherical unramified principal series) whose unit-comparison map $\eta_\infty : \mathbb{1}_{\mathcal{C}_\infty} \to u_\infty$ is canonical;

(iii) classifiable by Langlands–Vogan parameters (Vogan 1981 Chapters 2–5): the isomorphism classes of irreducible admissible $(\mathfrak{g}, K_\infty)$-modules correspond bijectively to triples $(\lambda, \mu, \varepsilon)$ with $\lambda \in \mathbb{C}$ (weight), $\mu \in \mathbb{Z}_{\geq 0}$ (discrete-series parameter), and $\varepsilon \in \{\pm 1\}$ (central character sign);

(iv) the empty-S base case of the restricted tensor product is $\mathrm{Rep}(K_\infty)$, not Vec.

Proof. **Step 1: Stability and presentability.** The category of $(\mathfrak{g}, K_\infty)$-modules is abelian (Wallach 1988 §0.1). Passing to the derived category and restricting to admissible modules (finite per K_∞-isotype) preserves stability (the derived category of an abelian category is stable). Presentability follows from Wallach 1988 Theorem 0.A.2: the category of admissible $(\mathfrak{g}, K_\infty)$-modules is an abelian Grothendieck category, so its derived category is presentable (Lurie HA 1.3.5.21).

Step 2: Distinguished unit. The unramified principal series $\mathrm{Ind}_{B(\mathbb{R})}^{GL_2(\mathbb{R})}(\chi_1 \boxtimes \chi_2)$ with $\chi_1 = \chi_2 = |\cdot|^0$ the trivial character gives the irreducible spherical unramified principal series; this is the archimedean analogue of the spherical Iwahori-fixed vector at a finite prime. Harish-Chandra 1958 "Spherical functions on a semisimple Lie group" identifies this module as the unique irreducible admissible representation of $GL_2(\mathbb{R})$ with a non-zero K_∞-fixed vector at weight 0. The unit-comparison map $\eta_\infty : \mathbb{1} \to u_\infty$ is the inclusion of the unit admissible module (the trivial character of the archimedean Hecke algebra) into the spherical unramified principal series.

Step 3: Langlands–Vogan classification. Vogan 1981 Theorem 5.1.1 gives the Langlands classification for $GL_2(\mathbb{R})$: the irreducible admissible $(\mathfrak{g}, K_\infty)$-modules are parametrized by Langlands data, which for $GL_2(\mathbb{R})$ reduces to the triple $(\lambda, \mu, \varepsilon)$. The classes are:

- principal series (including the spherical unramified one), parametrized by $\lambda \in \mathbb{C}$ and central character sign ε;
- discrete series D_k for $k \in \mathbb{Z}_{\geq 2}$, with lowest weight k;
- limits of discrete series $D_1^{\pm}$;
- irreducible unitary finite-dimensional modules (only the trivial module here).

Each class is K_∞-finite in each isotype, hence admissible. Wallach 1988 Ch. 5 organises these into the admissible spectrum.

Step 4: Base case identification. The empty-S stage of the restricted tensor product is $\bigotimes_{v \in \emptyset} \mathcal{C}_v = \mathbb{1}_{\mathrm{Pr}^{L,\mathrm{st}}} = \mathrm{Sp}$. The transition map $\iota_{\emptyset \subseteq \{\infty\}}$ inserts the spherical unit u_∞. The image of Sp under tensoring with u_∞ is $\mathrm{Sp} \otimes u_\infty$, which inside $\mathcal{C}_\infty$ is the full subcategory generated by u_∞. Since u_∞ is a K_∞-finite

admissible module, this subcategory is $\mathrm{Rep}(K_\infty)$ as a subcategory of admissible $(\mathfrak{g}, K_\infty)$-modules. The empty-S base is therefore $\mathrm{Rep}(K_\infty)$, not Vec. □

Compatibility with Finite-Place Sph-Fin Structure

Proposition 52.3.4 *(uniformity of the sph-fin definition across places).* The sph-fin condition at an archimedean place (Definition 52.3.2) is the natural admissibility restriction, and coincides with the finite-prime sph-fin condition (compact-generated ∞-category with finite-type compacts) under the identification of K_∞-finite admissible modules with finite-type modules over the archimedean Hecke algebra.

Proof. Wallach 1988 §0.A associates to each admissible $(\mathfrak{g}, K_\infty)$-module a module over the archimedean Hecke algebra $\mathcal{H}_\infty$, which is the convolution algebra of bi-K_∞-finite distributions on $GL_2(\mathbb{R})$. This gives a faithful embedding of admissible $(\mathfrak{g}, K_\infty)$-modules into modules over $\mathcal{H}_\infty$. Finite-type $\mathcal{H}_\infty$-modules correspond to K_∞-finite admissible modules (Harish-Chandra 1966 §4). Hence the archimedean sph-fin $C_\infty^{\text{sph-fin}}$ corresponds to the full subcategory of compactly generated $\mathcal{H}_\infty$-modules, matching the finite-prime definition. □

Corollary 52.3.5 *(archimedean factor enters the restricted tensor).* The archimedean factor C_∞ enters the restricted tensor product $\bigotimes'_{v\in|\overline{C}|} C_v$ on equal footing with the finite-prime factors, with distinguished unit u_∞ as in Theorem 52.3.3. The indexing set is $V = |\overline{C}| = \mathbb{P} \cup \{\infty\}$, and the cofinite unramified subset V^{sph} includes both finite unramified primes and the archimedean place.

Remark 52.3.6 *(archimedean admissibility tightens the (L_4) extension requirement).* The subcondition (L_4) of Theorem 48.2.1 was stated as "the archimedean factor extends the finite-place product by direct tensoring." L_{ACD}.0 tightens this: the archimedean factor is Harish-Chandra admissible rather than Iwahori-fixed, and the empty-S base case is $\mathrm{Rep}(K_\infty)$ rather than Vec. The original (L_4) statement is preserved as a corollary; the tightening is substantive, since no Iwahori subgroup of $GL_2(\mathbb{R})$ gives the natural finiteness cut at $v = \infty$.

52.4 L_{ACD}.1: Dg-Categorical Colimit Commutation

Statement

Theorem 52.4.1 (L_{ACD}.1 *closed given F2.c). (conditional on F2.c tightened, Theorem 50.1.3; F2.c tightened is itself a theorem, see Remark 52.7.2).* Let $\{(C_v, u_v, \eta_v)\}_v$ be a family of pointed E_2-monoidal stable presentable ∞-categories (in the sense of Definition 51.2.1, with η_v an E_2-algebra map per the tightening of Theorem 50.1.3) with $u_v = \mathbb{1}_{C_v}$ at almost every v. Let $V^{\text{sph}} \subseteq V$ be a cofinite subset of places. Assume each C_v carries a sph-fin subcategory $C_v^{\text{sph-fin}} \subseteq C_v$ compact-generating, and u_v is compact for $v \in V^{\text{sph}}$. Then the restricted tensor product commutes with sph-fin truncation:

$$\Big(\bigotimes_v{}' C_v\Big)^{\text{sph-fin}} \;\simeq\; \bigotimes_v{}' C_v^{\text{sph-fin}} \tag{52.1}$$

as stable presentable ∞-categories.

Proof. **Step 1: Both sides are compactly generated.** Theorem 50.1.3(M2) and Lemma 48.2.4 together show that $\otimes'_v C_v$ is compactly generated, with compact subcategory $\varinjlim_S \otimes_{v\in S} C_v^\omega$. The right-hand side of (52.1) is the restricted tensor product of sph-fin categories, itself compactly generated by Lemma 48.2.4.

Step 2: Compact objects match. Lurie HA 5.3.2.9 gives that a filtered colimit of compactly generated ∞-categories along compact-generator-preserving functors is compactly generated, with compact subcategory the filtered colimit of compact subcategories. Applied to the defining filtered colimit of the restricted tensor product:

$$\Big(\bigotimes_v{}' C_v\Big)^{\omega} \;=\; \varinjlim_{S} \bigotimes_{v\in S} C_v^{\omega}.$$

Step 3: Sph-fin is the compact subcategory. By the sph-fin definition in Lemma 48.2.4, the sph-fin condition *is* the compact-generation structure enforced by the distinguished spherical units. Hence

$$\Big(\bigotimes_v{}' C_v\Big)^{\text{sph-fin}} \;=\; \mathrm{Ind}\Big(\big(\bigotimes_v{}' C_v\big)^{\omega}\Big) \;=\; \mathrm{Ind}\Big(\varinjlim_{S} \bigotimes_{v\in S} C_v^{\omega}\Big).$$

Step 4: Ind commutes with filtered colim. Lurie HTT 5.3.5.15 (Ind-completion preserves filtered colimits of small ∞-categories). The Ind of a filtered colimit of small ∞-categories is the filtered colimit of Ind-completions. Hence

$$\mathrm{Ind}\Big(\varinjlim_{S} \bigotimes_{v\in S} C_v^{\omega}\Big) \;=\; \varinjlim_{S} \mathrm{Ind}\Big(\bigotimes_{v\in S} C_v^{\omega}\Big) \;=\; \varinjlim_{S} \bigotimes_{v\in S} C_v^{\text{sph-fin}} \;=\; \bigotimes_v{}' C_v^{\text{sph-fin}}.$$

Step 5: E_2-monoidal structure matches. F2.c tightened (Theorem 50.1.3(M3)) gives that the E_2-monoidal structure on the restricted tensor product is unique up to a contractible space of choices, and the uniqueness is cofinality-invariant. The E_2-structure on the LHS of (52.1) is inherited from $\otimes'_v C_v$ via restriction to the sph-fin subcategory; the E_2-structure on the RHS is inherited from $\otimes'_v C_v^{\text{sph-fin}}$. Both agree by the universal property of the canonical E_2-monoidal structure.

Assembling Steps 1–5: both sides of (52.1) are compactly generated stable presentable ∞-categories with isomorphic compact subcategories and isomorphic E_2-monoidal structures. The isomorphism follows. □

Remark 52.4.2 *(role of F2.c tightening).* L_{ACD}.1 is a consequence of F2.c tightened plus Lurie HA 5.3.2.9 and HTT 5.3.5.15. F2.c tightened supplies the universal property of the colimit's E_2-monoidal structure; HA 5.3.2.9 supplies the sph-fin preservation under the filtered colimit; HTT 5.3.5.15 supplies the Ind-filtered-colimit exchange. The three ingredients together close L_{ACD}.1. The source list is entirely Lurie HA + HTT, disjoint from Fargues–Scholze and from Raskin 2021 JAMS.

Explicit Commutation Square

Corollary 52.4.3 *(commutation square).* The following square in $\mathrm{Pr}^{L,\mathrm{st}}$ commutes up to equivalence:

$$\begin{array}{ccc} \big\{C_v^{\text{sph-fin}}\big\}_v & \xrightarrow{\otimes'} & \otimes'_v C_v^{\text{sph-fin}} \\ \big\downarrow & & \big\downarrow{\scriptstyle \simeq} \\ \big\{C_v\big\}_v & \xrightarrow{\otimes'} & \big(\otimes'_v C_v\big)^{\text{sph-fin}} \end{array}$$

where the vertical arrows are sph-fin inclusion / sph-fin truncation and the horizontal arrows are the Tate restricted tensor product.

Proof. Immediate from Theorem 52.4.1 plus functoriality of the restricted tensor product under compact-generator-preserving functors. □

52.5 $L_{ACD}.2$: Cross-Prime Hecke Coherence

Statement

Theorem 52.5.1 *(formal tensor-factor Hecke commutativity).* For a family $\{(C_v, u_v, \eta_v)\}_v$ of pointed E_2-monoidal stable presentable ∞-categories as in Theorem 52.4.1, equipped with local Hecke operators $T_v \in \mathrm{End}_{E_2}(C_v)$ (i.e. E_2-algebra endomorphisms of each factor) and archimedean $U(\mathfrak{gl}_2)^{K_\infty}$-action on C_∞:

(i) For any two distinct places $v \neq w$, the extensions $\widetilde{T}_v, \widetilde{T}_w : \otimes'_v C_v \to \otimes'_v C_v$ of the local operators by identity on all other factors commute up to canonical homotopy:

$$\widetilde{T}_v \circ \widetilde{T}_w \;\simeq\; \widetilde{T}_w \circ \widetilde{T}_v.$$

(ii) Associativity and unit coherences hold: for any three distinct places v_1, v_2, v_3, the square associators and unitors satisfy the standard symmetric-monoidal MacLane pentagon / triangle coherences (Lurie HA 5.1.2.6).

(iii) The archimedean $U(\mathfrak{gl}_2)^{K_\infty}$-equivariance commutes with every finite-prime T_p.

Remark 52.5.2 *(domain: formal versus global Hecke coherence).* The theorem establishes commutativity of local endofunctors on the restricted tensor product and the archimedean equivariance. Global Hecke functoriality of the automorphic category and the local-global Whittaker–Bernstein compatibility are distinct properties; both remain part of (BC-diamond-glue) and are outside the domain of Theorem 52.5.1.

Proof. **Step 1: Tensor-factor disjointness.** Each Hecke operator T_v acts on the single factor C_v of the restricted tensor product. The extension by identity on other factors, $\widetilde{T}_v := T_v \otimes \mathrm{id}_{\neq v}$, is an endofunctor of $\otimes'_v C_v$ that factors through the tensor factor at v. For distinct places $v \neq w$, the endofunctors $\widetilde{T}_v$ and $\widetilde{T}_w$ factor through disjoint tensor factors.

Step 2: Disjoint tensor factors commute up to canonical homotopy. Lurie HA 4.8.1 states that endofunctors of a tensor product $\mathcal{C} \otimes \mathcal{D}$ that factor through disjoint tensor factors commute up to a canonical homotopy, because they correspond to bi-colimit-preserving functors $\mathcal{C} \times \mathcal{D} \to \mathcal{C} \otimes \mathcal{D}$ and the product in the source is symmetric. Applied to $\widetilde{T}_v$ and $\widetilde{T}_w$ acting on $C_v \otimes C_w \otimes \otimes'_{u \neq v,w} C_u$: commutativity holds up to canonical homotopy.

Step 3: Higher coherences. Lurie HA 5.1.2.6 asserts that E_2-monoidal stable presentable ∞-categories form a $(\infty, 3)$-category in which the coherence data for a symmetric-monoidal pattern is contractible. The three-fold composition of Hecke operators at distinct places v_1, v_2, v_3 admits a unique coherent associator by the universal property of the restricted tensor product. The pentagon and triangle coherences are automatic.

Step 4: Archimedean equivariance. The $U(\mathfrak{gl}_2)^{K_\infty}$-action on C_∞ is the central Harish-Chandra action on the archimedean $(\mathfrak{g}, K_\infty)$-category. It factors through C_∞ alone. For any finite prime p, the Hecke operator T_p factors through C_p. The two factor through disjoint tensor factors (C_∞ and C_p). By Step 2, they commute up to canonical homotopy.

Full coherence. The full coherence of the symmetric-monoidal pattern is encoded by the requirement that $\otimes'_v C_v$ is an E_2-algebra object in $\mathrm{Pr}^{L,\mathrm{st}}$ carrying E_2-algebra endomorphisms $\widetilde{T}_v$ that factor through disjoint tensor factors. Lurie HA 5.1.2.4 (Dunn additivity $E_2 \otimes E_2 \simeq E_4$) would suggest that the composite space of such endomorphisms is naturally E_4-structured; however, restriction to the subspace of endomorphisms factoring through individual tensor factors (i.e. local Hecke operators) reduces

the structure back to E_2 per factor. This is the precise sense in which cross-prime Hecke coherence holds. □

Bernstein–Zelevinsky Compatibility

Conjecture 52.5.3 *(∞-categorical Bernstein lift).* The Bernstein–Zelevinsky decomposition of the abelian category of smooth $GL_2(\mathbb{Q}_p)$-representations lifts to the stable presentable local Hecke category C_p, with the Bernstein centre acting by orthogonal idempotent projectors and with the spherical finite subcategory generated by compact objects finite over the spherical Bernstein centre.

Proposition 52.5.4 *(Bernstein–Zelevinsky local compatibility).* Conditional on Conjecture 52.5.3. At each finite prime p, the local Hecke category C_p decomposes along Bernstein–Zelevinsky components (Bernstein–Zelevinsky 1976 Ann. ENS §2): each Bernstein component corresponds to a cuspidal datum $[M, \sigma]$ of a Levi $M \subseteq GL_2(\mathbb{Q}_p)$ and a cuspidal supercuspidal representation σ of M. The Hecke operator T_p preserves each Bernstein component.

Proof. Bernstein–Zelevinsky 1976 proves the decomposition of the category of smooth representations of $GL_2(\mathbb{Q}_p)$ into Bernstein components. Each component is invariant under the centre of the Hecke algebra, which includes the spherical Hecke operator T_p acting on the spherical principal series component (the unramified component). The passage from this abelian decomposition to C_p is exactly Conjecture 52.5.3. Under that datum, the idempotent projectors commute with T_p, so T_p preserves every lifted Bernstein component. □

Remark 52.5.5 *(role of Bernstein–Zelevinsky).* Bernstein–Zelevinsky 1976 supplies the local decomposition of the smooth representation category. After Conjecture 52.5.3, the same idempotents act on the stable local Hecke category and are compatible with cross-prime Hecke coherence, because Hecke operators at distinct primes act on disjoint tensor factors. The global statement is therefore conditional on the lift datum; it is not a consequence of the abelian Bernstein–Zelevinsky theorem alone.

52.6 $L_{ACD}.3$: Sph-Finite Preservation

Statement

Theorem 52.6.1 *($L_{ACD}.3$ automatic given $L_{ACD}.1$).* The sph-fin subcategory $D^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)])$ is preserved under the restricted-tensor colimit: the colimit of sph-fin categories embeds in the sph-fin subcategory of the colimit, and this embedding is an equivalence:

$$\varinjlim_{S} \bigotimes_{v \in S} C_v^{\text{sph-fin}} \xrightarrow{\sim} \Big(\bigotimes_{v}{}' C_v \Big)^{\text{sph-fin}}.$$

Proof. Immediate from Theorem 52.4.1: the right-hand side equals $\otimes'_v C_v^{\text{sph-fin}}$, which by definition of the restricted tensor product is the filtered colimit of finite tensor products of sph-fin factors, i.e. the left-hand side. □

Corollary 52.6.2 *(sph-fin preserved fully).* The forgetful functor $\mathrm{Pr}^{L,\text{st,sph-fin}} \to \mathrm{Pr}^{L,\text{st}}$ preserves the restricted tensor product of pointed E_2-monoidal categories satisfying Setup 50.1.1.

Proof. Consequence of Theorem 52.6.1. □

Uniformity of the Sph-Fin Subcategory

Proposition 52.6.3 *(uniformity across finite primes).* Conditional on Conjecture 52.5.3. The sph-fin subcategory $D^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])$ at a finite prime p is the full subcategory of ∞-categorically compact objects generated by the spherical vector $|0\rangle_p$, and the compact generators are finite over the local spherical Hecke algebra.

Proof. Conjecture 52.5.3 supplies the compact generation and the finiteness over the spherical Bernstein centre. The spherical vector generates the unramified component, and Proposition 52.5.4 identifies that component inside the local Hecke category. □

Proposition 52.6.4 *(uniformity at infinity).* The archimedean sph-fin subcategory $D^{\text{sph-fin}}((\mathfrak{g}, K_\infty)\text{-mod}^{\text{adm}})$ is the full subcategory of compact objects generated by the spherical unramified principal series u_∞, and the compact generators are K_∞-finite admissible modules (equivalently, finite-type over the archimedean Hecke algebra $\mathcal{H}_\infty$).

Proof. Proposition 52.3.4 supplies the identification of K_∞-finite admissible modules with finite-type $\mathcal{H}_\infty$-modules. Wallach 1988 Theorem 0.A.2 gives the Grothendieck-category structure on admissible modules, hence compact generation of the derived category. □

52.7 Consequence: Conditional Reduction of L_{ACD}

The Residual Lemma

Corollary 52.7.1 *(L_{ACD} conditional obstruction decomposition). Conditional statement.* Assume F2.c tightened (Theorem 50.1.3), the ∞-categorical Bernstein lift *Conjecture* 52.5.3, the local categorical comparison datum for the finite-prime categories, the archimedean boundary datum of *Theorem* 48.6.1, and the global identification of the restricted tensor product with the automorphic category. Then the remaining Bernstein-centre part of L_{ACD} is (BC-diamond-glue). The latter decomposes by Theorem 56.3.2 into (BCglue.local), requiring the actual coefficient, support and local categorical transport; (BCglue.glue), requiring compatible transitions and effective coherent descent on the common carrier; and (BC-diamond-glue.core), requiring equivariance of the arithmetic comparison for the central actions, including higher homotopies when derived centres are used. Without these inputs, (BC-diamond-glue) alone does not imply L_{ACD}.

Proof. By the initial arithmetic comparison split of L_{ACD} (Theorem 51.2.4) plus the residual splitting refinement (Section 51.4), one has a normalisation implication from the following data:

$$\begin{gathered} L_{ACD}.0, \dots, L_{ACD}.4, \quad \text{local comparison}, \\ \text{global identification}, \quad \text{(BC-diamond-glue)} \\ \Longrightarrow \quad L_{ACD}. \end{gathered}$$

The formal items have the following form:

- $L_{ACD}.0$: archimedean boundary datum (Theorem 52.3.3);
- $L_{ACD}.1$: theorem given F2.c tightened (Theorem 52.4.1);
- $L_{ACD}.2$: formal Hecke commutativity, with the finite-prime Bernstein part conditional on Conjecture 52.5.3 (Theorem 52.5.1);
- $L_{ACD}.3$: theorem (Theorem 52.6.1);

- $L_{ACD}.4$: theorem (Kneser 1966 and Platonov–Rapinchuk 1994 for SL_2; Tate for the determinant idele-class quotient).

Thus this chapter removes only the formal part of the obstruction. The categorical comparison data and (BC-diamond-glue) remain separate inputs. □

Remark 52.7.2 *(F2.c tightened is a theorem).* F2.c tightened (Theorem 50.1.3) is stated as a theorem in Chapter 50 (Lurie HA + Fresse 2017, disjoint from Fargues–Scholze). It supplies only the filtered-colimit and E_2-tensor formalism. It does not supply the ∞-categorical Bernstein lift, the local categorical comparison, the archimedean boundary spectral comparison, the global identification, or (BC-diamond-glue).

Domain of (BC-diamond-glue)

Remark 52.7.3 *((BC-diamond-glue) required theorem).* By Remark 48.2.8, (BC-diamond-glue) requires effective gluing of the specified coherent Springer sheaves on a common arithmetic carrier, together with identification of their centre action with the global Bernstein centre. The full L_{ACD} comparison also needs the local categorical comparison, the ∞-categorical Bernstein lift, the archimedean boundary datum, and the global identification.

Remark 52.7.4 *(cumulative reduction).* The original L_{ACD} contains the full adelic descent problem. The modular decomposition of Theorem 48.2.1 isolates a Bernstein-centre gluing problem, but it does not prove that this problem is the only obstruction. After the present chapter the visible residuals are the local categorical comparison, the ∞-categorical Bernstein lift, the archimedean boundary comparison, the global identification, and (BC-diamond-glue).

52.8 Compatibility with $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$ Factorization

The Completed L-Factor

The completed Riemann ξ-function is

$$\xi(s) \;=\; \tfrac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s) \;=\; \tfrac{1}{2}s(s-1)\cdot\Gamma_{\mathbb{R}}(s)\zeta(s)$$

with archimedean local L-factor $\Gamma_{\mathbb{R}}(s) := \pi^{-s/2}\Gamma(s/2)$ and

$$\zeta(s) \;=\; \prod_p \frac{1}{1-p^{-s}} \;=\; \prod_p L_p(s)$$

with finite-prime local L-factors $L_p(s) = (1-p^{-s})^{-1}$. The completed ξ satisfies the functional equation

$$\xi(s) \;=\; \xi(1-s).$$

Any honest L_{ACD} for $GL_2/\mathbb{Q}$ must produce a trace class whose Tate comparison sees $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$, not merely $\zeta(s)$. Multiplication by $\frac{1}{2}s(s-1)$ then gives the entire function $\xi(s)$.

Tate Character Identification

Proposition 52.8.1 *(archimedean character = $\Gamma_{\mathbb{R}}$).* The Tate local zeta integral of the archimedean Gaussian, after the standard factor 2 normalization, is $\Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2)$, the archimedean local L-factor of the trivial representation.

Proof. Tate 1950 §4.3 (Mellin transform of the Gaussian) computes

$$\int_0^\infty e^{-\pi x^2} x^s \frac{dx}{x} \;=\; \tfrac{1}{2}\pi^{-s/2}\Gamma(s/2) \;=\; \tfrac{1}{2}\Gamma_{\mathbb{R}}(s).$$

The archimedean spherical unramified principal series has Whittaker model whose K_∞-fixed vector is the Gaussian (up to normalisation; Jacquet–Langlands SLN 114 §1.5). The local L-factor at infinity is the Mellin transform of the Gaussian, hence $\Gamma_{\mathbb{R}}(s)$. □

Proposition 52.8.2 *(finite-prime Tate character = $L_p(s)$).* With multiplicative Haar measure normalized by $\mathrm{vol}(\mathbb{Z}_p^\times) = 1$, the Tate local zeta integral of the characteristic function of $\mathbb{Z}_p$ is $L_p(s) = (1 - p^{-s})^{-1}$, the finite-prime local L-factor of the trivial representation.

Proof. Tate 1950 §2 computes the local p-adic integral: the spherical vector $|0\rangle_p$ evaluates to $(1 - p^{-s})^{-1}$ under the standard local Tate integral. □

Theorem 52.8.3 *(Tate product gives $\Lambda_\zeta(s)$).* The product of the normalized Tate local characters over all places of $\mathbb{Q}$ is

$$\prod_v Z_v(s) \;=\; \Gamma_{\mathbb{R}}(s)\prod_p L_p(s) \;=\; \Gamma_{\mathbb{R}}(s)\zeta(s) \;=\; \frac{\xi(s)}{\frac{1}{2}s(s-1)},$$

as a meromorphic identity. Thus the Tate comparison target is $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$.

Proof. This is Tate's product formula for the standard adelic test function:

$$\prod_v Z_v(s) \;=\; \Gamma_{\mathbb{R}}(s)\prod_p L_p(s) \;=\; \Gamma_{\mathbb{R}}(s)\zeta(s).$$

The standard completed ξ-function is obtained from this meromorphic factor by the elementary multiplier $\frac{1}{2}s(s-1)$. □

Functional Equation Compatibility

Corollary 52.8.4 *(functional equation preserved).* The completed Tate product $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$ satisfies the functional equation $\Gamma_{\mathbb{R}}(s)\zeta(s) = \Gamma_{\mathbb{R}}(1-s)\zeta(1-s)$, equivalently $\xi(s) = \xi(1-s)$.

Proof. Theorem 52.8.3 gives Λ_ζ. Tate 1950 identifies the Fourier transform of the standard adelic test function with itself and obtains $\Lambda_\zeta(s) = \Lambda_\zeta(1-s)$. Multiplication by $\frac{1}{2}s(s-1)$ gives the displayed equation for ξ. □

Remark 52.8.5 *(significance of the parallel archimedean factor).* Without the parallel archimedean factor, the restricted tensor product $\otimes'_{p<\infty} C_p$ could at most compare with $\zeta(s)$, not with $\Lambda_\zeta(s)$. The finite-prime product satisfies no functional equation of its own; only the completed Tate product $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\zeta(s)$ does. Hence $\mathrm{L}_{\mathrm{ACD}}.0$ (archimedean stratum) is a *mathematical necessity*, not a cosmetic addition: it is required before any restricted-tensor construction can be compared with the completed Tate character.

Remark 52.8.6 *(trace comparison is extra structure).* The Tate calculation above is not a computation of Hochschild trace in the local Hecke categories. A categorical realization must still construct a trace-to-Tate comparison map and prove that the chosen local units map to the standard local test functions.

52.9 Residual Conditions

Residual LACD Conditions

L_{ACD} contains the local categorical comparison, the ∞-categorical Bernstein lift, the archimedean boundary comparison, the global identification, and (BC-diamond-glue).

Subcondition	Form	Source
L_{ACD}.0 (archimedean stratum)	**Boundary datum**	Harish-Chandra 1966; Vogan 1981; Wallach 1988
L_{ACD}.1 (colimit commutation)	**Theorem** (F2.c tightened)	Lurie HA 5.3.2.9 + F2.c
L_{ACD}.2 (cross-prime Hecke)	**Formal theorem; conditional Bernstein part**	Lurie HA; ∞-categorical BZ lift
L_{ACD}.3 (sph-fin preservation)	**Theorem** (from .1)	Immediate
L_{ACD}.4 (derived strong approximation and determinant quotient)	**Theorem**	Kneser 1966; Platonov–Rapinchuk 1994; Tate 1950
F2.c tightened	**Theorem under pointed E_2 hypotheses** (see Rem. 52.7.2)	Lurie HA; Fresse 2017
∞-categorical BZ lift	**Conjectural**	Conjecture 52.5.3
local categorical comparison and global identification	**Open**	F1.a and L_{ACD} input
(BC-diamond-glue)	**Conjectural**	Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321; construction ε

Table 52.1: Form of L_{ACD} components. Formal pieces are separated from comparison data.

F1 Closure Chain

Theorem 52.9.1 *(F1 residual after local comparison and descent hypotheses). Comparison hypothesis.* Assume F2.c tightened (Theorem 50.1.3), the local categorical comparison (F1.a), the ∞-categorical Bernstein lift, the archimedean boundary comparison, and the global automorphic descent hypotheses. Then F1 (global arithmetic Arinkin–Gaitsgory for $GL_2/\mathbb{Q}$, Conjecture 42.1.1) reduces to (BC-diamond-glue) (Conjecture 48.5.4). Without those hypotheses, (BC-diamond-glue) alone does not close F1.

Proof. By Theorem 43.2.1, F1 reduces to (F1.a) + (F1.b) + (F1.c) + (F1.d). The item (F1.a) is an assumed local categorical comparison; (F1.c) is the Emerton–Gee stack input. Items (F1.b) and (F1.d) combine into L_{ACD} (Corollary 43.2.3). By Corollary 52.7.1, L_{ACD} reduces to (BC-diamond-glue) only after the comparison hypotheses listed in the statement are supplied. □

Remark 52.9.2 *(form of F1 after this chapter).* F1 does not reduce to (BC-diamond-glue) alone. The reduction still contains the local comparison, the ∞-categorical Bernstein lift, the archimedean boundary comparison, and the global descent input. Construction ε addresses only the Bernstein-centre gluing part.

Hypothesis	Role in L_{ACD} reduction	Source
F2.c tightened	Universal property for colimit E_2-structure	Lurie HA, pointed E_2 hypotheses
Lurie HA 5.3.2.9	Sph-fin preservation under filtered colimit	Lurie HA
Lurie HA 5.1.2.4	Dunn additivity for E_n-operads	Lurie HA
Lurie HA 5.1.2.26	Unit centrality in E_n-monoidal cat	Lurie HA
Lurie HTT 5.3.5.15	Ind-completion preserves filtered colimits	Lurie HTT
Harish-Chandra 1966	Admissibility of $(\mathfrak{g}, K_\infty)$-mod	Primary source
Vogan 1981	Langlands–Vogan classification at $\mathbb{R}$	Primary source
Wallach 1988/1992	Real reductive groups spectrum theory	Primary source
Jacquet–Langlands SLN 114	Archimedean local representation	Primary source
Bernstein–Zelevinsky 1976	Bernstein decomposition of p-adic Hecke	Primary source
∞-categorical BZ lift	Stable lift of Bernstein projectors	Conjecture 52.5.3; conjectural
Tate 1950	Adelic Mellin/theta and functional equation	ξ-compatibility
Kneser 1966	Strong approximation for SL_2	L_{ACD}.4 derived subgroup theorem
Tate 1950	Idele-class determinant quotient for GL_2	L_{ACD}.4 determinant line
(BC-diamond-glue)	Bernstein-centre gluing	Construction ε, not yet theorem

Table 52.2: Hypotheses used in this chapter. The non-theorem inputs also include the local comparison, the archimedean boundary comparison, and the global identification.

Hypotheses Inventory

52.10 Conditional Reduction of L_{ACD}

The modular decomposition (Theorem 48.2.1, Theorem 51.2.4, Section 51.4) identifies five subconditions L_{ACD}.0–L_{ACD}.4, with L_{ACD}.4 combines Kneser's strong approximation for SL_2 with Tate's determinant quotient for GL_2. The formal pieces treated here are:

- L_{ACD}.0 as archimedean boundary datum via Harish-Chandra admissibility, Vogan 1981 classification, and Wallach 1988/1992 real-reductive-groups spectrum theory (Theorem 52.3.3);
- L_{ACD}.1 via F2.c tightened, Lurie HA 5.3.2.9, and HTT 5.3.5.15 (Theorem 52.4.1);
- L_{ACD}.2 (formal tensor-factor commutativity) via Lurie HA 5.1.2.4 (Dunn additivity), with finite-prime Bernstein compatibility conditional on Conjecture 52.5.3 (Theorem 52.5.1);
- L_{ACD}.3 from L_{ACD}.1 (Theorem 52.6.1).

The residual of L_{ACD} is not only (BC-diamond-glue). It also contains the local categorical comparison, the ∞-categorical Bernstein lift, the archimedean boundary comparison, and the global identification (Corollary 52.7.1).

The parallel archimedean factor (L_{ACD}.0) is required: without it, the restricted tensor product can at most compare with $\zeta(s)$, not with $\Gamma_{\mathbb{R}}(s)\zeta(s)$, and the Tate functional equation is invisible (Remark 52.8.5).

F1 (global arithmetic Arinkin–Gaitsgory for $GL_2/\mathbb{Q}$) reduces to (BC-diamond-glue) only under the stated comparison and descent hypotheses (Theorem 52.9.1).

The source list for L_{ACD}.0, L_{ACD}.1, and L_{ACD}.3 is disjoint from the Fargues–Scholze list: Harish-Chandra, Jacquet–Langlands, Vogan, Wallach (archimedean representation theory), Lurie HA, Fresse

2017 (higher operadic machinery), and Bernstein–Zelevinsky 1976 (Bernstein decomposition). The ∞-categorical Bernstein lift is not proved from these sources; it is the separate conjectural datum Conjecture 52.5.3.

Chapter 53

BZN^{Ar}: Formal Noetherian Hochschild and Derived Structure on Emerton–Gee

The arithmetic Ben-Zvi–Nadler comparison factors through four independent inputs. The finite-type theorem of Gaitsgory–Rozenblyum applies to smooth finite-type derived stacks. A candidate global spectral object is a Selmer deformation functor on one coefficient category. A formal geometric representative must be constructed before the formal comparison can be applied. That comparison requires a categorical Hochschild-colimit hypothesis, an arithmetic loop-space hypothesis, and a flat-singular-support hypothesis. The inertia shadow does not contain the full Weil/(φ,Γ) datum, and the primes 2 and 3 carry non-semisimple Hecke summands.

53.1 Formal Boundary of the Comparison

Structural Inputs

Chapter 49 isolates the desired arithmetic Hochschild trace equivalence

$$\mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \;\simeq\; \mathcal{O}\big(\mathrm{LocSys}^{W,\varphi^\Gamma}_{GL_2}\big)^{\mathrm{flat}}$$

as an equivalence of E_1-algebras in stable presentable ∞-categories. The finite-type BZN theorem supplies only one factor of the argument. The arithmetic comparison requires the following additional inputs:

R1.fin-type. The Gaitsgory–Rozenblyum theorem (AMS DAG Vol. II Part V Ch. III) that $\mathrm{HH}_\bullet(\mathrm{IndCoh}(\mathcal{X})) \simeq \mathcal{O}(L\mathcal{X})$ holds for smooth finite-type derived stacks $\mathcal{X}$. *Form: theorem* (Gaitsgory–Rozenblyum). The Selmer-derived stack $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$ is initially a formal deformation functor. If its chosen geometric representative is formal Noetherian rather than finite-type, R1.formal below is the required extension.

R1.formal. The extension of the Gaitsgory–Rozenblyum theorem to formal Noetherian derived stacks. For $\mathcal{X}$ a formal Noetherian derived algebraic stack and $\mathcal{C} = \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$,

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;\simeq\; \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}\big)^{\mathrm{flat}}.$$

Form: conjectural; a genuinely open extension requiring new arguments beyond the finite-type case.

R2. Construct the global Selmer deformation functor on a fixed coefficient category, with an identified determinant and actual maps from the local-condition functors. Its tangent is then the corresponding Selmer complex. Comparison with local parameter stacks, geometric representability, formal Noetherianity, and nilpotent-support compatibility are further requirements on the chosen local conditions.

R3. Comparison from the inertia shadow $\mathrm{Map}(B\widehat{\mathbb{Z}},-)$ to the full Weil/(φ,Γ) local-system target. *Form: conjectural*; the inertia-only identification via $\mathrm{Map}(B\widehat{\mathbb{Z}},-)$ constitutes a procyclic shadow of the full Weil/(φ,Γ) target.

R4. Non-semisimple summand at wild primes $p = 2, 3$: $\mathrm{Ext}^{\mathrm{I}}$ contributions to $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p})$ invisible to semisimple templates. *Form: conjectural*; carried by the wild Hecke category.

R2 and R1.formal

The conditions R2 and R1.formal are:

(i) **R2** defines a global Selmer deformation functor by a homotopy pullback. Its local functors must use the same residual coefficient field and determinant convention as the global functor. Local parameter stacks can be used only after their comparison maps with these functors are constructed. Geometric representability and derived Noetherianity remain requirements for the proposed spectral stack. They are not consequences of a product-colimit presentation.

(ii) **R1.formal** follows from three hypotheses (R1.formal.a, b, c). The first is a Hochschild trace theorem after the categorical colimit presentation of $\mathrm{IndCoh}_{\mathrm{Nilp}}$ is supplied. The second and third are respectively the arithmetic loop-space comparison and the flat-singular-support comparison.

R1.fin-type is external. R3 is not definitional: it is the passage from the procyclic inertia shadow to the full $\mathrm{Weil}/(\varphi, \Gamma)$ target. R4 is the non-semisimple wild-prime summand.

Derived Enhancement of the Emerton–Gee Stack

Emerton–Gee arXiv:1908.07185 is written in the language of Noetherian formal algebraic stacks in the sense of the Stacks Project, with the smoothness and mass-formula structure at the level of ordinary (non-derived) schemes. Gaitsgory–Rozenblyum DAG requires a derived enhancement: the cotangent complex must be computed as a perfect complex (or almost-perfect, in the formal case) in the ∞-category of quasi-coherent sheaves, and the ind-colimit presentation must preserve this structure at every stage. The translation is not automatic. It asks for cotangent-complex functoriality under the chosen formal presentation, compatibility with formal thickening, and preservation under the Selmer fibre product. These are hypotheses on the derived enhancement, not consequences of the underived mass formula alone.

Finite-Type Hypotheses in the Gaitsgory–Rozenblyum Argument

The Gaitsgory–Rozenblyum proof of $\mathrm{HH}_\bullet(\mathrm{IndCoh}(\mathcal{X})) \simeq \mathcal{O}(L\mathcal{X})$ uses three ingredients that each rest on finite-type smoothness and require new arguments in the formal Noetherian setting:

(i) Atiyah duality for IndCoh: the self-duality $\mathrm{IndCoh}(\mathcal{X})^\vee \simeq \mathrm{IndCoh}(\mathcal{X})$ under the Atiyah pairing, which requires $\mathcal{X}$ smooth finite-type.

(ii) Smooth-base-change for IndCoh, which also uses finite-type.

(iii) Loop-space duality: the free loop space $L\mathcal{X}$ of a finite-type smooth stack is itself smooth (with dimension equal to $\dim \mathcal{X}$, by the standard calculation).

For formal Noetherian $\mathcal{X}$, each ingredient requires a formal analogue: Atiyah duality must be extended to the formal setting (conjectural in general), smooth base-change must be replaced by formal-smooth base-change (subject of ongoing work, e.g., Mok 2025), and the loop space $L\mathcal{X}$ is in general not smooth finite-type.

The formal comparison therefore has the form of a criterion. Given the categorical colimit presentation of $\mathrm{IndCoh}_{\mathrm{Nilp}}$, Hochschild trace commutes with it; the loop and flat-locus comparisons remain separate geometric hypotheses.

53.2 Logical Form of the Inputs

The input structure is as follows:

R2 tangent complex. The continuous deformation functor has tangent $C^\bullet(G, \mathrm{ad}\bar{\rho})[1]$, retaining automorphisms in degree -1. A chosen identification of its determinant replaces the coefficients by $\mathrm{ad}^\circ \bar{\rho}$, including in residual characteristic two. A comparison with a derived local parameter stack must identify that stack's formal deformation functor first. See Chapter 53.3.1.

R2 global Galois constraint. Restriction of a global representation gives a morphism to the product of full local deformation functors. The pointed local-condition functors map to that same product, over the same category $\mathrm{Art}_{W(k)}$. Their homotopy pullback is (69.1), and its tangent is the mapping fiber of restriction minus the local tangent maps. The trace-zero notation in (69.2) uses a determinant identification preserved by arrows.

R2 geometric enhancement. A geometric representative must have the finiteness, cotangent, and singular-support properties needed by the intended category of sheaves. A smooth atlas is a smooth map to a stack. Its existence alone does not make the stack smooth over the coefficient base. Pointwise tangent bounds also do not prove perfectness of a family of cotangent complexes. These are additional hypotheses in Chapter 53.3.5.

R1.formal three inputs. The Gaitsgory–Rozenblyum theorem, ported from finite-type to formal Noetherian, requires three separate arguments: (i) HH-colim-continuity (whether $\mathrm{HH}_\bullet$ commutes with the ind-colimit presentation of the formal stack); (ii) arithmetic loop-space formal computation (whether $L^{\mathrm{Ar}}\mathcal{X} \simeq \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ admits a workable formal description); (iii) flat-locus pullback (whether the nilpotent-singular-support-flat locus on the loop space matches the Emerton–Gee flat locus of Chapter 49.4.7). The first is a trace theorem once the categorical colimit exists; the other two are geometric hypotheses. (See Chapter 53.4.1.)

R1.formal sub-reductions. R1.formal.a is the Hochschild trace statement for a given filtered colimit in the Morita $(\infty, 2)$-category. R1.formal.b reduces to the existence of a cotangent-complex formal loop-space identification (a precise statement in Lurie DAG and Gaitsgory–Rozenblyum Vol. II). R1.formal.c reduces to the compatibility of Arinkin–Gaitsgory nilpotent singular support with the (φ, Γ)-module Fargues–Scholze flat locus. (See Chapter 53.4.2 and Chapter 53.4.9.)

Consistency with the initial arithmetic comparison. The arithmetic comparison of Chapter 49.5.5 uses a pro-étale extension of Ben-Zvi–Francis–Nadler integral transforms. In the present notation this is the R1.formal.b loop-space hypothesis together with the R1.formal.c flat-locus hypothesis.

53.3 R2: The Emerton–Gee Cotangent Complex

The Local Formal Deformation Problem

Proposition 53.3.1 *(local tangent and the geometric comparison).* Let k be a finite field of characteristic ℓ, and let $\bar{\rho} : G_{\mathbb{Q}_p} \to \mathrm{GL}_2(k)$ be continuous. The unframed derived continuous deformation functor on $\mathrm{Art}_{W(k)}$ has tangent

$$T\mathrm{Def}_{G_{\mathbb{Q}_p}} \simeq C^\bullet(G_{\mathbb{Q}_p}, \mathrm{ad}\bar{\rho})[1].$$

A derived enhancement of a local parameter stack has this tangent at $\bar{\rho}$ if its formal deformation functor is equivalent to this one. The claimed equivalence must preserve the coefficient category, residual identification, and allowed arrows.

Proof. Proposition 10.6.1 computes the linearized representation equation and its infinitesimal conjugations, and then its response to simplicial square-zero modules. An equivalence of formal deformation functors identifies those responses, hence their tangent complexes. It is the required extra hypothesis for the stack comparison. □

The framed first-order tangent is Z^1, whereas strict conjugacy classes give H^1. In the unframed stack, H^0 remains in tangent degree -1. It is not removed from the tangent complex by being an automorphism group. With a determinant identification, Proposition 10.6.2 gives $C^\bullet(G_{\mathbb{Q}_p}, \mathrm{ad}^0\bar{\rho})[1]$. Fixing only the determinant value with all strict conjugations is a different deformation problem.

Remark 53.3.2 *(pointwise bounds and perfectness).* If the continuous cohomology groups are finite-dimensional and vanish outside 0, 1, 2, the tangent at this field-valued point is perfect of amplitude contained in $[-1, 1]$. Indeed, over a field a bounded complex with finite-dimensional cohomology is equivalent to a bounded complex of finite-dimensional vector spaces. Its H^0 produces tangent degree -1, and its H^2 produces degree one. Neither term disappears by changing the word used for the moduli object. This pointwise statement does not prove perfectness over a formal coefficient family. It also gives no uniform bound for real places at coefficient characteristic two, by Proposition 10.8.1.

A Common Recipient for Cotangent Comparisons

PROPOSITION 53.3.3 *(the pointed cotangent pro-system).* Let $X = \varinjlim_i X_i$ be an objectwise filtered colimit of pointed functors on derived affine k-schemes, with compatible k-points x_i. Suppose X_i has cotangent complex L_i at x_i. For a square-zero coefficient module N, the space of lifts of the point to $k \oplus N$ is

$$\mathrm{Der}_x(X, N) \simeq \varinjlim_i \mathrm{Map}_{D(k)}(L_i, N).$$

The transition maps give a well-typed inverse system $L_j \to L_i$ in $D(k)$. This assertion does not identify a cotangent object in $\mathrm{IndCoh}(X)$ without additional representability and categorical comparison data.

Proof. By definition, the lift space is the homotopy fiber at x of $X(k \oplus N) \to X(k)$. Filtered colimits of spaces commute with finite homotopy limits, so this fiber is the filtered colimit of the corresponding fibers for X_i. Each is represented by L_i by the cotangent universal property. A transition $X_i \to X_j$ induces $\mathrm{Map}(L_i, N) \to \mathrm{Map}(L_j, N)$, hence $L_j \to L_i$, compatibly with composition. □

Closed immersions do not make the cotangent complexes of their source and target equal by pullback. For the origin $i : \mathrm{Spec}\, k \hookrightarrow \mathbb{A}^1_k$, $i^*\mathbb{L}_{\mathbb{A}^1_k/k} = k$ in degree zero, whereas $\mathbb{L}_{k/k} = 0$. The relative cotangent complex is $k[1]$, and the transitivity triangle is $k \to 0 \to k[1]$. Thus an ind-presentation must retain its actual cotangent maps. There is no automatic inverse-limit formula obtained by moving objects from different sheaf categories into $\mathrm{IndCoh}(X)$.

COROLLARY 53.3.4 *(cotangents of a derived product).* Let X, Y be derived stacks over a common base $\mathrm{Spec}\, R$ with cotangent complexes, and write π_X, π_Y for the projections from their derived product. Then

$$\mathbb{L}_{X \times^{\mathbf{R}}_R Y/R} \simeq \pi_X^*\mathbb{L}_{X/R} \oplus \pi_Y^*\mathbb{L}_{Y/R}.$$

Proof. Fix a map from T to the derived product and a square-zero extension $T[N]$. Its lifts are exactly pairs of lifts to X and Y over R. Their spaces of derivations are therefore a product. The direct sum on the right represents this product of mapping spaces for every test T and coefficient module N. The cotangent universal property gives the stated equivalence. □

The Selmer Tangent and Its Geometric Requirements

Theorem 53.3.5 *(Selmer deformation functor).* Fix the common coefficient category, determinant identification, residual representation, and pointed local functors of Definition 69.1.1. Their homotopy pullback $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\partial,\mathcal{L}}$ exists as a functor. If the local tangent maps are $L_v \to C^\bullet(G_{\mathbb{Q}_v}, \mathrm{ad}^\circ\bar\rho)$, its tangent is

$$T\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\partial,\mathcal{L}} \simeq C^\bullet_{\mathcal{L}}(G_{\mathbb{Q},S}, \mathrm{ad}^\circ\bar\rho)[1].$$

To use this functor as the geometric spectral target, the following remain additional requirements:

(i) a geometric representative and comparisons with the chosen local parameter stacks on the same coefficient category.

(ii) the Noetherian, perfectness, and cotangent-amplitude properties needed for the intended sheaf theory.

(iii) a definition of the specified nilpotent singular support and its compatibility with the Selmer cotangent maps.

Proof. The pullback is computed in functors to spaces. Its tangent is the fiber of the global and local tangent maps, as proved in Theorem 10.7.1. The further geometric assertions are hypotheses, not conclusions of this functor calculation. In particular, nonzero $H^2_{\mathcal{L}}$ is compatible with quasi-smoothness of a derived scheme, as shown in Example 10.7.2. □

Corollary 53.3.6 *(the inertia shadow does not determine the full target).* . Given Chapter 53.3.5, R3 still requires the full-target comparison:

$$\mathrm{Map}\big(B\widehat{\mathbb{Z}}, \mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}\big) \longrightarrow \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}\big(B\widehat{\mathbb{Z}}\big),$$

as a procyclic shadow, and then a comparison with $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$.

Proof. By Chapter 49.4.1 and Chapter 49.4.5, $\mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}}) = L^{\mathrm{Ar}}BGL_2 = \mathrm{Map}(B\widehat{\mathbb{Z}}, BGL_2)$. The map from $\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}})$ is obtained only after choosing an inertia-shadow comparison morphism $\iota^{\mathrm{Sel}}\colon \mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}} \to \mathrm{LocSys}^{\mathrm{Ar}}_{GL_2}(B\widehat{\mathbb{Z}})$ (Chapter 49.4.6). That inertia-only morphism retains only the procyclic structure, discarding Frobenius and (φ,Γ) data; the full comparison $\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}) \simeq \mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$ requires a separate argument (R3). □

Source and Convention Comparison for R2

The deformation functor. The construction uses continuous derived deformation functors on $\mathrm{Art}_{W(k)}$, with specified residual point and determinant convention. The local and global maps must exist there before their homotopy pullback is formed. A description by a local parameter stack requires a comparison of formal functors, not only an agreement of first-order dimensions.

Degrees and sheaf categories. The tangent of the unframed deformation functor is a shifted cochain complex. Automorphisms remain in degree -1.

A geometric cotangent complex lives initially in quasi-coherent sheaves on its own base. An identification with an ind-coherent object uses the relevant comparison functor and its hypotheses. The pointwise inverse system in Chapter 53.3.3 has the common recipient $D(k)$. It makes no global categorical identification.

Products and formal presentations. The product formula in Chapter 53.3.4 follows from pairs of derivations over a common base. A closed-immersion presentation has relative cotangent terms and must retain their transition maps. Neither formula proves formal Noetherianity or the singular-support compatibility needed by the arithmetic Hochschild comparison.

Remark 53.3.7 *(derived geometric enhancement).* An equivalence between a chosen derived local parameter stack and its continuous deformation functor would identify their tangents by Chapter 53.3.1. It would still leave the global representability, finiteness, and support requirements of Chapter 53.3.5. First-order tangent data, or an ordinary moduli presentation, do not supply that equivalence.

53.4 R1.formal: Formal Hochschild Criterion

The Three Inputs

Theorem 53.4.1 *(formal BZN criterion).* . Let $\mathcal{X}$ be a derived formal algebraic stack in the Gaitsgory–Rozenblyum sense, Noetherian, presented as an ind-colimit $\mathcal{X} = \varinjlim_i \mathcal{X}_i$ of finite-type derived stacks under closed immersions (as in the Emerton–Gee structure theorem). Let $C(\mathcal{X}) = \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$. Assume the finite-type BZN comparison on each $\mathcal{X}_i$, and assume the three conditions below. Then

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;\simeq\; \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}\big)^{\mathrm{flat}},$$

namely R1.formal, holds.

(R1.formal.a) *HH-colim continuity.* The Hochschild trace preserves the ind-colimit presentation of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$:

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;\simeq\; \varinjlim_i \mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_i)\big),$$

under the transition maps induced by closed immersions. **Form: theorem after the categorical colimit presentation is given** (trace continuity; proved in Chapter 53.4.2).

(R1.formal.b) *Arithmetic loop-space formal computation.* For a formal Noetherian derived stack $\mathcal{X}$ as above, the free loop space admits a formal ind-colimit description

$$L^{\mathrm{Ar}}\mathcal{X} \;\simeq\; \varinjlim_i L^{\mathrm{Ar}}\mathcal{X}_i$$

compatible with the closed immersions; equivalently, $L^{\mathrm{Ar}} = \mathrm{Map}(B\widehat{\mathbb{Z}}, -)$ commutes with the ind-colimit presentation. **Form: conjectural** (Lurie ∞-topos formalism in the pro-étale formal setting; see Chapter 53.4.4).

(R1.formal.c) *Flat-locus pullback compatibility.* The flat locus $L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{flat}}$ (cut out by the Arinkin–Gaitsgory nilpotent-singular-support condition lifted to the loop space) is compatible with the ind-colimit structure:

$$\mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}\big)^{\mathrm{flat}} \;\simeq\; \varinjlim_i \mathcal{O}\big(L^{\mathrm{Ar}}\mathcal{X}_i\big)^{\mathrm{flat}},$$

with the flat loci on finite-type pieces matching the (φ, Γ)-module Fargues–Scholze flat locus of Chapter 49.4.7. **Form: conjectural** (Arinkin–Gaitsgory singular support extended to this formal Selmer setting; see Chapter 53.4.7).

Proof. Assume (R1.formal.a), (R1.formal.b), and (R1.formal.c). By (R1.formal.a),

$$\mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})) \;\simeq\; \varinjlim_i \mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_i)).$$

By the Gaitsgory–Rozenblyum theorem applied term-wise,

$$\varinjlim_i \mathrm{HH}_\bullet(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_i)) \;\simeq\; \varinjlim_i \mathcal{O}(L\mathcal{X}_i)^{\mathrm{flat}}.$$

By (R1.formal.b), $\varinjlim_i L\mathcal{X}_i \simeq L^{\mathrm{Ar}}\mathcal{X}$ (noting $L = L^{\mathrm{Ar}}$ on finite-type pieces via the reduction $S^1 \to B\widehat{\mathbb{Z}}$ in the pro-étale setting; this is the content of Chapter 49.5.3 on each finite-type piece). By (R1.formal.c),

$$\varinjlim_i \mathcal{O}(L\mathcal{X}_i)^{\mathrm{flat}} \;\simeq\; \mathcal{O}(L^{\mathrm{Ar}}\mathcal{X})^{\mathrm{flat}}.$$

Composing gives R1.formal. □

R1.formal.a: HH Colimit Continuity

Theorem 53.4.2 *(Hochschild trace along a categorical colimit).* . Let $\mathcal{X} = \varinjlim_i \mathcal{X}_i$ be a formal presentation by derived stacks under closed immersions. Assume that the canonical functor

$$\varinjlim_i \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_i) \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$$

is an equivalence in the E_2-monoidal Morita $(\infty, 2)$-category of stable presentable categories. Then

$$\mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})\big) \;\simeq\; \varinjlim_i \mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_i)\big)$$

as E_1-algebras in stable presentable ∞-categories.

Proof. Hochschild homology is the trace of the identity endofunctor in the Morita $(\infty, 2)$-category of stable presentable categories. The trace functor is symmetric monoidal and preserves filtered colimits of dualizable objects and dualizable morphisms; this is the form of Lurie HA 5.5.3 used here, and it is also obtained from the cyclic bar description of Toën. Applying the trace to the assumed categorical colimit gives the displayed equivalence. The E_1-algebra structure is transported by Dunn additivity from the E_2-monoidal convolution structure. □

Remark 53.4.3 *(where the geometry enters).* The theorem is purely categorical. It does not prove that $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ is the filtered colimit of the categories on the finite pieces. That assertion is a geometric compatibility statement for formal completion, singular support, and the closed-immersion transition functors.

R1.formal.b: Arithmetic Loop-Space Formal Computation (Conditional)

Proposition 53.4.4 *(R1.formal.b domain).* . R1.formal.b reduces to:

(b.1) The internal mapping stack $\mathrm{Map}(B\widehat{\mathbb{Z}}, -)$ commutes with filtered colimits in derived pro-étale stacks under closed immersions.

(b.2) For a formal Noetherian derived stack $\mathcal{X}$ with $\mathcal{X} = \varinjlim_i \mathcal{X}_i$, the natural map $\varinjlim_i \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}_i) \to \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ is an equivalence in the pro-étale topology.

Both (b.1) and (b.2) are Conjectural.

Proof of reduction. R1.formal.b as stated is $L^{\mathrm{Ar}}\mathcal{X} \simeq \varinjlim_i L^{\mathrm{Ar}}\mathcal{X}_i$. By Chapter 49.4.1, $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$. The ind-colimit compatibility of this mapping stack is precisely (b.1) (the general statement about the mapping functor) plus (b.2) (verification of the specific map for the ind-colimit presentation of $\mathcal{X}$). Conversely, given (b.1) and (b.2), R1.formal.b is immediate. □

Remark 53.4.5 *(Compactness and the arithmetic mapping object).* An object M is compact when its space-valued mapping functor $\mathrm{Map}(M, -)$ preserves filtered colimits. Preservation by an internal mapping object must instead be checked after evaluation on the test objects of its ambient category. Neither assertion follows from finite cardinality of a group.

For a prime p, the space $B(\mathbb{Z}/p)$ is not compact in spaces. Let g generate $\mathbb{Z}/p$. The periodic group resolution has alternating differentials $1 - g$ and $1 + g + \cdots + g^{p-1}$. Applying homomorphisms to the trivial module $\mathbb{F}_p$ makes both differentials zero, so its cohomology is nonzero in every nonnegative degree.

A compact space is a retract, up to homotopy, of a finite complex, and has bounded cohomology. Thus this classifying space is not compact.

The profinite cyclic group uses all finite cyclic quotients with divisibility transition maps. The p-power tower describes only $\mathbb{Z}_p$. A presentation by classifying objects requires the specified topology, and an inverse limit does not by itself preserve compactness. Statements (b.1) and (b.2) require the actual comparison maps for the proposed formal arithmetic targets. The finite-module Artin–Rees theorem does not supply them, as the limit exchange in (80.12) illustrates.

Remark 53.4.6 *(size of the loop-space hypothesis).* The hypothesis has three parts: compactness of $B\widehat{\mathbb{Z}}$ against the relevant formal targets, commutation of $\mathrm{Map}(B\widehat{\mathbb{Z}}, -)$ with the chosen formal-Noetherian ind-colimits, and compatibility with IndCoh-functoriality. Each part is a statement in the pro-étale topology. Finite-level mapping behavior and passage to the profinite limit each require their own proof.

R1.formal.c: Flat-Locus Pullback Compatibility (Conditional)

Proposition 53.4.7 *(R1.formal.c domain).* . R1.formal.c reduces to:

(c.1) *Arinkin–Gaitsgory nilpotent singular support extends to derived formal algebraic stacks.* The conic subcategory $\mathrm{IndCoh}_{\mathrm{Nilp}} \subset \mathrm{IndCoh}$ is defined for derived formal algebraic stacks in the GR DAG Vol. II sense, preserving the Arinkin–Gaitsgory functoriality (arXiv:1201.6343).

(c.2) *Flat locus preserved under ind-colimit.* For an ind-colimit $\mathcal{X} = \varinjlim_i \mathcal{X}_i$, the flat locus on the loop space commutes with the ind-colimit: $L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{flat}} \simeq \varinjlim_i L^{\mathrm{Ar}}\mathcal{X}_i^{\mathrm{flat}}$.

(c.3) *Flat locus matches FS locus.* On each finite-type piece $\mathcal{X}_i$, the Arinkin–Gaitsgory flat locus of the loop space coincides with the (φ, Γ)-module Fargues–Scholze flat locus of Chapter 49.4.7.

All three statements are hypotheses.

Proof of reduction. R1.formal.c as stated is $\mathcal{O}(L^{\mathrm{Ar}}\mathcal{X})^{\mathrm{flat}} \simeq \varinjlim_i \mathcal{O}(L^{\mathrm{Ar}}\mathcal{X}_i)^{\mathrm{flat}}$, with the flat loci on finite-type pieces matching Chapter 49.4.7. Unpacking: this requires the flat locus to be *defined* on each finite-type $\mathcal{X}_i$ (which is a statement about nilpotent singular support extending to derived formal algebraic stacks; this is (c.1)), to *commute with ind-colimit* (which is (c.2)), and to *match the FS flat locus* on each finite-type piece (which is (c.3)). Conversely, (c.1) + (c.2) + (c.3) imply R1.formal.c by pasting the three statements together. □

Remark 53.4.8 *(flat support is a separate geometry).* Arinkin–Gaitsgory singular support is defined by the cotangent geometry of a quasi-smooth stack. The Fargues–Scholze flat locus is defined by (φ, Γ)-module geometry. Equality of the two loci on the Emerton–Gee finite pieces is a comparison theorem, not a definition. Compatibility with the formal colimit is another theorem condition.

Sufficient Criterion for F3.BZN^{Ar}

Theorem 53.4.9 *(sufficient criterion for F3.BZN^{Ar}).* . Suppose the structural splitting Chapter 51.2.5 is imposed. The conjunction

- R1.fin-type (Gaitsgory–Rozenblyum: theorem on smooth finite-type).
- R1.formal.a (Hochschild trace along the given categorical colimit).
- R1.formal.b (arithmetic loop-space formal computation: conjectural).
- R1.formal.c (flat-locus pullback compatibility: conjectural).
- R2 (Selmer-derived target, tangent complex, formal Noetherianity, and nilpotent-support compatibility).
- R3 (arithmetic free loop space identification: full-target comparison still required, Chapter 53.3.6).
- R4 (non-semisimple summand at wild primes $p = 2, 3$: wild Hecke summands included).

implies F3.BZN^{Ar}.

Proof. Chapter 51.2.5 expresses F3.BZN^{Ar} as R1 + R2 + R3 + R4, where R1 further splits into R1.fin-type + R1.formal (Chapter 53.1). R1.fin-type is Gaitsgory–Rozenblyum; R1.formal splits into R1.formal.a (Chapter 53.4.2, theorem) plus R1.formal.b (Chapter 53.4.4, conjectural) plus R1.formal.c (Chapter 53.4.7, conjectural) by Chapter 53.4.1. R2 supplies the Selmer target and tangent complex and includes the required finiteness and singular-support hypotheses. R3 supplies the full Weil/(φ, Γ) comparison. R4 inserts the wild-prime summands. These inputs are exactly the factors in the structural splitting, hence their conjunction implies F3.BZN^{Ar}. □

Source and Convention Comparison for R1.formal

Source independence. The argument for R1.formal draws on four disjoint source lists: Lurie HA 5.5.3 / 4.8 / 7.4 (HH, cotangent, colimits); Gaitsgory–Rozenblyum DAG Vol. II Part V Ch. III (HH on smooth finite-type); Arinkin–Gaitsgory arXiv:1201.6343 (nilpotent singular support); Fargues–Scholze arXiv:2102.13459 (local Langlands).

HH conventions. Lurie HA places HH on symmetric monoidal stable presentable ∞-categories in spectra; Gaitsgory–Rozenblyum uses a derived-category trace on IndCoh; Toën 2014 uses a direct simplicial-object computation. All three are equivalent: HH of a stable ∞-category is the colimit over the cyclic category of the self-tensor-product sequence (McCarthy–Schwede, Blumberg–Mandell).

Ambient category. All objects live in derived pro-étale stacks with the $(\infty, 2)$-category of correspondences for IndCoh-valued functoriality.

Hypotheses. The main hypothesis on $\mathcal{X}$ is Noetherianness together with derived-formal-algebraic structure. For the Selmer target this includes the formal Noetherian and nilpotent-support compatibility conditions of Chapter 53.3.5.

Functoriality. HH-colim continuity is a functorial statement on the ∞-category of stable presentable ∞-categories; the criterion by three inputs is itself functorial in $\mathcal{X}$.

Source of the implication. The criterion Chapter 53.4.1 is one-way. The finite-type theorem, Hochschild trace continuity, loop-space compatibility, and flat-locus compatibility imply the formal BZN comparison. The converse is not used.

53.5 Conditional Form of F3.BZN^{Ar}

Corollary 53.5.1 *(conditional arithmetic BZN comparison).* . F3.BZN^{Ar} follows from Chapter 53.4.9 and the conjunction of:

- R1.formal.b (arithmetic loop-space formal computation, conjectural).
- R1.formal.c (flat-locus pullback compatibility, conjectural).
- R2 finiteness and nilpotent-support compatibility for the chosen Selmer deformation problem.
- R3 (full-target loop-space identification, including the Weil/(φ, Γ) comparison).
- R4 (the non-semisimple Hecke summands at $p = 2, 3$).

R1.fin-type is the finite-type theorem. R1.formal.a is the trace theorem for a given categorical colimit. The other entries are geometric hypotheses.

Proof. By Chapter 53.4.9: the conjunction R1.fin-type + R1.formal.a + R1.formal.b + R1.formal.c + R2 + R3 + R4 implies F3.BZN^{Ar}, where R2 includes the finiteness and support hypotheses of Chapter 53.3.5. The corollary is the same implication with the finite-type theorem and trace theorem separated from the geometric hypotheses. □

Remark 53.5.2 *(formal-loop and flat-support inputs).* The pro-étale extension used in Chapter 49.5.5 contains two distinct geometries. The first is the commutation of Map$(B\widehat{\mathbb{Z}}, -)$ with the formal Selmer presentation. The second is the equality between the Arinkin–Gaitsgory flat singular-support locus and the Fargues–Scholze (φ, Γ)-flat locus.

Remark 53.5.3 *(pro-étale extension).* Chapter 49 Remark 49.5.4 notes that Chapter 49.5.3 uses a pro-étale extension of Ben-Zvi–Francis–Nadler that is formal but not in the literature. In the present notation that extension is the R1.formal.b hypothesis, together with the R1.formal.c comparison of flat loci.

53.6 Boundary Conditions

Form of the Inputs

The seven inputs have different logical weights. R1.fin-type is the Gaitsgory–Rozenblyum finite-type theorem. R1.formal.a is a trace theorem after the categorical colimit presentation is known. R2 fixes the Selmer target and tangent complex, but its use in formal BZN requires formal Noetherianity and nilpotent-support compatibility for the chosen local conditions. R1.formal.b, R1.formal.c, R3, and R4 are geometric hypotheses.

Logical Consequence

The arithmetic BZN comparison is therefore not a consequence of a product formula for local stacks. It is a statement about a Selmer derived fibre product, a formal Hochschild trace, a pro-étale loop object, a flat singular-support locus, and wild Hecke summands. The finite-type theorem and the trace theorem do not eliminate the loop, flat-locus, full-target, or wild-prime hypotheses.

Open Problems

The reduction of Chapter 53.4.9 poses three precise open problems.

(i) **R1.formal.b.** Does $\mathrm{Map}(B\widehat{\mathbb{Z}}, -)$ commute with ind-colimits under closed immersions in derived pro-étale stacks? The relevant tools are Lurie's ∞-topos formalism (HTT 6, HA 4.4) combined with Bhatt–Scholze pro-étale (§7). A positive answer proves R1.formal.b; a counterexample restricts Chapter 49.5.3 to the cofinal finite-type subclass.

(ii) **R1.formal.c.** Does the Arinkin–Gaitsgory nilpotent-singular-support flat locus coincide with the (φ, Γ)-module Fargues–Scholze flat locus on each finite-type piece of the Emerton–Gee ind-colimit? The comparison between Fargues–Scholze arXiv:2102.13459 and Arinkin–Gaitsgory arXiv:1201.6343 can be checked on unramified crystalline representations with fixed Hodge–Tate weight.

(iii) **R4.** What are the $\mathrm{Ext}^{\mathrm{I}}$-contributions to $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p})$ at wild primes $p = 2, 3$, and do they shift the arithmetic BZN identification? The Etingof–Ostrik 2004 finite-tensor-category framework applies; a model case is $p = 2$ with tame restriction to the depth-1 local category.

53.7 Formal Noetherian Boundary

The global spectral target for $\mathrm{F3.BZN}^{\mathrm{Ar}}$ is the Selmer-derived stack $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ with tangent complex $C^\bullet_{\mathcal{L}}(G_{\mathbb{Q},S}, \mathrm{ad}^{\circ}\rho)[1]$ (Chapter 53.3.5); formal Noetherianity, quasi-smoothness, and nilpotent-support compatibility for the chosen local deformation problem remain hypotheses. R3 is a full-target hypothesis under R2 (Chapter 53.3.6).

R1.formal follows from three conditions (Chapter 53.4.1). R1.formal.a is Hochschild trace continuity along the given categorical colimit (Chapter 53.4.2). R1.formal.b is the arithmetic loop-space formal computation, and R1.formal.c is flat-locus pullback compatibility (Chapter 53.4.4 and Chapter 53.4.7).

Thus $\mathrm{F3.BZN}^{\mathrm{Ar}}$ is conditional on R1.formal.b, R1.formal.c, the finiteness and support part of R2, R3, and R4 (Chapter 53.5.1). The pro-étale extension of Ben-Zvi–Francis–Nadler is not a formal theorem of the finite-type theory; in this notation it is the loop-space hypothesis together with the flat-locus comparison.

Chapter 54

$\mathrm{BZN}^{\mathrm{Ar}}$: Loop-Space Convention and Wild-Prime Summands

The arithmetic trace comparison has two separate requirements. First, the internal mapping stack $\underline{\mathrm{Map}}(B\widehat{\mathbb{Z}}, \mathcal{X})$ must be compared with finite-quotient and ind-completed loop models under explicit $\widetilde{\text{formal}}$-convergence hypotheses. Second, local arithmetic categories at the primes two and three must be constructed with their coefficient rings, extension groups and trace maps.

The finite-algebra calculations below show why the second requirement cannot be replaced by a Loewy-length argument. A radical-square-zero algebra can have nonzero Ext in arbitrarily high degrees. Even when two local trace complexes are concentrated in degrees zero and one, their tensor over a common field can have a nonzero degree-two term. An integral distinct-primary model behaves differently, but needs actual integral carriers and flatness hypotheses. These calculations constrain the proposed arithmetic comparison; they do not construct its categories, trace maps or completed global assembly.

54.1 The Two Loop-Convention and Wild-Prime Conditions

Origin of the Two Conditions

The structural comparison of Chapter 51 at §51.4 contains four conditions in the F3.$\mathrm{BZN}^{\mathrm{Ar}}$ reduction. Three of these (the formal-Noetherian extension of Gaitsgory–Rozenblyum; the cotangent-complex check for the Emerton–Gee stack; and the R1 relabeling) were absorbed into the R1 split R1.fin-type + R1.formal stated in Chapter 51. The remaining two, not absorbed into the existing reduction, are:

- **R3.** Ambiguity in the loop-space convention. Three candidate definitions of $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ are in play:

  (a) *Cofiltered-limit convention.* $L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X} := \varprojlim_n \mathrm{Map}(B(\mathbb{Z}/n), \mathcal{X})$, the limit over finite quotients of $\widehat{\mathbb{Z}}$.

  (b) *Internal-Hom convention.* $L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X} := \underline{\mathrm{Map}}_{\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}}(B\widehat{\mathbb{Z}}, \mathcal{X})$, the internal mapping stack in the ∞-category of formal Noetherian derived stacks.

  (c) *Ind-construction convention.* $L^{\mathrm{Ar}}_{\mathrm{ind}}\mathcal{X} := \varinjlim_n \mathrm{Ind}\big(\mathrm{Map}(B(\mathbb{Z}/n), \mathcal{X}^{\mathrm{perf}})\big)$, the ind-completion over finite quotients, applied to the perfect locus and re-ind-extended.

  These agree for $\mathcal{X}$ finite-type smooth, but the formal Noetherian setting is sensitive to the order of limits and ind-completions.

- **R4.** Local arithmetic extension and trace data. For the proposed exceptional contributions at $p = 2, 3$, specify the coefficient categories, compute their extensions and construct maps to their trace complexes. A positive-degree trace contribution is not a formal consequence of non-semisimplicity. Its global effect also depends on the common coefficient ring and tensor product.

Logical Structure

R3 is a convention plus a convergence hypothesis: the internal Hom is the chosen definition, and comparison with the other two definitions requires compactness and formal-colimit compatibility. R4 includes the local categories, trace comparisons and tensor assembly. The explicit algebra calculations in Section 54.4 show the additional hypotheses needed for a degree-one-only answer.

Notation

Throughout this chapter:

- $\widehat{\mathbb{Z}} = \prod_p \mathbb{Z}_p$, the profinite completion of $\mathbb{Z}$.
- $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$: the ∞-category of formal Noetherian derived (pro-étale) stacks in the sense of Gaitsgory–Rozenblyum's AMS DAG monographs Vol. II Part III. An object is a pro-object $\{\mathcal{X}_n\}$ of derived Noetherian stacks with $\mathcal{X}_n$ classically a Noetherian topological ring with derived enhancement.
- For $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$, its formal completion $\mathcal{X}^{\wedge}$ is the image of $\mathcal{X}$ under the reflective embedding into the formal-Noetherian ∞-category.
- $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$: the Iwahori Hecke category at the prime p (Bezrukavnikov arXiv:1209.0403).
- The coefficient field is specified in each calculation. The field $\overline{\mathbb{Q}}_\ell$ has characteristic zero, whereas $\overline{\mathbb{F}}_\ell$ has characteristic ℓ. An integral calculation below uses $R = \mathbb{Z}$ instead.
- $\mathrm{Ext}^i_{\mathcal{A}}$: Ext^i in the abelian category $\mathcal{A}$; subscripts indicate the ambient category.

54.2 Structure of the Argument

The argument for R3 has three parts; the argument for R4 has three further parts. For R3: the three candidate definitions are compared with explicit fibre-product formulas (Proposition 54.3.2); the fibre-product formulas are conditionally identified on formal Noetherian derived algebraic stacks via Gaitsgory–Rozenblyum and Postnikov-tower convergence (Theorem 54.3.4); the internal-Hom convention is adopted as canonical and confirmed consistent with Chapter 49 (Definition 54.3.7, Proposition 54.3.9). For R4, the periodic resolution and the path-count formula compute extensions over explicit finite algebras. The four-term tensor formula then distinguishes common-field and distinct-primary integral assembly. Questions 54.4.8 and 54.4.9 specify the arithmetic comparisons that these elementary calculations leave open.

54.3 R3: Arithmetic Loop-Space Convention

The Three Candidate Definitions

Throughout this section $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ is a formal Noetherian derived algebraic stack over $\mathbb{Z}$ (or over $\mathrm{Spf}\,\mathbb{Z}_p$ when working locally at a prime). We demand:

- $\mathcal{X}$ is locally presented as the formal completion of a derived Noetherian affine scheme $\mathcal{X}_0 = \mathrm{Spec}\, A^{\bullet}_0$ along an ideal $I \subset \pi_0(A^{\bullet}_0)$;
- the cotangent complex $\mathbb{L}_{\mathcal{X}}$ has finite Tor-amplitude $[a, b]$ over the structure sheaf;
- the Postnikov tower $\pi_{\leq n}\mathcal{X} \to \mathcal{X}$ stabilises in each tor-layer (equivalently, $\mathcal{X}$ is t-bounded in the sense of Gaitsgory–Rozenblyum Vol. I §2).

For the arithmetic target these conditions must be checked for the Selmer-derived stack $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$; the local Emerton–Gee theorem supplies only the local formal inputs.

Definition 54.3.1 *(the three candidate arithmetic free loop spaces).* For $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$, define

$$\begin{aligned} L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X} &:= \varprojlim_{n\geq 1} \mathrm{Map}\big(B(\mathbb{Z}/n\mathbb{Z}), \mathcal{X}\big), \\ L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X} &:= \underline{\mathrm{Map}}_{\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}}\big(B\widehat{\mathbb{Z}}, \mathcal{X}\big), \\ L^{\mathrm{Ar}}_{\mathrm{ind}}\mathcal{X} &:= \varinjlim_{n\geq 1} \mathrm{Ind}\big(\mathrm{Map}(B(\mathbb{Z}/n\mathbb{Z}), \mathcal{X}^{\mathrm{perf}})\big), \end{aligned}$$

where:

- in (a) the limit is along the cofiltered system $\{\mathbb{Z}/n\}_{n\in\mathbb{N}}$ under divisibility;
- in (b) the internal mapping stack is computed in the ∞-category $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ of formal Noetherian derived pro-étale stacks;
- in (c) $\mathcal{X}^{\mathrm{perf}}$ denotes the perfect locus (dualisable objects in the formal quasi-coherent derived category), and Ind is the ind-completion in stable presentable ∞-categories.

Explicit Computation of the Three Candidate Definitions

Proposition 54.3.2 *(three candidate loop-space formulas). Conjectural statement.* Let $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ be formal Noetherian derived algebraic with cotangent complex $\mathbb{L}_{\mathcal{X}}$ of finite Tor-amplitude. Then:

(i) *Cofiltered-limit formula.*

$$L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X} \;=\; \varprojlim_{n}\Big(\mathcal{X} \times_{\mathcal{X}\times\mathcal{X}} \mathcal{X}_{(n)}\Big),$$

where $\mathcal{X}_{(n)} \subset \mathcal{X}\times\mathcal{X}$ is the n-th formal neighbourhood of the diagonal.

(ii) *Internal-Hom formula.*

$$L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X} \;=\; \mathcal{X} \times^{\mathrm{d},\wedge}_{\mathcal{X}\times\mathcal{X}} \mathcal{X},$$

the derived formal self-intersection of $\mathcal{X}$ along its diagonal, computed in $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ with the derived tensor product taken over the formal diagonal.

(iii) *Ind-construction formula.*

$$L^{\mathrm{Ar}}_{\mathrm{ind}}\mathcal{X} \;=\; \mathrm{Ind}\Big(\varinjlim_{n} \mathcal{X}^{\mathrm{perf}} \times_{\mathcal{X}^{\mathrm{perf}}\times\mathcal{X}^{\mathrm{perf}}} \mathcal{X}^{\mathrm{perf}}_{(n)}\Big).$$

Evidence. (1) The mapping stack from $B(\mathbb{Z}/n)$ to $\mathcal{X}$ is the fixed-point locus of the order-n automorphism action, which is the derived fibre product along the n-th iterate of the diagonal. In characteristic zero (for the rational structure at each prime) this reduces to the formal neighbourhood $\mathcal{X}_{(n)}$. Taking the limit over n under divisibility restricts to the formal self-intersection in the limit.

(2) Internal Hom in $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ is computed by the derived loop formula $\mathcal{X} \times^{\mathrm{d}}_{\mathcal{X}\times\mathcal{X}} \mathcal{X}$ (Gaitsgory–Rozenblyum's AMS DAG monographs Vol. I Ch. 8 Thm. 8.1.1.9); the formal-Noetherian decoration adds a completion along the diagonal, yielding the indicated $\times^{\mathrm{d},\wedge}$.

(3) Perfect locus: dualisable objects in $\mathrm{QCoh}(\mathcal{X})$ form $\mathcal{X}^{\mathrm{perf}}$, a compactly generated full subcategory. The mapping stack restricts to $\mathcal{X}^{\mathrm{perf}}$ in each factor; the cofiltered colimit over n and the subsequent ind-completion together recover the dualisable content. By the same derived fibre-product formula restricted to perfects plus ind-completion, we obtain the stated expression. □

Remark 54.3.3 *(separation of the three limits).* The three formulas differ in the order of $(\varinjlim/\varprojlim)$ operations and in whether they apply to $\mathcal{X}$ or to $\mathcal{X}^{\mathrm{perf}}$. Equality of the three models requires convergence of the Postnikov tower, generation by perfect objects under ind-completion, and compatibility of formal completion with the profinite limit.

Conventions for the Three Loop Models

Conventions. Derived mapping stack convention follows Gaitsgory–Rozenblyum Vol. I Ch. 8; profinite classifying-stack convention follows Deligne 1990 §5; the two are compatible via $B\widehat{\mathbb{Z}} = \varprojlim_n B(\mathbb{Z}/n)$.

Ambient category. All three candidate constructions take values in the ∞-category $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ of formal Noetherian derived pro-étale stacks. Definitions (a) and (b) are manifestly in this category; (c) enters via ind-completion of the perfect locus, which sits inside the same category via Gaitsgory–Rozenblyum Vol. I Ch. 5.

Hypotheses. Finite Tor-amplitude of $\mathbb{L}_{\mathcal{X}}$ and t-boundedness of the Postnikov tower are explicit hypotheses of Proposition 54.3.2.

Equivalence of the Three Definitions on Formal Noetherian Derived Stacks

THEOREM 54.3.4 *(conditional comparison of the three arithmetic loop spaces). Conditional statement.* Let $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ be formal Noetherian derived algebraic with cotangent complex $\mathbb{L}_{\mathcal{X}}$ of finite Tor-amplitude and t-bounded. Assume:

(i) $B\widehat{\mathbb{Z}}$-mapping stacks are computed by the profinite limit of the finite cyclic mapping stacks on $\mathcal{X}$;

(ii) formal completion along the diagonal commutes with the relevant derived tensor products;

(iii) the perfect locus generates the same loop object after ind-completion.

Then there are canonical equivalences of formal Noetherian derived stacks

$$L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X} \xleftarrow{\sim} L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X} \xrightarrow{\sim} L^{\mathrm{Ar}}_{\mathrm{ind}}\mathcal{X}.$$

All three express the derived formal self-intersection of $\mathcal{X}$ along its diagonal.

Proof. Under the first two hypotheses, $L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X}$ and $L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X}$ compute the same completed derived self-intersection of the diagonal. Under the third hypothesis, the ind-construction gives the ind-completion of the same self-intersection on the perfect locus. The maps are the canonical comparison maps induced by the universal property of internal Hom, formal completion, and ind-completion. □

Remark 54.3.5 *(what fails without the hypotheses).* Noetherianness, t-boundedness, and finite Tor-amplitude do not by themselves identify all three loop models. They are the natural ambient hypotheses under which the three comparison maps can be asked to be equivalences.

COROLLARY 54.3.6 *(application to the Selmer-derived target). Comparison hypothesis.* If the Selmer-derived target $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ satisfies the formal-Noetherian and bounded cotangent hypotheses of Theorem 54.3.4, then the three candidate definitions of $L^{\mathrm{Ar}}\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ all compute the derived formal self-intersection along the diagonal and agree canonically.

Hypotheses of the Loop Comparison

Conventions. Postnikov-tower and formal-completion conventions agree between Gaitsgory–Rozenblyum and Lurie HA.

Ambient category. All three constructions sit in $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$; their equivalence is an equivalence in that ambient.

Hypotheses. Finite Tor-amplitude, t-boundedness, Noetherianness are stated in the hypothesis set of Theorem 54.3.4.

Functoriality. The zig-zag (54.3.4) is functorial in $\mathcal{X}$: each arrow is a canonical natural transformation between functors $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}} \to \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$.

Named theorems. Gaitsgory–Rozenblyum supplies the formal-completion and compact-generation inputs. The profinite mapping-stack comparison remains an explicit hypothesis.

The equivalence of Theorem 54.3.4 is conditional on the stated hypotheses.

Canonical Choice and Consistency with Chapter 49

Definition 54.3.7 *(canonical arithmetic free loop space).* For $\mathcal{X} \in \mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ formal Noetherian derived algebraic with the hypotheses of Theorem 54.3.4, the *canonical arithmetic free loop space of* $\mathcal{X}$ is

$$L^{\mathrm{Ar}}\mathcal{X} \;:=\; L^{\mathrm{Ar}}_{\mathrm{intHom}}\mathcal{X} \;=\; \underline{\mathrm{Map}}_{\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}}\big(B\widehat{\mathbb{Z}}, \mathcal{X}\big).$$

Under Theorem 54.3.4, $L^{\mathrm{Ar}}\mathcal{X}$ is canonically equivalent to both $L^{\mathrm{Ar}}_{\mathrm{cofilt}}\mathcal{X}$ and $L^{\mathrm{Ar}}_{\mathrm{ind}}\mathcal{X}$; we adopt the internal Hom as definitional.

Remark 54.3.8 *(why internal Hom is canonical).* The internal Hom construction is canonical in two senses:

(i) *Functoriality in the source.* $\underline{\mathrm{Map}}(B\widehat{\mathbb{Z}}, -)$ is manifestly functorial in $\mathcal{X}$ without choosing a cofiltered presentation of $B\widehat{\mathbb{Z}}$ or an ind-completion presentation of $\mathcal{X}$.

(ii) *Universal property.* By the standard closed-monoidal structure on $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ (Lurie HTT §7.3, transported via Gaitsgory–Rozenblyum Vol. I), the internal Hom is the right adjoint to the product functor $(- \times B\widehat{\mathbb{Z}})$. The cofiltered and ind-construction versions require extra choices to realise this universal property.

Proposition 54.3.9 *(consistency with Chapter 49).* The canonical convention of Definition 54.3.7 coincides with the arithmetic free loop space of Definition 49.4.1 in Chapter 49: both define $L^{\mathrm{Ar}}\mathcal{X}$ as the internal mapping stack $\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ in the ∞-category of formal Noetherian derived pro-étale stacks.

Proof. Compare Definition 54.3.7 with Definition 49.4.1: both read $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$ computed as internal Hom in $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$. The definitions are literally identical. Chapter 49's usage in Sections 49.4 and 49.5 (Theorem 49.5.5) matches this internal-Hom interpretation. □

Internal Hom and Its Universal Property

Conventions. The adjoint-functor convention of Lurie HTT matches the closed-monoidal structure on formal derived stacks in Gaitsgory–Rozenblyum Vol. I.

Ambient category. $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ is the same as in Chapter 49.

Hypotheses. The closed-monoidal structure requires only that $\mathrm{dSt}^{\wedge}_{\mathrm{Noeth}}$ have arbitrary small colimits and products; both are standard.

Functoriality and universal property. Functoriality in $\mathcal{X}$ is the defining property of the internal Hom; its universal property is Lurie HTT §7.3.

The canonical-choice result Proposition 54.3.9 is a statement about notation. It does not prove the comparison with the cofiltered or ind-completed models.

R3 Boundary

R3 has two parts. The canonical choice is the internal Hom (Definition 54.3.7); and this choice is consistent with Chapter 49's usage (Proposition 54.3.9). The comparison with the cofiltered and ind-completed models is the conditional statement of Theorem 54.3.4.

54.4 Wild-Prime Extension and Trace Comparisons

A Yoneda extension is computed in a specified abelian category; a Hochschild class belongs to a specified trace complex. Relating the two requires a map, not just equality of dimensions. Two elementary calculations also constrain the possible degrees of a global trace: a radical-square-zero algebra can have higher Ext, and tensoring two complexes supported in degrees zero and one can produce degree two. We first make these calculations over explicit coefficient rings. Their arithmetic realization remains a separate comparison problem.

Finite Algebras and Higher Extensions

LEMMA 54.4.1 *(degreewise finiteness of extensions).* Let A be a finite-dimensional algebra over a field k. There are finitely many isomorphism classes of simple right A-modules, and $\mathrm{Ext}^n_A(M,N)$ is finite-dimensional for finite-dimensional M, N and each $n \geq 0$. The total graded Ext space need not be finite-dimensional. No identification with Hochschild homology is included in this statement.

Proof. Every simple module is a quotient of the regular module, whose finite composition series contains only finitely many simple factors. A finite-dimensional module admits a surjection from a finite sum of copies of A. Its kernel is finite-dimensional; repeating constructs a resolution with a finite-dimensional projective term in each degree. Applying $\mathrm{Hom}_A(-,N)$ gives a finite-dimensional space in each degree, hence finite-dimensional cohomology. The following example proves the final assertion about total dimension. □

PROPOSITION 54.4.2 *(a periodic resolution).* For $A = k[\epsilon]/(\epsilon^2)$ and $S = A/(\epsilon)$,

$$\mathrm{Ext}^n_A(S,S) = k \qquad (n \geq 0).$$

Thus Loewy length two does not imply projective dimension one. In characteristic two, $A \cong k[C_2]$, so the finite tensor category of finite-dimensional $k[C_2]$-modules also has infinite-dimensional total Yoneda algebra.

Proof. Multiplication by ϵ has kernel and image both equal to $k\epsilon$. The augmentation kernel is the same subspace. Hence

$$\cdots \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \longrightarrow S \longrightarrow 0$$

is an exact free resolution. Applying $\mathrm{Hom}_A(-, S)$ gives one copy of k in every nonnegative degree, with zero differential because ϵ acts trivially on S. If $\mathrm{char}\, k = 2$, writing $\epsilon = g - 1$ for the generator of C_2 gives $\epsilon^2 = g^2 - 2g + 1 = 0$. The two-dimensional algebras are therefore isomorphic. The group-algebra coproduct gives its usual tensor category. □

Proposition 54.4.3 *(paths and radical-square-zero Ext).* Let Q be a finite quiver, J its arrow ideal, and $B = kQ/J^2$. Use right modules and concatenate paths from left to right. For the simple $S_i = e_iB/e_iJ$,

$$\dim_k \mathrm{Ext}^n_B(S_i, S_j) = \#\{\text{oriented paths of length } n \text{ from } i \text{ to } j\}.$$

Consequently all $\mathrm{Ext}^{n\geq 2}$ between simples vanish if and only if Q has no composable pair of arrows.

Proof. The projective cover is $P_i = e_iB$, and its radical has one copy of S_j for each arrow $i \to j$, because every product of two arrows is zero. Thus $\Omega S_i = \bigoplus_{i\to j} S_j$. Iteration gives one copy of S_j in $\Omega^n S_i$ for each length-n path. The resulting minimal projective resolution has its differentials in the radicals. Every map from a projective to a simple kills that radical, so applying $\mathrm{Hom}_B(-, S_j)$ gives zero differentials. This proves the formula, including $n = 0$. A composable pair gives a nonzero degree-two group. If no such pair exists, there are no paths of any length at least two. □

Example 54.4.4 *(a three-vertex block and its Yoneda product).* Take $Q = (0 \xrightarrow{a} 1 \xrightarrow{b} 2)$ and $B = kQ/(ab)$. The right projectives have bases $P_0 = \langle e_0, a\rangle$, $P_1 = \langle e_1, b\rangle$, and $P_2 = \langle e_2\rangle$. There is an exact resolution

$$0 \longrightarrow P_2 \xrightarrow{e_2\mapsto b} P_1 \xrightarrow{e_1\mapsto a} P_0 \longrightarrow S_0 \longrightarrow 0.$$

Indeed the middle map kills b, since $ab = 0$; its kernel is kb, and its image is the augmentation kernel ka. It follows that

$$\mathrm{Ext}^1_B(S_0, S_1) = k, \qquad \mathrm{Ext}^1_B(S_1, S_2) = k, \qquad \mathrm{Ext}^2_B(S_0, S_2) = k.$$

The product of the two adjacent degree-one classes is the nonzero degree-two class: the short exact sequence $0 \to S_1 \to P_0 \to S_0 \to 0$ gives the dimension-shifting isomorphism $\mathrm{Ext}^1_B(S_1, S_2) \cong \mathrm{Ext}^2_B(S_0, S_2)$, whose connecting map is Yoneda composition. Thus the relation $ab = 0$ in B does not make the corresponding Yoneda product zero. Reversing all arrows reverses the ordered pairs in the Ext groups; it does not eliminate degree two.

For comparison, the unquotiented path algebra kQ has $\mathrm{rad}\, P_0 \cong P_1$ and $\mathrm{rad}\, P_1 \cong P_2$, hence length-one projective resolutions of its simples. This is a different algebra; its P_0 has Loewy length three. An arithmetic identification with one of these algebras must specify which relations it preserves.

Regular Hochschild Homology of the Finite Models

The same two algebras permit complete trace calculations. They show that extensions between simples and regular Hochschild homology can behave differently even in these small examples. Throughout this subsection k is any field, the algebras are ordinary and ungraded, and all tensors are algebraic. For an algebra R, put $R^e = R \otimes_k R^{\mathrm{op}}$ and $HH_n(R) = \mathrm{Tor}^{R^e}_n(R, R)$, with regular coefficients. This is Hochschild homology, not the cohomology of derivations used for the Bost–Connes algebra.

PROPOSITION 54.4.5 *(the regular trace of the dual numbers).* For $A = k[\epsilon]/(\epsilon^2)$,

$$\begin{aligned} HH_0(A) &= A, \\ HH_{2r+1}(A) &= A/(2\epsilon A) && (r \geq 0), \\ HH_{2r}(A) &= \operatorname{ann}_A(2\epsilon) && (r \geq 1). \end{aligned}$$

If $\operatorname{char} k \neq 2$, each positive-degree group has dimension one; odd groups are $A/(\epsilon)$ and positive even groups are ϵA. If $\operatorname{char} k = 2$, then $HH_n(A) = A$ for every $n \geq 0$.

Proof. Identify $A^e = k[x, y]/(x^2, y^2)$, with x acting on the left and y on the right. Set $u = x - y$, $v = x + y$. Consider

$$\cdots \xrightarrow{u} A^e \xrightarrow{v} A^e \xrightarrow{u} A^e \xrightarrow{\mu} A \longrightarrow 0, \qquad \mu(x) = \mu(y) = \epsilon.$$

There is one free term in each nonnegative degree; the differential from an odd degree is multiplication by u, and from a positive even degree multiplication by v. The composites vanish because $uv = vu = 0$. For $r = \alpha + \beta x + \gamma y + \eta xy$,

$$ur = \alpha(x - y) + (\gamma - \beta)xy, \qquad vr = \alpha(x + y) + (\beta + \gamma)xy.$$

Hence $\ker u = \langle x + y, xy \rangle = \operatorname{im} v$, $\ker v = \langle x - y, xy \rangle = \operatorname{im} u$, and $\ker \mu = \langle x - y, xy \rangle$. Both images have dimension two, including in characteristic two. This is an exact free bimodule resolution.

Tensoring with the regular A makes u zero and v multiplication by 2ϵ. Thus the odd differentials are zero and the positive even differentials are 2ϵ, giving the asserted quotients and annihilators. If two is invertible, $\operatorname{ann}_A(2\epsilon) = \epsilon A$; if two is zero, all differentials vanish.

The normalized Hochschild complex checks the signs directly. Since $A/k1 = k\epsilon$, its degree-n term is $A \otimes (k\epsilon)^{\otimes n}$. Interior products vanish, and the first and cyclic last faces give

$$b_n(c \otimes \epsilon^{\otimes n}) = (1 + (-1)^n)c\epsilon \otimes \epsilon^{\otimes(n-1)}.$$

This is the same alternating zero and 2ϵ differential. □

The simple-module calculation in Proposition 54.4.2 gives $\operatorname{Ext}^n_A(S, S) = k$ in every degree and characteristic. In characteristic two its dimension is one, whereas the regular Hochschild group has dimension two. The two calculations use different resolutions and different coefficient carriers.

PROPOSITION 54.4.6 *(the regular trace of the directed three-vertex model).* For $B = k(0 \xrightarrow{a} 1 \xrightarrow{b} 2)/(ab)$,

$$HH_0(B) = ke_0 \oplus ke_1 \oplus ke_2, \qquad HH_n(B) = 0 \quad (n \geq 1).$$

Thus the nonzero Ext groups and Yoneda product of Example 54.4.4 do not force nonzero positive-degree regular Hochschild homology.

Proof. Let $S = ke_0 \oplus ke_1 \oplus ke_2$, $J = ka \oplus kb$. Then $B = S \oplus J$, $J^2 = 0$, and $J \otimes_S J = k(a \otimes b)$; there are no composable triples. The relative normalized bimodule bar terms are $P_n = B \otimes_S J^{\otimes_S n} \otimes_S B$, with

$$\begin{aligned} P_0 &= \bigoplus_{i=0}^{2} Be_i \otimes_k e_iB, \\ P_1 &= (Be_0 \otimes_k e_1B) \oplus (Be_1 \otimes_k e_2B), \\ P_2 &= Be_0 \otimes_k e_2B. \end{aligned}$$

Each is a projective bimodule: each summand is an idempotent direct summand of the free bimodule $B \otimes_k B$. The differentials, retaining arrows in the bar notation, are

$$d_1(l \otimes j \otimes r) = lj \otimes r - l \otimes jr,$$
$$d_2(l \otimes a \otimes b \otimes r) = la \otimes b \otimes r + l \otimes a \otimes br.$$

The missing middle term is $-l \otimes ab \otimes r = 0$.

Here is a direct exactness check. The dimensions of P_0, P_1, P_2 are 8, 4, 1, and a basis of P_1 is

$$q_1 = e_0 \otimes a \otimes e_1, \qquad q_2 = e_0 \otimes a \otimes b,$$
$$q_3 = e_1 \otimes b \otimes e_2, \qquad q_4 = a \otimes b \otimes e_2.$$

Their d_1-images are respectively

$$a \otimes e_1 - e_0 \otimes a, \quad a \otimes b, \quad b \otimes e_2 - e_1 \otimes b, \quad -a \otimes b.$$

The first three are independent, so $\ker d_1 = k(q_2 + q_4)$. The generator $e_0 \otimes a \otimes b \otimes e_2$ of P_2 maps to $q_2 + q_4$; hence d_2 is injective and exactness holds at P_1. Multiplication $P_0 \to B$ is surjective, annihilates $\operatorname{im} d_1$, and has kernel of dimension $8 - 5 = 3$. This proves exactness also at P_0, in every characteristic. Thus $0 \to P_2 \to P_1 \to P_0 \to B \to 0$ is a projective bimodule resolution.

The regular trace of a summand is

$$B \otimes_{B^e} (Be_i \otimes_k e_j B) \cong e_j B e_i.$$

The map sends the class of $c \otimes (l \otimes r)$ to rcl; its inverse sends $t \in e_j B e_i$ to the class of $t \otimes (e_i \otimes e_j)$. Balancing verifies that these maps are well defined and inverse. A path from i to j can therefore contribute only if there is a return path from j to i. Here $e_1 B e_0 = e_2 B e_1 = e_2 B e_0 = 0$ and $e_i B e_i = k e_i$. The traced complex is k^3 in degree zero and zero in every positive degree, as asserted. □

In this example the relation $ab = 0$ contributes a genuine bimodule-resolution term in degree two, but regular trace kills it because its endpoints differ. Extension groups between simples retain the directed paths; Hochschild homology requires cyclic endpoint matching. Neither calculation constructs the arithmetic Ext-to-trace comparison in the following questions.

The Local Arithmetic Comparisons

Remark 54.4.7 *(non-semisimplicity and the coefficient category).* The example $k[C_2]$ in characteristic two is non-semisimple: $0 \to S \to A \to S \to 0$ is not split. Transferring such a result to an arithmetic Iwahori block requires that block, its coefficient ring and its relation to the finite algebra to be specified. The primes 2, 3 alone do not determine a coefficient category. The fields $\overline{\mathbb{Q}}_\ell$ and $\overline{\mathbb{F}}_\ell$ have characteristics zero and ℓ, respectively, and require different specialization arguments.

Question 54.4.8 *(the proposed contribution at two).* Construct the arithmetic block and its trace complex C_2^{wild}, with a comparison realizing the proposed one-dimensional degree-one contribution

$$H_1(C_2^{\mathrm{wild}}) \cong W_2, \qquad W_2 \cong k.$$

The coefficient field and the map from extension data to this trace homology are part of the construction. In characteristic two, the trivial and sign characters of C_2 are the same character, since $-1 = 1$. They

cannot serve as two distinct simples in an off-diagonal Ext calculation. The dual-number model does give a one-dimensional self-Ext in degree one, but it also gives nonzero Ext in every higher degree. A claim of local amplitude at most one therefore needs an actual resolution or a trace calculation that accounts for the higher extension classes.

Question 54.4.9 *(the proposed contribution at three).* Construct the arithmetic block, coefficient field and comparison maps that would realize

$$H_1(C_3^{\mathrm{wild}}) \cong W_3, \qquad W_3 \cong k \oplus k.$$

In the explicit three-vertex algebra of Example 54.4.4, the two classes are in $\mathrm{Ext}^1(S_0, S_1)$ and $\mathrm{Ext}^1(S_1, S_2)$, with the fixed right-module convention, and they have a nonzero Yoneda product in degree two. An arithmetic comparison must preserve these directions and account for that product. In characteristic three, $X^3 - 1 = (X-1)^3$, so there is no primitive third root of unity. A primitive-cube-root specialization in characteristic zero is a different model, requiring an explicit comparison with a modular coefficient category. Neither a choice of root nor a Calabi–Yau or Frobenius structure by itself constructs the map from Yoneda extensions to Hochschild homology.

Hypothesis 54.4.10 *(the large-prime trace datum).* For the chosen common coefficient ring R, suppose that the arithmetic local trace complexes C_p have been constructed and that, for every $p \geq 5$, there is a specified equivalence $C_p \simeq B_p[0]$ with an R-module B_p. This is a hypothesis on the actual trace complexes, including their arithmetic comparison; it is not inferred solely from an assertion about a Yoneda algebra or a numerical prime threshold.

COROLLARY 54.4.11 *(conditional large-prime vanishing).* Under Hypothesis 54.4.10, $H_i(C_p) = 0$ for every $i > 0$ and $p \geq 5$.

Proof. The specified equivalence identifies the homology with that of a module placed in degree zero. □

COROLLARY 54.4.12 *(conditional vanishing of the large-prime wild part).* If a wild summand is specified inside such a C_p, its positive-degree homology vanishes for $p \geq 5$.

Proof. Homology preserves a direct-sum decomposition, so the summand's positive-degree homology is a direct summand of zero. □

The Four Terms in a Derived Tensor Product

Complexes are now homologically graded: the differential lowers degree, and $M[i]$ places a module M in degree i. All tensors in this subsection are algebraic derived tensors over the displayed common ring. A completed tensor requires its own continuity and exactness assertions.

LEMMA 54.4.13 *(two split local complexes).* For a commutative ring R, suppose $C_2 \simeq B_2 \oplus W_2[1]$ and $C_3 \simeq B_3 \oplus W_3[1]$ in $D(R)$, with specified splittings. Then

$$\begin{aligned} C_2 \otimes^{\mathbb{L}}_R C_3 \simeq\ & (B_2 \otimes^{\mathbb{L}}_R B_3) \\ & \oplus \big((W_2 \otimes^{\mathbb{L}}_R B_3) \oplus (B_2 \otimes^{\mathbb{L}}_R W_3)\big)[1] \\ & \oplus (W_2 \otimes^{\mathbb{L}}_R W_3)[2]. \end{aligned} \tag{54.1}$$

Over a field, with $B_2 = B_3 = k$, $W_2 = k$, and $W_3 = k^2$, this is $k \oplus k^3[1] \oplus k^2[2]$.

Proof. Choose projective resolutions of the four modules. Distributing the tensor of the two finite direct sums gives the four displayed terms and their shifts. Over a field the modules are already flat, so the zero-differential representatives compute the derived tensor. The total differential is $d(x \otimes y) = dx \otimes y + (-1)^{|x|} x \otimes dy = 0$. For a basis vector x of W_2 and a basis y, z of W_3, $x \otimes y$ and $x \otimes z$ are independent degree-two cycles and cannot be boundaries. More generally, the tensor of two nonzero vector spaces over a field is nonzero: linear functionals nonzero on chosen vectors detect a nonzero elementary tensor. Graded commutativity does not cancel products between different factors. □

Lemma 54.4.14 *(distinct-primary integral coefficients).* If M_2 is a 2-primary torsion abelian group and M_3 is a 3-primary torsion abelian group, then $M_2 \otimes^{\mathrm{L}}_{\mathbb{Z}} M_3 = 0$. If B_2, B_3 are flat abelian groups in degree zero, it follows that $(B_2 \oplus M_2[1]) \otimes^{\mathrm{L}}_{\mathbb{Z}} (B_3 \oplus M_3[1])$ is concentrated in degrees zero and one. For $B_2 = B_3 = \mathbb{Z}$, $M_2 = \mathbb{Z}/2$, and $M_3 = (\mathbb{Z}/3)^2$, it is $\mathbb{Z} \oplus (\mathbb{Z}/2 \oplus (\mathbb{Z}/3)^2)[1]$.

Proof. Resolve $\mathbb{Z}/2^a$ by $[\mathbb{Z} \xrightarrow{2^a} \mathbb{Z}]$. After tensoring with $\mathbb{Z}/3^b$, its differential is an isomorphism, so the complex is acyclic. Finite primary groups are finite direct sums of cyclic primary groups. Arbitrary primary torsion groups are filtered unions of finite subgroups; tensor and Tor commute with these filtered colimits. There is no higher Tor beyond degree one over $\mathbb{Z}$, since the kernel of a surjection from a free abelian group is free. This proves the first assertion. Flatness of B_2, B_3 removes higher Tor from the other three terms in (54.1), proving the remaining claims. Without flat degree-zero factors, those terms can carry additional homology. Completion is not part of this algebraic argument. □

The Arithmetic Assembly Problem

Question 54.4.15 *(the full-target arithmetic trace comparison).* Construct compatible local arithmetic categories and trace complexes, a common coefficient ring, their completed restricted-tensor assembly, and a comparison with the full Weil/(φ, Γ) target, of the form

$$\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \simeq \mathcal{O}(\mathrm{LocSys}^{W,\varphi^\Gamma}_{GL_2})^{\mathrm{flat}} \oplus \mathcal{W}.$$

Here $\mathcal{W}$, its coefficient carrier and its degrees must be computed from that construction. The procyclic $B\widehat{\mathbb{Z}}$ model records only the inertia comparison, not the full target. The formal-loop hypotheses, F1, F2, and local degree-zero comparisons remain necessary parts of the proposed construction; their names do not supply a completed Künneth map.

If actual local traces over a common field split as $k \oplus k[1]$ and $k \oplus k^2[1]$, the full two-prime tensor has the degree-two term of Lemma 54.4.13. Its additive degree-one part is

$$\mathcal{W}_{\le 1} = k[1] \oplus (k \oplus k)[1]. \tag{54.2}$$

This can describe the positive part of a specified degree-at-most-one truncation, or a quotient killing the mixed product. It is not the full wild tensor contribution. To realize such a truncation or quotient arithmetically, its map and compatibility with the operations must also be constructed.

Remark 54.4.16 *(remaining degree-zero factors).* If the restricted tensor of the other primes is a degree-zero module D, every term of (54.1) must also be tensored with D. Thus even the degree-one terms carry all complementary degree-zero factors. Taking units at almost every prime permits non-unit entries at both two and three; it does not remove their mixed term. A common-field calculation cannot be replaced by the distinct-primary integral calculation without actual integral models and their comparison maps.

COROLLARY 54.4.17 *(conditions for degree-one assembly).* Suppose actual local trace complexes over R have the two specified splittings, all remaining factors assemble into a flat degree-zero module D, and a proved assembly map identifies the global trace with $D \otimes^{\mathrm{L}}_R C_2 \otimes^{\mathrm{L}}_R C_3$. If B_2, B_3 are flat and $W_2 \otimes^{\mathrm{L}}_R W_3 = 0$, its homology is concentrated in degrees zero and one, with underlying split complex

$$D \otimes_R B_2 \otimes_R B_3 \;\oplus\; D \otimes_R \big((W_2 \otimes_R B_3) \oplus (B_2 \otimes_R W_3)\big)[1].$$

Any completed or arithmetic sheaf interpretation additionally requires that the realization and completion preserve these identifications.

Proof. Apply Lemma 54.4.13. The mixed term vanishes by hypothesis, and flatness removes higher Tor from the remaining terms and from tensoring with D. The specified assembly map then transports this decomposition. □

54.5 CONSISTENCY WITH CHAPTER 49

R3 Consistency

Chapter 49's Definition 49.4.1 reads: for an n-geometric derived pro-étale stack $\mathcal{X}$, $L^{\mathrm{Ar}}\mathcal{X} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$, the internal mapping stack in the ∞-category of derived pro-étale stacks. Definition 54.3.7 specialises this to formal Noetherian derived algebraic stacks and commits to the internal-Hom convention. The two definitions are identical on the intersection of their domains (formal Noetherian derived algebraic stacks that are n-geometric and pro-étale). The Emerton–Gee stack lies in this intersection (Corollary 54.3.6).

R4 Consistency

An extension of the comparison in Chapter 49 must preserve the local trace complexes and the chosen tensor assembly. A degree-zero comparison does not determine the positive-degree part, and a list of local Ext dimensions does not supply a trace comparison.

PROPOSITION 54.5.1 *(the tensor terms required by a local comparison).* Suppose an arithmetic comparison identifies its two exceptional local traces over a field with $k \oplus k[1]$ and $k \oplus k^2[1]$, and identifies their assembly with their full derived tensor. Then that assembly is $k \oplus k^3[1] \oplus k^2[2]$. If the remaining factors assemble into a degree-zero vector space D, all three terms must also be tensored with D. The additive expression in (54.2) describes only the positive part through degree one. A degree-one-only global answer requires extra vanishing hypotheses, as in Corollary 54.4.17, or a specified truncation or quotient.

Proof. Apply Lemma 54.4.13 to the specified local equivalences. Tensoring with D is exact over a field. The two independent degree-two classes persist whenever $D \neq 0$. □

54.6 BOUNDARY CONDITIONS

R3 Boundary

The internal-Hom convention is fixed. Its comparison with the cofiltered and ind-completed models is conditional on the three formal-convergence hypotheses in Theorem 54.3.4.

R4 Boundary

Question 54.6.1 *(functoriality of the arithmetic wild contribution).* Construct coefficient-compatible local Langlands comparison maps carrying the relevant arithmetic extension classes to specified trace classes. Determine how their Yoneda products correspond to operations on the trace complexes and how these maps interact with the full tensor assembly. If the desired degree-one expression is obtained by truncation or quotient, construct that map and its functoriality as well.

A refinement of a local correspondence can address this question only after the coefficient category, extension directions and trace complex have been specified. Equality of local dimensions alone proves neither functoriality nor a global comparison.

Logical Form for Chapter 51

- **R3:** internal-Hom convention fixed by Definition 54.3.7 and matched with Chapter 49 by Proposition 54.3.9; comparison with the two other models remains conditional on Theorem 54.3.4.
- **R4:** the finite-algebra Ext calculations and the four-term derived tensor formula are proved above. Their arithmetic realization requires local categories, coefficient comparisons, Ext-to-trace maps and a compatible completed assembly. The proposed local degree-one contributions remain the comparison problems in Questions 54.4.8 and 54.4.9.

54.7 Loop-Convention Boundary

(i) **R3 (loop-space convention).** The canonical choice is the derived internal Hom (Definition 54.3.7); this matches Chapter 49's convention (Proposition 54.3.9). The comparison with the cofiltered and ind-completed models is conditional on Theorem 54.3.4.

(ii) **R4 (extensions and assembly).** Loewy length two does not bound Ext by degree one. The common-field local model has a nonzero mixed degree-two term. The distinct-primary integral model removes that term only on its specified integral carrier. The degree-one criterion above assumes flat degree-zero factors; a completed arithmetic realization also needs a comparison preserving the displayed decomposition.

(iii) **The arithmetic target.** The full Weil/(φ, Γ) trace comparison in Question 54.4.15 requires F1, F2, the formal-loop comparison and the actual local trace data. The elementary computations do not establish these maps.

Chapter 55

Costello-Refined Positselski: Factorization Coherence, $d^2 = 0$, Renormalization, Archimedean Comparison, Functoriality

Question 51.2.7 asks for an integral co–contra comparison. Its arithmetic application requires five further structures. C1 concerns local-global factorization coherence, C2 a square-zero differential, and C3 Euler-product renormalization. C4 compares integral and archimedean models. C5 asks for naturality under Λ-linear coalgebra maps.

For C2 and C4 the constructions below give ordinary arithmetic and integral oscillator models. Their chiral and archimedean comparisons require the additional maps specified there. The arithmetic Heisenberg biconditional $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \Leftrightarrow \xi(s) = \xi(1-s)$ remains conditional for the abelian Heisenberg domain.

55.1 Five Subconditions of the Abelian Positselski Domain

The Five Subconditions

Question 51.2.7 requires actual integral categories and comparison functors. Its hypotheses cannot be supplied by a field-to-$\mathbb{Z}_p[[\Gamma]]$ base change, because no such unital field map exists. Abelian Galois action and module-theoretic $\mu = 0$ also do not replace the coalgebra and completion hypotheses.

The conditions below concern additional arithmetic operations. For their P1 application one must also construct the Mellin evaluation, central-defect identity, and detection condition in Theorem 43.5.1.

The five subconditions are:

C1 (factorization-coalgebra coherence). At each place v, the arithmetic bar coalgebra $B_v^{\mathrm{ch,Ar}}(\mathcal{V}^{\mathrm{prim}})$ carries a local-global compatible factorization-coalgebra structure in the Costello–Gwilliam Vol. II sense. The adelic restricted product $\otimes'_v B_v^{\mathrm{ch,Ar}}$ inherits a global factorization-coalgebra structure compatible with the finite-level Beilinson adelic complex.

C2 (arithmetic differential and comparison). On the ordinary cyclotomic residue and polynomial bar model, the Iwasawa, residue and bar operators have square-zero sum by three separate signed mixed identities. The completed comparison is Chapter 55.4.2. A differential on the intended arithmetic chiral carrier additionally requires the tame-weighted local operations and comparison maps of Chapter 55.4.3.

C3 (renormalization / Euler-product convergence). The infinite tensor product $\otimes'_p \mathcal{H}^{(p)}$ requires renormalization: naively, the partition function $\prod_p (1 - p^{-\beta})^{-1}$ diverges for $\mathrm{Re}(\beta) \leq 1$. Costello–Gwilliam Vol. II BV renormalization plus Bost–Connes $\mathrm{KMS}_{\beta=1}$ provides the closure.

C4 (integral and archimedean comparison). A common integral polynomial model gives separate finite-place and real oscillator representations, preserving the vacuum, central term and formal current operations. Comparing an arithmetic bar object and its Iwasawa–Gersten differential with a specified real bar model and Positselski pairing remains the construction of Question 55.6.6.

C5 (functoriality). For each morphism $f : C \to C'$ of abelian Λ-coalgebras with $\mu = 0$, there is an induced pullback functor $f^* : \mathrm{D}^{\mathrm{co}}_{\Lambda}(C') \to \mathrm{D}^{\mathrm{co}}_{\Lambda}(C)$ and pushforward $(f^\vee)_* : \mathrm{D}^{\mathrm{ctr}}_{\Lambda}((C')^\vee) \to \mathrm{D}^{\mathrm{ctr}}_{\Lambda}(C^\vee)$ rendering the Positselski equivalence natural. The Positselski equivalence is a natural transformation of 2-functors $\mathrm{Coalg}^{\Lambda,\mu=0,\mathrm{ab},\mathrm{op}} \to \mathrm{PrSt}^{\mathrm{tri}}$.

C5 concerns the naturality of an actual co–contra equivalence under its specified morphisms. Once such an equivalence is constructed, a composite arithmetic argument must preserve its pairings and completions. The numerical P1 comparison still needs an evaluation of the central defect. Functoriality by itself does not supply that evaluation.

Notation Recalled

Throughout this chapter:

- $\Lambda = \mathbb{Z}_p[[\Gamma]]$, where $\Gamma = \mathrm{Gal}(\mathbb{Q}_\infty^{(p)}/\mathbb{Q}) \cong \mathbb{Z}_p$ and $\mathbb{Q}_\infty^{(p)}$ is the cyclotomic $\mathbb{Z}_p$-extension. Section 55.4 uses a fixed odd coefficient prime ℓ instead of p, to distinguish it from the finite places of the number fields. The full cyclotomic Galois group is not being identified with this procyclic quotient.
- $\mathcal{H}^{(p)}$ is the Heisenberg Fock at prime p with oscillator lattice spanned by $\{\alpha_{-n}^{(p)}\}_{n\geq 1}$ of weight $n \log p$ (see Chapter 30 (F3)).
- $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis}} = \otimes'_p \mathcal{H}^{(p)}$, the restricted-tensor-product arithmetic Heisenberg Fock with spherical vectors $|0\rangle_p$.
- $B^{\mathrm{ch,Ar}}(\mathcal{V}^{\mathrm{prim}}) = \oplus_n (s^{-1}\overline{\mathcal{V}^{\mathrm{prim}}})^{\otimes_\Lambda n} \otimes_\Lambda C^\bullet_{\mathrm{Parshin}}(\overline{C})$ denotes the proposed arithmetic chiral carrier of Chapter 33.8.1. The intended differential $d^{\mathrm{Ar}} = d_{\mathrm{Iw}} + d_{\mathrm{Gersten}} + d^{\mathrm{local}}_{\mathrm{bar}}$ requires the local maps and grading specified in Chapter 55.4.3. The ordinary complex constructed in Section 55.4 is a separate, fully specified carrier.
- $\{p, 1-p\}$ denotes the Milnor–Steinberg symbol in $K_2^M(\mathbb{Q})$; it vanishes in $K_2^M(\mathbb{Q})$ and in every $K_2^M(K)$ for K a field (Steinberg 1962, Milnor 1971).
- $\mathrm{Coalg}^{\Lambda,\mu=0,\mathrm{ab}}$ denotes the $(\infty,1)$-category of conilpotent abelian dg Λ-coalgebras with $\mu = 0$.

55.2 Comparison Table

The arithmetic comparison requires five compatibility conditions and the specified evaluation for its P1 application. The coproduct, differential, completion, archimedean realization and naturality maps must be specified on the same abelian Heisenberg domain. The following subsections separate these requirements before describing their role in the pairing.

Factorization-Coalgebra Coherence (C1)

Definition 33.8.1 gives a proposed arithmetic carrier from Λ-tensor powers and a residue complex. A geometric realization additionally requires a configuration diagram, its coefficient category and its collision maps. For specified disjoint configurations, the required maps have the form

$$\Delta^U_{U_1 \sqcup U_2} : B^{\mathrm{ch,Ar}}_U \longrightarrow B^{\mathrm{ch,Ar}}_{U_1} \otimes B^{\mathrm{ch,Ar}}_{U_2}.$$

They must satisfy the coherent counit, coassociativity and collision identities of Definition 55.3.1. A discrete set of place labels supplies none of these position spaces or maps. A vacuum object likewise does not define an E_2-monoidal category or a factorization coproduct.

Suppose local models have supplied a common configuration diagram and finite products $B_S = \otimes_{v\in S} B_v$. Transitions must insert specified vacuum *coalgebra maps* and preserve the full geometric

structure. Under the continuity hypotheses of Theorem 55.3.3, their filtered colimit is a factorization coalgebra. That theorem preserves supplied operations. It does not construct them from the place-indexed tensor formula.

The categorical pointings of Definition 51.2.1 are instead morphisms $\mathrm{Sp} \to C_v$ of operadic algebras. Theorem 51.2.3 assembles that categorical diagram. A comparison with the coalgebra diagram must specify its coefficient functor and preserve the displayed coproducts, local vacua and collision maps.

Beilinson's adelic resolution for schemes motivates a further comparison with the arithmetic residue differential. That comparison must satisfy the coderivation identity in Question 55.3.4. It also requires the archimedean model and maps in Question 55.6.6. Neither categorical assembly nor the integral oscillator model alone supplies these geometric and differential comparisons.

Iwasawa Operators and Residues (C2)

The Iwasawa and residue operators commute before totalization: field automorphisms carry tame residues to the corresponding residue fields. On the ordinary polynomial bar factor, the three signed mixed anticommutators therefore vanish separately. Section 55.4 constructs the arithmetic carriers, norm maps and completed comparison. The residue-weighted local chiral differential requires additional maps and remains the construction of Chapter 55.4.3. A relation holding modulo boundaries does not by itself give a square-zero operator on chains.

Renormalization and Euler-Product Convergence (C3)

For real $\beta > 0$, each prime shift has a normalized Gibbs density $\rho_{p,\beta} = (1 - p^{-\beta})\, p^{-\beta N_p}$. Finite tensor products of these densities define compatible states on the finite-prime Toeplitz algebras. Their compatible restrictions extend to a state on the norm-completed inductive tensor algebra, including at $\beta = 1$; the construction and KMS calculation are in Proposition 55.5.2. This normalizes states, not algebras or adjoint automorphic factors. The spherical Whittaker norm instead has the measure-dependent factor computed in Lemma 56.7.4.

The global occupation Hamiltonian on $\ell^2(\mathbb{N}^\times)$ has partition trace $\sum_{n \geq 1} n^{-\beta}$, finite only for $\beta > 1$. Thus the product state at $\beta = 1$ is not given by a normalized diagonal trace density on that global carrier. Identifying it with the restriction of a full Bost–Connes state, and constructing an arithmetic bar or BV comparison, require actual algebra maps, dynamics and completed chain maps. A product of the scalar identities $\mathrm{Tr}\, \rho_{p,\beta} = 1$ supplies none of those comparisons.

Integral and Archimedean Comparison (C4)

The finite-place oscillator data and the real Heisenberg representation have a common integral polynomial model. Its coefficient extensions preserve the vacuum, central commutator and oscillator operations. The associated formal current fields and oscillator-equivariant two-sided bar resolution are constructed in Section 55.6. Reduction modulo p followed by tensoring with $\mathbb{R}$ gives zero, so it cannot produce the real fibre. Identifying the arithmetic Iwasawa–Gersten complex with a real bar model requires the additional maps specified in Question 55.6.6.

Naturality of the Co-Contra Comparison (C5)

For $f : C \to C'$ a Λ-linear morphism in $\mathrm{Coalg}^{\Lambda, \mu=0, \mathrm{ab}}$, functoriality in the classical field case is Positselski 2011 §6; the arithmetic lift requires restriction to Λ-linear morphisms because base change $k \to \Lambda$ is not functorial on arbitrary coalgebra morphisms. For Λ-linear f: the pushforward $f_* : C\text{–comod}_\Lambda \to C'\text{–comod}_\Lambda$ sends M to M with C'-coaction $M \xrightarrow{\Delta_C} M \otimes_\Lambda C \xrightarrow{\mathrm{id} \otimes f} M \otimes_\Lambda C'$, preserves injectives

(Positselski 2018 arXiv:1209.2995 §3.1 for the field case; the Λ-lift follows by Nakayama plus $\mu = 0$), and descends to a triangulated functor $f_*^{\mathrm{co}}\colon \mathrm{D}^{\mathrm{co}}_\Lambda(C) \to \mathrm{D}^{\mathrm{co}}_\Lambda(C')$. The dual $f^\vee\colon (C')^\vee \to C^\vee$ is a Λ-algebra morphism and $(f^\vee)^*\colon \mathrm{D}^{\mathrm{ctr}}_\Lambda((C')^\vee) \to \mathrm{D}^{\mathrm{ctr}}_\Lambda(C^\vee)$ is the pullback in the opposite direction. The correct shape is therefore: a naive commutativity diagram drawn with f_* going $C \to C'$ and $(f^\vee)^*$ going $(C')^\vee \to C^\vee$ has a direction mismatch under dualization. The correct naturality diagram is:

$$\begin{array}{ccc} \mathrm{D}^{\mathrm{co}}_\Lambda(C) & \xrightarrow{\Psi_C} & \mathrm{D}^{\mathrm{ctr}}_\Lambda(C^\vee) \\ {\scriptstyle f^*}\uparrow & & \uparrow{\scriptstyle (f^\vee)_*} \\ \mathrm{D}^{\mathrm{co}}_\Lambda(C') & \xrightarrow{\Psi_{C'}} & \mathrm{D}^{\mathrm{ctr}}_\Lambda((C')^\vee) \end{array} \tag{55.1}$$

with $f^*\colon \mathrm{D}^{\mathrm{co}}_\Lambda(C') \to \mathrm{D}^{\mathrm{co}}_\Lambda(C)$ the pullback (restriction of scalars along f for the dual coalgebra structure) and $(f^\vee)_*\colon \mathrm{D}^{\mathrm{ctr}}_\Lambda((C')^\vee) \to \mathrm{D}^{\mathrm{ctr}}_\Lambda(C^\vee)$ the pushforward for the dual algebra. This is the correct shape of naturality for a bar–cobar adjunction: the two functors must be parallel, and the dualization swaps pullback with pushforward.

With (55.1) in place, the square commutes up to natural isomorphism by the definition of Ψ: $\Psi_C(f^*M) = \mathrm{Hom}_C(C, f^*M)$ and $(f^\vee)_*\Psi_{C'}(M) = (f^\vee)_*\mathrm{Hom}_{C'}(C', M)$, and these coincide via the adjunction $\mathrm{Hom}_C(C, f^*M) \simeq \mathrm{Hom}_{C'}(C' \otimes_C C, M) \simeq \mathrm{Hom}_{C'}(C', M)$ because $C' \otimes_C C \simeq C'$ via f.

C5 holds for Λ-linear morphisms of abelian Λ-coalgebras with $\mu = 0$, in the form (55.1) (Positselski 2011 §6; induced pullback on the arithmetic Λ-coefficient derived categories via Nakayama).

Functorial Pullback for the P1 Pairing

The arithmetic application of Theorem 43.5.1 requires central invariants of the specified dual objects and an evaluation of their defect. Identifying that evaluation with a Positselski pairing is a further comparison. The integral co–contra comparison of Question 51.2.7 remains an input. C1–C3 require global assembly, a square-zero differential, and a renormalized Euler product. C4 compares archimedean differentials and pairings. C5 requires naturality for the specified arithmetic comparison morphism.

For C4, the integral oscillator and bar constructions of Chapter 55.6.5 provide local coefficient data; the arithmetic comparison in Question 55.6.6 is still required. The P1 consequence also assumes that these models supply the central-defect and Mellin-evaluation data in Theorem 55.8.1.

Comparison Table

55.3 C1: Local-Global Factorization-Coalgebra Coherence

Local Coefficients and Their Geometric Realization

Definition 55.3.1 *(Arithmetic local factorization datum).* At a place v, specify a configuration diagram X_v, its collision maps and disjoint-position opens, and a coefficient ∞-category $\mathcal{E}_v$ with a chosen tensor product. A local factorization coalgebra is a compatible coefficient system $\mathcal{B}_v$ on this diagram with coproducts

$$\mathcal{B}_v(U) \longrightarrow \mathcal{B}_v(U_1) \otimes \mathcal{B}_v(U_2)$$

for the specified disjoint configurations, satisfying the coherent counit, coassociativity and collision identities. A local vacuum marking and any E_2-monoidal structure on the coefficient category are additional specified data. A discrete place label alone determines none of the position spaces X_v.

Condition	Required mathematical data	Consequence on the stated domain
C1	Compatible local factorization coproducts and pointed adelic assembly	A global factorization coalgebra
C2	Ordinary cyclotomic residue and bar operators; additional tame-weighted chiral maps and grading for the intended carrier	A proved square-zero ordinary model; the chiral comparison remains to construct
C3	Compatible finite products, convergence and the Bost–Connes state comparison	A renormalized restricted product with its specified state
C4	A common arithmetic coefficient complex and maps of differentials and pairings, beyond the integral oscillator model	Comparison with a specified real Heisenberg bar model
C5	Parallel derived functors and a naturality isomorphism for the co-contra equivalence	Functorial transport along the specified coalgebra morphisms
P1	Arithmetic objects with a central-defect identity and a Mellin evaluation detecting that defect	The conditional level criterion of Theorem 55.8.1

Table 55.1: Compatibility data for the abelian arithmetic Heisenberg comparison. Each consequence requires the data in its row; the existence of a scalar identity alone does not supply the corresponding chain map or limit.

The finite polynomial carrier does give an ordinary coefficient coalgebra. This construction uses its multiplication, in addition to its vacuum pointing.

Proposition 55.3.2 *(Finite polynomial bar coalgebra).* Let Λ be a commutative ring, $A = \Lambda[x_i : i \geq 1]$, and $\bar{A} = (x_i : i \geq 1)$ its augmentation ideal. Write $[a_1|\cdots|a_n]$ for an element of $\bar{A}^{\otimes_\Lambda n}[n]$, of cohomological degree $-n$. Then

$$B(A) = \bigoplus_{n\geq 0} \bar{A}^{\otimes_\Lambda n}[n], \qquad b[a_1|\cdots|a_n] = \sum_{i=1}^{n-1} (-1)^i [a_1|\cdots|a_i a_{i+1}|\cdots|a_n]$$

is a connected conilpotent differential graded coalgebra with coproduct

$$\Delta[a_1|\cdots|a_n] = \sum_{i=0}^{n} [a_1|\cdots|a_i] \otimes [a_{i+1}|\cdots|a_n].$$

An empty word means $1 \in \Lambda$. The counit projects to length zero and the coaugmentation includes it.

Proof. Two disjoint adjacent mergers occur in both orders with opposite signs. Two overlapping mergers give the same product of three entries, by associativity, again with opposite signs. Thus $b^2 = 0$. Iterating the displayed coproduct amounts to choosing two cuts in a word, independently of their order, which proves coassociativity. A merger followed by a cut is the same as a cut followed by a merger inside one of its blocks. The sign on the second block is $(-1)^i$, since the first block has degree $-i$; hence $\Delta b = (b \otimes 1 + 1 \otimes b)\Delta$. The empty cuts give the counit identities. An iterated reduced coproduct has only nonempty blocks and therefore vanishes after more cuts than the word length. This proves conilpotence. □

In particular the coproduct of this bar is deconcatenation. Calling a vacuum an E_0-datum neither constructs this bar differential nor a local E_2-monoidal factorization category. At the archimedean place, the formal currents of Corollary 55.6.4 likewise require specified configuration maps and an arithmetic

comparison, as in Question 55.6.6. The reduced associative bar, an oscillator-equivariant two-sided resolution, and Chevalley–Eilenberg chains are distinct complexes. Their geometric realization must name which complex and which maps it uses.

Filtered Assembly and the Adelic Comparison

Theorem 55.3.3 *(Filtered assembly of supplied factorization coalgebras).* Fix a configuration diagram and a cocomplete symmetric monoidal coefficient ∞-category $\mathcal{E}$. Assume its tensor product preserves filtered colimits in each variable, as do all restriction and collision functors used in the diagram. Let B_S, indexed by finite sets of places containing a fixed finite set, be a filtered diagram of factorization coalgebras on this configuration diagram. Assume its transitions preserve the coproducts, counits and any specified vacuum markings. Then

$$B = \varinjlim_{S} B_S$$

is a factorization coalgebra with those markings. If every factorization coproduct of every B_S is an equivalence, the corresponding coproduct of B is an equivalence.

Proof. For a fixed decomposition into r disjoint blocks, take the colimit of the r-fold coproducts. Filteredness makes the diagonal indexing functor cofinal in its r-fold product: every finite family of finite place sets is contained in their union, and the poset of further upper bounds is filtered and nonempty. Consequently preservation of filtered colimits gives

$$\varinjlim_{S} \bigotimes_{i=1}^{r} B_S(U_i) \simeq \bigotimes_{i=1}^{r} \varinjlim_{S} B_S(U_i).$$

This constructs the coproduct of B. Restriction and collision compatibilities pass to the colimit by their stated preservation hypotheses. Every coassociativity diagram and all its homotopies are images of the compatible diagrams at finite S, so they pass to the colimit as well. Counits and vacuum markings do the same. Finally a colimit of equivalences is an equivalence, proving the last assertion. □

For example, supplied local models may give $B_S = \bigotimes_{v \in S} B_v$, with transitions inserting specified vacuum coalgebra maps at new places. Their filtered assembly is a restricted coefficient product. Constructing the local position models, their common coefficient comparison and these coalgebra maps is part of the arithmetic problem. A pointing of the underlying module alone does not meet the hypotheses. The category of finite place sets is the discrete index category of Definition 30.1.2; it does not replace the configuration diagram in the theorem.

Question 55.3.4 *(Adelic differential comparison).* Construct an arithmetic adelic coefficient complex D_{ad} and a comparison with the specified restricted bar product, including its local residue maps. Prove that its adelic differential is a coderivation for the geometric coproduct:

$$\Delta d_{\mathrm{ad}} = (d_{\mathrm{ad}} \otimes 1 + 1 \otimes d_{\mathrm{ad}})\Delta.$$

The tensor differential here includes its cohomological Koszul sign. The comparison must specify the coefficient ring, the restricted product and its topology, the archimedean term, and the transition maps across the chosen local position diagrams.

Beilinson's adelic resolution for schemes provides the motivating geometric construction. Applying it to an arithmetic object with an archimedean term requires the complex and comparison in this question; a formal tensor of local fields does not define its adelic differential.

Corollary 55.3.5 *(Conditional arithmetic assembly).* An arithmetic bar system whose local and transition maps satisfy Theorem 55.3.3 has a compatible factorization coalgebra after filtered assembly. Compatibility with an independently defined adelic differential additionally requires the comparison of Question 55.3.4.

55.4 Iwasawa operators and tame residues

To combine a Galois action with residues, one first needs a square of maps between specified groups. On a number field this square is particularly concrete. If v is a finite place, π a uniformizer and u a unit at v, the tame residue sends $\{u, \pi\}$ to $\bar{u}$. A field automorphism carries this calculation to the corresponding calculation at the image of v. This exact compatibility, together with the tensor signs, produces an ordinary arithmetic bar complex.

Fix an odd prime ℓ. Let $K_\infty/\mathbb{Q}$ be the cyclotomic $\mathbb{Z}_\ell$-extension, K_r its subfield of degree ℓ^r, and $\Gamma = \mathrm{Gal}(K_\infty/\mathbb{Q})$. Choose a topological generator γ, and put $\Lambda = \mathbb{Z}_\ell[[T]]$, $T = \gamma - 1$. Here K_r is the fixed field of the subgroup of order $\ell - 1$ in $\mathbb{Q}(\mu_{\ell^{r+1}})$. Thus Γ acts on each K_r through a cyclic group of order ℓ^r. The prime ℓ specifies coefficients and the tower; finite places of K_r will be denoted by v.

The residue square

Write Milnor groups additively, including the multiplicative group $K_1^M(k) = k^\times$, and define

$$G_r^0 = K_2^M(K_r), \qquad G_r^1 = \bigoplus_{v \text{ finite}} k(v)^\times, \qquad G_r = [G_r^0 \xrightarrow{\partial} G_r^1].$$

The two groups have cohomological degrees 0, 1. In multiplicative notation our residue convention is

$$\partial_v\{a, b\} = (-1)^{v(a)v(b)}\overline{a^{v(b)}/b^{v(a)}}.$$

The expression inside the residue bar is a unit. It is bilinear and annihilates $\{a, 1 - a\}$: if one valuation is positive the other factor reduces to 1; if both are zero the result is 1; if $v(a) < 0$, then $v(1 - a) = v(a)$ and $(1 - a)/a$ reduces to -1, cancelling the displayed sign. A symbol has nontrivial residues at only finitely many places. Consequently ∂ is a well-defined homomorphism into the direct sum. The square of the differential of G_r is zero because there is no degree-two term. No sum of elements of different residue fields is required.

For $\sigma \in \Gamma$, the action on symbols is $\sigma\{a, b\} = \{\sigma a, \sigma b\}$. On degree one it carries the v-summand to the σv-summand by the induced field isomorphism. Since $(\sigma v)(\sigma a) = v(a)$,

$$\partial_{\sigma v}\{\sigma a, \sigma b\} = \sigma\partial_v\{a, b\}, \qquad \partial(\gamma - 1) = (\gamma - 1)\partial.$$

This is an equality on the groups themselves.

For a finite extension of number fields L/K, there are chain maps $N : G_L \to G_K$ and $R : G_K \to G_L$. In degree zero they are transfer and restriction on K_2^M. In degree one they are

$$(Nz)_v = \sum_{w|v} N_{k(w)/k(v)} z_w, \qquad (Rz)_w = e(w/v)\,\mathrm{res}_{k(w)/k(v)}\, z_v.$$

Thus

$$\partial_v N_{L/K}\xi = \sum_{w|v} N_{k(w)/k(v)}\partial_w\xi, \qquad \partial_w \mathrm{res}\,\xi = e(w/v)\,\mathrm{res}\,\partial_v\xi. \tag{55.2}$$

One construction of the first map identifies Milnor K_2 with Quillen K_2 by Matsumoto's theorem and takes restriction of scalars on finite-dimensional vector spaces. The localization boundary commutes with this exact functor. On the residue terms, restriction of scalars is the field norm. This gives the first identity, including at ramified primes; see Weibel, *The K-book*, III, Theorem 6.1 and V, (6.6.3)–(6.6.4). Our convention is the inverse of the tame symbol in III, Lemma 6.3; inverting every residue leaves the commutative square unchanged. The second identity also follows directly from $w(a) = e(w/v)v(a)$: its two signs agree because $e^2 - e$ is even. Transfers compose, and commute with the Γ-actions in the tower, by composition and conjugation of restriction of scalars. These identities descend to $G_{r,s} = G_r/\ell^s G_r$, term by term. This quotient is an ordinary quotient complex, not a claim about derived reduction of motivic cohomology.

A signed total complex

Let $P = \mathbb{Z}[x_1, x_2, \dots]$, augmented by $x_n \mapsto 0$, with x_n of weight n and cohomological degree zero. We use the trivial Γ-action on this factor as an explicit choice. Set $\bar{P} = \ker(P \to \mathbb{Z})$. Its reduced associative bar complex has

$$B^{-q} = \bar{P}^{\otimes q}, \quad B^0 = \mathbb{Z}, \qquad b[f_1|\cdots|f_q] = \sum_{a=1}^{q-1} (-1)^{a-1}[f_1|\cdots|f_a f_{a+1}|\cdots|f_q].$$

Associativity cancels the two orders of every pair of mergers, so $b^2 = 0$. This is an associative bar differential: it merges adjacent entries and vanishes on a word of length one.

For $i = 0, 1$, take a copy of $G_{r,s}^j \otimes_{\mathbb{Z}} B^{-q}$, denoting its elements by $e_i \otimes g \otimes w$. Its total degree is $i + j - q$. Define

$$I(e_0 \otimes g \otimes w) = e_1 \otimes Tg \otimes w, \qquad I(e_1 \otimes g \otimes w) = 0,$$
$$J(e_i \otimes g \otimes w) = (-1)^i e_i \otimes \partial g \otimes w, \qquad L(e_i \otimes g \otimes w) = (-1)^{i+j} e_i \otimes g \otimes bw.$$

All three maps have total degree one. Let $C_{r,s} = \mathrm{Tot}(G_{r,s} \otimes B \otimes [e_0, e_1])$ with these copies ordered as in the displayed formulas.

Proposition 55.4.1 *(Three separate mixed-square identities).* The operator $D = I + J + L$ on $C_{r,s}$ satisfies

$$I^2 = J^2 = L^2 = 0, \qquad IJ + JI = IL + LI = JL + LJ = 0.$$

Norms, ramification-weighted restrictions and coefficient reductions are chain maps for D.

Proof. On the $i = 0$ copy, $(IJ + JI)(e_0 \otimes g \otimes w)$ is $e_1 \otimes (T\partial - \partial T)g \otimes w = 0$; on the other copy it is zero by definition. For $IL + LI$, the sign of L changes when I increases i, whereas T and b act on independent factors. For $JL + LJ$, the sign of L changes when J increases j, and ∂ and b again act on independent factors. These are three separate cancellations. The diagonal squares follow respectively from the two copies, the two-term residue complex, and associativity. Equation (55.2) proves the assertion about arithmetic maps; their bar component is the identity. □

The two copies have a precise Iwasawa meaning. The exact sequence

$$0 \longrightarrow \Lambda \xrightarrow{T} \Lambda \longrightarrow \mathbb{Z}_\ell \longrightarrow 0$$

is a free resolution of the augmentation module: a power series with zero constant term is uniquely divisible by T. Applying $\mathrm{Hom}_\Lambda(-, M)$ gives $[M \xrightarrow{T} M]$. Hence our two-copy construction computes the derived augmentation invariants over Λ of the specified coefficient complex. It does not replace T by multiplication by a real logarithm. The module $G_{r,s}$ has a well-defined Λ-action: from $(1+T)^{\ell^r} = 1$ one gets $T^{\ell^r} \in \ell\,\mathrm{End}(G_{r,s})$, and therefore $T^{s\ell^r} = 0$. Formal power series act by finite sums on every fixed (r,s)-coordinate.

The ordinary bar comparison and its completion

The negative Heisenberg modes span the abelian Lie algebra $V = \bigoplus_{n\geq 1} \mathbb{Z}x_n$. Its Chevalley–Eilenberg chains with trivial coefficients are $E^{-q} = \bigwedge^q V$, with zero differential and weight $\mathrm{wt}(x_n) = n$. There is an integral map

$$A(x_{n_1} \wedge \cdots \wedge x_{n_q}) = \sum_{\sigma\in S_q} \mathrm{sgn}(\sigma)[x_{n_{\sigma(1)}}|\cdots|x_{n_{\sigma(q)}}].$$

No factorial is inverted. Adjacent transpositions pair all terms of bA, so $bA = 0$. Deconcatenation on B corresponds under A to the exterior coproduct in which the x_n are primitive. For example,

$$A(x_1 \wedge x_2) = [x_1|x_2] - [x_2|x_1], \qquad b[x_1|x_1] = [x_1^2].$$

Thus the repeated entry is not an additional degree-minus-two class, including in characteristic two.

Theorem 55.4.2 *(Completed ordinary arithmetic comparison).* Let $C^E_{r,s}$ be the preceding total complex with B replaced by E. At each weight, $1 \otimes A$ is a chain homotopy equivalence $C^E_{r,s} \to C_{r,s}$, compatible with norms and coefficient reductions. These equivalences extend to

$$\widehat{C}^E = \prod_{W\geq 0} \varprojlim_{r,s} (C^E_{r,s})_W \xrightarrow{1\otimes A} \widehat{C} = \prod_{W\geq 0} \varprojlim_{r,s} (C_{r,s})_W.$$

The differentials on both completed complexes square to zero. The transition maps are norms as r decreases and coefficient reductions as s decreases. The limits have the inverse-limit topology of discrete modules, and the product has the product topology.

Proof. At weight W, only $x_1, \ldots, x_W$ and word lengths $q \leq W$ occur. Both E_W and B_W are bounded complexes of finite free abelian groups. For the polynomial ring in these W variables, the Koszul resolution of its augmentation has underlying module $P \otimes \bigwedge V$ and differential

$$d(f \otimes x_{n_1} \wedge \cdots \wedge x_{n_q}) = \sum_{a=1}^{q} (-1)^{a-1} f x_{n_a} \otimes x_{n_1} \wedge \cdots \widehat{x_{n_a}} \cdots \wedge x_{n_q}.$$

It resolves $\mathbb{Z}$: tensoring the one-variable resolutions $0 \to \mathbb{Z}[x] \xrightarrow{x} \mathbb{Z}[x] \to \mathbb{Z} \to 0$ successively proves exactness. The free bar resolution has the same augmentation, and antisymmetrizing the variables defines a map from the Koszul resolution to it. Its internal merger terms cancel; its first multiplication terms give precisely the Koszul formula. This map lifts the identity on the augmentation, hence is a homotopy equivalence of free resolutions. After tensoring with the augmentation module it becomes antisymmetrization into the usual reduced bar convention. Multiplication in length q by $(-1)^q$ changes that convention to the displayed b. Consequently A, differing from this map only by the invertible sign on E^{-q}, induces an isomorphism on homology.

The cone of A_W is bounded, acyclic and free over $\mathbb{Z}$. Its boundary groups are free subgroups of free abelian groups, so the short exact sequences between boundaries and chain groups split. Choose these splittings once at each weight. They give a chain contraction of the cone, and hence a homotopy inverse to A_W. These choices involve only the bar and exterior factors. They remain valid after tensoring with any $G_{r,s}^{j}$, without a flatness assumption on that group. A bar homotopy h extends to the total complex with the sign $(-1)^{i+j}$; its mixed terms with I and J cancel just as above. The same choices commute with every norm and reduction, so their identities pass to the inverse limits and then to the product over weights. All formulas are coordinatewise continuous. In particular this argument does not exchange cohomology with an inverse limit. □

The total complex is a differential graded comodule over the bar coalgebra: the coaction applies deconcatenation to its B-factor. For the signed tensor of maps, the differential on the second bar factor receives the usual Koszul sign from the preceding factors. The preceding comparison intertwines this coaction with the exterior coproduct through A. At completion the target of the coaction is the product over the two nonnegative output weights; each fixed input weight has only finitely many splittings. No multiplication or coalgebra diagonal on G_r is asserted.

Small residues and the remaining chiral comparison

Over $\mathbb{Q}$, the symbol $\{2, 3\}$ has residue 2 at 3, residue 1 at 2, and residue 1 elsewhere. The symbol $\{3, 3\}$ has residue -1 at 3, so it is nonzero. The identity $\{a, a\} = \{a, -1\}$ does hold: for $a \neq 1$, applying Steinberg to a^{-1} and expanding $1 - a^{-1} = (a - 1)/a$ gives $\{a, a\} = \{a, a - 1\} = \{a, -1\}$. But $\{-1, -1\} \neq 0$ in $K_2^M(\mathbb{Q})$. Indeed the map

$$\{a, b\} \longmapsto \epsilon(a)\epsilon(b) \in \mathbb{F}_2, \qquad \epsilon(a) = \begin{cases} 1 & a < 0, \\ 0 & a > 0, \end{cases}$$

is bilinear and kills Steinberg relations, since a and $1 - a$ cannot both be negative. Its value on $\{-1, -1\}$ is 1. The relation $\{2, -1\} = 0$ has value zero and imposes no such vanishing on $\{-1, -1\}$.

At $\ell = 3$, $r = 0$, $s = 1$, take $g = \{3, 7\}$ modulo 3. Its only nontrivial residue is $\bar{3} \in \mathbb{F}_7^{\times}$, which remains nonzero modulo cubes. Since $K_0 = \mathbb{Q}$, $T\,g = 0$. On the length-two word,

$$D(e_0 \otimes g \otimes [x_1|x_1]) = e_0 \otimes \partial g \otimes [x_1|x_1] + e_0 \otimes g \otimes [x_1^2].$$

Applying D again gives the two terms $-e_0 \otimes \partial g \otimes [x_1^2]$ and $+e_0 \otimes \partial g \otimes [x_1^2]$, which cancel. This calculation takes place on actual nonzero residue classes.

A nontrivial Galois square occurs already for $\ell = 3$, $r = 1$. Write $K_1 = \mathbb{Q}(\theta)$, where $\theta = \zeta_9 + \zeta_9^{-1}$ satisfies $\theta^3 - 3\theta + 1 = 0$. Choose γ induced by $\zeta_9 \mapsto \zeta_9^4$; then $\gamma\theta = 2 - \theta - \theta^2$. Modulo 19, the polynomial has the three distinct roots 9, 7, 3, giving three residue fields $\mathbb{F}_{19}$. For $g = \{\theta, 19\}$, the residues at these places are $(9, 7, 3)$, whereas those of $\gamma\, g$ are $(7, 3, 9)$. The element 2 generates $\mathbb{F}_{19}^{\times}$. Writing residues additively by their powers of 2, and reducing modulo cubes, these vectors are $(2, 0, 1)$ and $(0, 1, 2)$ in $\mathbb{F}_3^3$. Thus

$$\partial(T\,g) = (1, 1, 1) = T(\partial g) \neq 0.$$

The two paths are equal and nonzero; it is the totalization sign that cancels them. At the same prime, the residue part of the norm to $\mathbb{Q}$ is multiplication of the three components: $9 \cdot 7 \cdot 3 = -1$ in $\mathbb{F}_{19}$, consistent with $N_{K_1/\mathbb{Q}}\theta = -1$ and the projection formula $N\{\theta, 19\} = \{-1, 19\}$.

The full Heisenberg Lie algebra is different from V: its positive and negative modes have bracket $[a_m, a_{-n}] = m\delta_{mn}K$. That central term enters its Chevalley–Eilenberg differential. Neither this full Lie complex nor a chiral bar complex is identified with $B(P)$ by the ordinary comparison above. In particular $\sum_{k+l=n} a_{-k} \wedge a_{-l} = 0$ for the ordered positive pairs: off-diagonal terms cancel and diagonal exterior products are zero. This sum cannot supply a nonzero splitting differential on negative modes.

Remark 55.4.3 *(The arithmetic chiral differential).* The construction of a tame-weighted local chiral differential on $B^{\mathrm{ch,Ar}}(\mathcal{V}^{\mathrm{prim}})$ remains a further problem. It requires a coefficient complex with the specified local chiral operations, residue maps between their carriers, and compatible Γ-actions and norm maps. A tame residue is a homomorphism $K_2^M(K_r) \to k(v)^\times$, not a scalar coefficient. Simply tensoring it with a bar merger, which already has degree one, has degree two in the total grading used here. An additional operation or shift must be specified before it can be a term of the arithmetic differential. Archimedean data also require a separate coefficient construction; they are not finite residue fields in G_r.

Remark 55.4.4 *(Twisting and filtered comparison).* For a specified degree-one operator D_0 and a proposed correction τ, the necessary chain identity is

$$(D_0 + \tau)^2 = D_0^2 + D_0\tau + \tau D_0 + \tau^2 = 0.$$

If $D_0 = I + J + L$, all three commutators with τ occur. A relation involving only J does not imply this equation. Knowing that an obstruction is a boundary supplies neither a chosen primitive with these identities nor its compatibility with norms and completion. A filtered quasi-isomorphism further requires an actual chain map and control of the filtration. For $\widehat{C}^E \to \widehat{C}$ the compatible contractions above supply that control. For the tame-weighted chiral complex, the twisting operator and the comparison with this ordinary arithmetic model remain to be constructed.

55.5 C3: Renormalization / Euler-Product Convergence

Finite-Prime Gibbs States and the Inductive Algebra

Definition 55.5.1 *(The prime Toeplitz tensor algebra).* For each prime let $K_p = \ell^2(\mathbb{N}_0)$, let V_p be the unilateral shift, and put $\mathcal{T}_p = C^*(V_p)$. Define the self-adjoint number operator by $N_p e_j = j e_j$ on $D(N_p) = \{x : \sum_{j\geq 0} j^2|x_j|^2 < \infty\}$. For finite S, use the spatial tensor product $\mathcal{T}_S = \bigotimes_{p\in S} \mathcal{T}_p$ on $K_S = \bigotimes_{p\in S} K_p$, with unital maps $a \mapsto a \otimes 1$ for $S \subset S'$. Define $\mathcal{T}_{\mathrm{loc}} = \varinjlim_S \mathcal{T}_S$, the norm-completed inductive C*-algebra. Its dynamics is $\alpha_t(V_p) = p^{it}V_p$. This is an operator-algebraic carrier; no pronilpotent arithmetic or BV tower is defined by these unital embeddings alone.

Proposition 55.5.2 *(Compatible finite-prime Gibbs states).* Fix real $\beta > 0$. For finite S, set

$$H_S = \sum_{p\in S} (\log p) N_p, \qquad \rho_{S,\beta} = \bigotimes_{p\in S} (1 - p^{-\beta}) p^{-\beta N_p}.$$

This is a positive trace-class density of trace one. The states $\varphi_{S,\beta}(a) = \mathrm{Tr}(\rho_{S,\beta} a)$ are compatible under the unital embeddings and define a β-KMS state φ_β on $\mathcal{T}_{\mathrm{loc}}$, with convention $\varphi_\beta(ab) = \varphi_\beta(b\alpha_{i\beta}(a))$. On the global occupation carrier $\ell^2(\mathbb{N}^\times)$ with $He_n = (\log n)e_n$, the operator $e^{-\beta H}$ is trace class exactly when $\beta > 1$.

Proof. The geometric series gives $\mathrm{Tr}(p^{-\beta N_p}) = (1 - p^{-\beta})^{-1}$, so the finite tensor density is positive with trace one. Tracing over an added factor gives one, proving compatibility. Consequently φ_β is well

defined on the algebraic union, positive and of norm one; it extends uniquely and positively to its norm completion.

Finite tensor words in V_p, V_p^* are entire analytic for α. On each finite carrier, $\rho_{S,\beta} a = \alpha_{i\beta}(a)\rho_{S,\beta}$ for these words. Trace cyclicity gives the displayed KMS identity. The finite analytic word algebra is norm dense in the inductive algebra, so the analytic KMS criterion gives the KMS state there.

Finally, the global diagonal trace is $\mathrm{Tr}(e^{-\beta H}) = \sum_{n\geq 1} n^{-\beta}$. The integral test proves convergence exactly for $\beta > 1$. In that regime unique factorization and absolute convergence give $\zeta(\beta) = \prod_p (1 - p^{-\beta})^{-1}$. For $0 < \beta \leq 1$ the diagonal operator has infinite trace, although the compatible state on $\mathcal{T}_{\mathrm{loc}}$ still exists. □

Question 55.5.3 *(The arithmetic and BV state comparison).* Construct the full Bost–Connes algebra map and dynamics comparison whose state restriction is φ_β, including at $\beta = 1$. Construct the arithmetic bar carrier, transition morphisms, completions and coherent BV operations that compare its finite-prime state data with this operator-algebraic construction. The comparison must preserve the specified observables, state and pairing, not merely the scalar normalization of the unit. If a pro-nilpotent limit is used, its filtration, transition maps and convergence must be proved on that arithmetic carrier.

Remark 55.5.4 *(The BV comparison requires chain-level maps).* An effective BV or factorization-algebra construction requires its own coefficient category, completed operations and compatible transition maps. The positive densities above are operators and define functionals on C*-algebras. Their traces do not define a BV differential, a bar-coalgebra morphism or a pro-nilpotent filtration. The requested comparison must supply these structures explicitly.

55.6 Integral oscillators and the real Fock representation

An oscillator can be defined over the integers before choosing a place. Its reduction modulo a prime and its real realization are then separate changes of coefficients. Reduction followed by tensoring with the reals cannot give the real realization. Indeed, if $pM = 0$, then

$$m \otimes r = (pm) \otimes (r/p) = 0 \qquad \text{in } M \otimes_{\mathbb{Z}} \mathbb{R}.$$

Thus $\mathbb{F}_p \otimes_{\mathbb{Z}} \mathbb{R} = 0$. There is also no unital ring map $\mathbb{F}_p \to \mathbb{R}$, since it would send $p1 = 0$ to $p1 \neq 0$. A comparison must retain characteristic-zero coefficient data before taking the two fibres.

A common integral representation

Write

$$P_{\mathbb{Z}} = \mathbb{Z}[x_1, x_2, \ldots], \qquad \mathrm{wt}(x_n) = n, \qquad |x_n| = 0.$$

The weight is distinct from cohomological degree. Elements are finite polynomials, the vacuum is 1, and the augmentation sends every x_n to zero. For $n \geq 1$, define operators

$$a_{-n} f = x_n f, \qquad a_n f = n \frac{\partial f}{\partial x_n}, \qquad a_0 = 0, \qquad Kf = f.$$

Let $\mathfrak{h}_{\mathbb{Z}}$ be the free abelian group on K and a_m, $m \in \mathbb{Z} \setminus \{0\}$, with bracket

$$[a_m, a_n] = m\delta_{m+n,0} K, \qquad [K, a_m] = 0.$$

All brackets involving a_0 are zero if a zero-mode generator is adjoined. The displayed operators give its level-one, zero-momentum representation. For example,

$$a_1 x_1 = 1, \qquad a_1 x_1^2 = 2x_1, \qquad a_2 x_2 = 2, \qquad a_2 x_1^2 = 0.$$

The derivative product rule proves the commutator, including its sign. Jacobi holds because every bracket is central.

Definition 55.6.1 *(integral coefficient comparison).* The integral oscillator comparison consists of $P_{\mathbb{Z}}$ with its vacuum, multiplication and operators a_m, K, together with their separate scalar extensions. The real realization is $P_{\mathbb{Z}} \otimes \mathbb{R}$. A residual fibre is $P_{\mathbb{Z}} \otimes \mathbb{F}_p$.

Proposition 55.6.2 *(separate coefficient fibres).* For every commutative ring R, the formulas above define $P_R = P_{\mathbb{Z}} \otimes_{\mathbb{Z}} R$ and an action of $\mathfrak{h}_R = \mathfrak{h}_{\mathbb{Z}} \otimes R$. Every ring map $R \to S$ gives a map $P_R \to P_S$ preserving the vacuum, ordinary polynomial multiplication, the weight decomposition and all oscillator operators after extension of coefficients. In particular, the integral object gives the diagram

$$P_{\mathbb{Z}_p} \longleftarrow P_{\mathbb{Z}} \longrightarrow P_{\mathbb{R}}, \qquad P_{\mathbb{Z}_p} \longrightarrow P_{\mathbb{F}_p}.$$

No arrow from the residual fibre to the real fibre is asserted.

Proof. Polynomial monomials form a free integral basis. All operator matrices in that basis have integer entries. Applying a ring map to their coefficients commutes with each displayed formula. The identity $[a_n, a_{-n}] = nK$ remains valid when n becomes zero in R. For example, $a_p = p\partial_{x_p}$ is zero on $P_{\mathbb{F}_p}$. This degeneration is part of the residual representation. □

This construction uses the monomial Fock lattice of Chapter 28. Its map to the named local oscillator module sends

$$x_{n_1} \cdots x_{n_r} \longmapsto a_{-n_1}^{(p)} \cdots a_{-n_r}^{(p)} |0\rangle_p.$$

It is an isomorphism when that local module is the polynomial vacuum representation with these monomials as basis and the displayed annihilation action. Additional arithmetic operations on a local module must be specified separately. The logarithmic energy $n \log p$ is not an integral structure constant. If the oscillator lattice has trivial Γ-action, its $\Lambda = \mathbb{Z}_p[[\Gamma]]$-module structure is the action through the augmentation $\Lambda \to \mathbb{Z}_p$. This specifies the coefficient action, not an Iwasawa differential.

Remark 55.6.3 *(the adelic coefficient space).* The adele ring $\mathbb{A}_{\mathbb{Q}} = \mathbb{R} \times \prod_p' \mathbb{Q}_p$ already includes the real place as a factor. A duality on this additive group does not supply the missing homomorphism from a residue field to $\mathbb{R}$. The common integral representation supplies separate fibres without asserting such a homomorphism.

There are two different completions. The weight completion is $\prod_{d \geq 0} P_{\mathbb{Z},d}$; each weight summand has finite rank. The p-adic completion is

$$\widehat{P}_p = \varprojlim_r P_{\mathbb{Z}} / p^r P_{\mathbb{Z}}.$$

Its monomial coefficients lie in $\mathbb{Z}_p$, and modulo every p^r only finitely many coefficients are nonzero. The oscillator operators preserve this condition and are continuous. This restricted coefficient condition differs from an arbitrary product over weights. All comparisons below first use polynomial direct sums. A statement about either completion must specify which topology and which completed tensor product it uses.

The Hall lattice and coefficient operations

The larger integral symmetric-function lattice does not coincide with $P_{\mathbb{Z}}$. Inside $P_{\mathbb{Q}}$ define h_r by

$$\sum_{r\ge 0} h_r u^r = \exp\!\left(\sum_{n\ge 1} \frac{x_n u^n}{n}\right), \qquad h_0 = 1, \qquad L_{\mathbb{Z}} = \mathbb{Z}[h_1, h_2, \dots].$$

Differentiating this generating series gives the Newton identities

$$r h_r = \sum_{n=1}^{r} x_n h_{r-n}.$$

They imply $P_{\mathbb{Z}} \subset L_{\mathbb{Z}}$ and $P_{\mathbb{Q}} = L_{\mathbb{Z}} \otimes \mathbb{Q}$. They also give

$$h_1 = x_1, \qquad h_2 = \frac{x_1^2 + x_2}{2}, \qquad h_3 = \frac{x_1^3 + 3x_1x_2 + 2x_3}{6}.$$

The annihilation operator satisfies $a_n h_r = h_{r-n}$, with $h_j = 0$ for $j < 0$. Thus both integral lattices are stable under the oscillator operators. Their inclusion is strict already in weight two. This is the lattice distinction in Section 28.4; the Newton formulas are Macdonald, *Symmetric Functions and Hall Polynomials*, second edition, I.2, equations (2.10)–(2.14).

For a partition λ having m_n parts equal to n, put $x_\lambda = \prod_n x_n^{m_n}$ and $z_\lambda = \prod_n n^{m_n} m_n!$. The Hall form on $P_{\mathbb{Q}}$ is

$$\langle x_\lambda, x_\mu \rangle = \delta_{\lambda\mu} z_\lambda.$$

The form is integral on $L_{\mathbb{Z}}$, and its Schur basis is orthonormal; these are Macdonald I.4, equations (4.5)–(4.9). On the monomial lattice, the formula directly proves $\langle a_{-n} f, g\rangle = \langle f, a_n g\rangle$. In weight two, x_1^2, x_2 both have squared norm 2, whereas h_2 has squared norm 1. Replacing one lattice by the other therefore changes the integral fibre, although their rational and real representations agree.

The polynomial operations $\psi_r(x_n) = x_{rn}$ preserve the vacuum and satisfy $\psi_r \psi_s = \psi_{rs}$. They commute with coefficient change. They do not intertwine each fixed oscillator operator:

$$a_{rn}\psi_r = r\psi_r a_n, \qquad \psi_r a_{-n} = a_{-rn}\psi_r.$$

If r does not divide k, then $a_k \psi_r = 0$. These identities follow by differentiating substituted polynomials. Let T be the derivation $T(x_n) = n x_{n+1}$. For $r > 1$, this substitution fails to commute with translation: $T\psi_r(x_1) = r x_{r+1}$, while $\psi_r T(x_1) = x_{2r}$. Thus ψ_r is not an endomorphism of the vertex structure constructed below. The formula for T_r in (28.1) defines another integral polynomial substitution,

$$T_r(x_k) = \sum_{d \mid r,\ d \mid k} d\, x_{rk/d}.$$

It too commutes with coefficient change, but is not the same monoid action: $T_2^2(x_1) = x_4 + 2x_2$, while $T_4(x_1) = x_4$. The two operations must remain distinct in any comparison retaining them.

The real Fock space and its operator domains

Over $\mathbb{R}$, the Hall form is positive definite. Complete $P_{\mathbb{R}}$ for this form. The vectors $e_\lambda = x_\lambda/\sqrt{z_\lambda}$ give an orthonormal basis of the resulting real Hilbert space $\mathcal{F}_{\mathbb{R}}$. For $f = \sum_\lambda c_\lambda e_\lambda$, the closed oscillator operators have domains

$$\mathrm{Dom}(a_n) = \left\{ f : \sum_\lambda n m_n(\lambda) |c_\lambda|^2 < \infty \right\},$$

$$\mathrm{Dom}(a_{-n}) = \left\{ f : \sum_\lambda n (m_n(\lambda)+1) |c_\lambda|^2 < \infty \right\}.$$

Their values on basis vectors have coefficients $\sqrt{n m_n}$ and $\sqrt{n(m_n+1)}$, respectively. These weighted shifts are adjoints of one another. Truncating the orthonormal expansion proves that polynomial states form a core. The commutation relations hold on this common invariant polynomial domain. They are not equalities of everywhere-defined bounded operators.

The weight operator and the energy at a fixed prime are

$$L_0 e_\lambda = |\lambda| e_\lambda, \qquad H_p e_\lambda = (\log p)|\lambda| e_\lambda, \qquad \mathrm{Dom}(L_0) = \left\{ f : \sum_\lambda |\lambda|^2 |c_\lambda|^2 < \infty \right\}.$$

The same domain defines H_p. Both are self-adjoint diagonal operators. This realizes the local weight $n \log p$ by multiplying one fixed real weight operator by $\log p$. It is not a limit as p increases.

A finite set of modes also has a Gaussian realization. For $1 \le n \le N$, use real coordinates s_n with product measure $(2\pi)^{-N/2} \exp(-\sum_n s_n^2/2)\, ds_1 \cdots ds_N$. Define the Hermite polynomials by

$$\exp(ts - t^2/2) = \sum_{k \ge 0} \mathrm{He}_k(s) \frac{t^k}{k!}.$$

Gaussian integration of the product of two generating functions gives $\exp(tu)$, hence $\langle \mathrm{He}_k, \mathrm{He}_l \rangle = k! \delta_{kl}$. Therefore

$$U_N \left(\prod_{n=1}^{N} x_n^{m_n} \right) = \prod_{n=1}^{N} n^{m_n/2} \mathrm{He}_{m_n}(s_n)$$

is an isometry onto the polynomial span, and extends to its Hilbert closure. Differentiating the generating function gives

$$U_N a_n U_N^{-1} = \sqrt{n}\, \partial_{s_n}, \qquad U_N a_{-n} U_N^{-1} = \sqrt{n}\, (s_n - \partial_{s_n})$$

on that polynomial domain. These are adjoints by Gaussian integration by parts. This comparison preserves the oscillator action, but transports polynomial multiplication to a different product: $U_N(x_1^2) = s_1^2 - 1$, while $U_N(x_1)^2 = s_1^2$. Define the transported product by $F \diamond G = U_N(U_N^{-1} F\, U_N^{-1} G)$. Then $s_1 \diamond s_1 = s_1^2 - 1$. The multiplication to be preserved must therefore be specified even between two real realizations of the same oscillator representation.

Formal currents and a vertex-algebra comparison

The oscillator representation also supplies local current operations. Use an independent formal coordinate z and put

$$J(z) = \sum_{m \in \mathbb{Z}} a_m z^{-m-1}, \qquad T(x_n) = n x_{n+1}, \qquad T(1) = 0,$$

extending T as a derivation of polynomial multiplication. Then $[T, a_m] = -m a_{m-1}$ and $[T, J(z)] = \partial_z J(z)$. On every polynomial state all sufficiently large positive modes vanish. The commutator relation gives

$$J(z)J(w) \sim \frac{1}{(z-w)^2}, \qquad (z-w)^2[J(z), J(w)] = 0,$$

where the singular term in the first formula is expanded for the first variable outside the second. The second formula compares the two formal expansions. Its central coefficient is 1.

For $n_i \geq 1$, define the field of a monomial state by

$$Y(x_{n_1} \cdots x_{n_r}, z) =: \prod_{i=1}^{r} \partial_z^{(n_i-1)} J(z) :, \qquad \partial_z^{(k)} z^m = \binom{m}{k} z^{m-k}.$$

Normal ordering places all creation operators to the left of annihilation operators. The vacuum field is the identity. For any fixed input state and any fixed coefficient of z, the expression is a finite sum. Every coefficient is an integral operator on $P_{\mathbb{Z}}$. The divided derivatives have integer binomial coefficients, including when m is negative.

Over $\mathbb{Q}$ these are the Heisenberg vertex-algebra fields. Frenkel, *Vertex Algebras and Algebraic Curves*, Bourbaki seminar 875, §2.3, equations (2)–(4) and Proposition 2.4, constructs these fields from the oscillator representation and translation operator. Its reconstruction theorem applies because the vacuum is cyclic, $T1 = 0$, the displayed translation identity holds, and J is local with itself. Each coefficient of the vacuum, translation and Jacobi identities is an integral identity on the torsion-free module $P_{\mathbb{Z}}$. Its validity over $\mathbb{Q}$ therefore proves it over $\mathbb{Z}$. Consequently coefficient change preserves all these vertex operations, not only the commutative polynomial product. Translation over an arbitrary ring uses its integral divided operators, determined by

$$T^{(k)} x_n = \binom{n+k-1}{k} x_{n+k}, \qquad T^{(k)}(fg) = \sum_{i+j=k} T^{(i)} f \, T^{(j)} g.$$

Here $T^{(0)} = \mathrm{id}$ and $T^{(k)}1 = 0$ for $k > 0$. Over $\mathbb{Q}$, these formulas give $T^{(k)} = T^k/k!$ and hence $T^{(i)}T^{(j)} = \binom{i+j}{i} T^{(i+j)}$. Torsion-freeness gives the same identity over $\mathbb{Z}$.

Corollary 55.6.4 *(the real current fibre).* The real fibre and its complexification are the ordinary level-one Heisenberg vertex algebra on the formal line. The coefficient comparison preserves every formal mode product and the divided translation operators.

Proof. The vacuum polynomial representation and its state fields are the explicit Heisenberg construction above. All formulas are defined before extension to $\mathbb{R}$ or $\mathbb{C}$. □

This construction supplies no map from an arithmetic Gersten complex or an Iwasawa differential. Nor does it identify the commutative finite-place product in (F5) with the singular current product: the latter is additional structure.

Three different complexes

The ordinary augmented polynomial algebra, its oscillator representation, and the Heisenberg Lie algebra give different bar constructions. Their coefficient comparisons can be made explicit.

For a commutative ring R, the reduced associative bar of P_R is

$$B_r(P_R) = \overline{P}_R^{\otimes_R r}, \qquad |B_r| = -r, \qquad b[f_1|\cdots|f_r] = \sum_{i=1}^{r-1} (-1)^{i-1} [f_1|\cdots|f_i f_{i+1}|\cdots|f_r].$$

Here $\overline{P}_R$ is the augmentation ideal, $B_0 = R$, and the coproduct cuts a word in all possible positions. Associativity gives $b^2 = 0$. Free monomial bases give exact chain identifications

$$B(P_{\mathbb{Z}}) \otimes R \cong B(P_R)$$

preserving differential, coproduct and counit. For example, $b[x_1|x_2] = [x_1x_2]$, and $[x_1|x_2] - [x_2|x_1]$ is a cycle. The Koszul complex on the polynomial variables computes its homology:

$$H^{-r}B(P_R) \cong \Lambda_R^r\left(\bigoplus_{n\geq 1} Rx_n\right).$$

To justify this over every R, tensor the two-term resolutions for a finite list of polynomial variables. Each variable is a non-zero-divisor modulo its predecessors, and the resulting free complex resolves R. Every calculation uses finitely many variables, so the union gives the stated result. Antisymmetrizing a wedge gives the corresponding bar cycle, with no factorial denominator. The positive modes do not preserve the augmentation ideal: $a_n x_n = n$. They therefore do not define the same entrywise action on this reduced bar.

To retain all oscillator operators, use instead the unnormalized two-sided bar resolution

$$\mathcal{B}_R^{-r} = P_R^{\otimes_R(r+2)}, \qquad \partial = \sum_{i=0}^{r}(-1)^i \mu_i \quad (r \geq 1), \qquad \epsilon : \mathcal{B}_R^0 \to P_R,$$

where μ_i multiplies factors i and $i+1$, and ϵ is multiplication. On a tensor let a_{-n} multiply its first factor by x_n, and let a_n be $n\partial_{x_n}$ summed over all factors. These operators commute with ∂. For annihilation this is the derivative product rule; creation commutes with the first multiplication and with every later face. Their commutator is n times the identity, because only differentiation of the first factor meets creation. The augmentation intertwines these actions. Unit insertion at the left contracts the augmented complex over R: the first face is the identity and all remaining faces cancel in pairs. Thus ϵ is a quasi-isomorphism of oscillator representations. The contracting homotopy need not intertwine creation operators. All these maps commute with coefficient change, using algebraic tensors. For two variables, the first boundary is explicitly

$$\partial(1 \otimes x_1 \otimes x_2) = x_1 \otimes x_2 - 1 \otimes x_1x_2.$$

This resolution supplies a nontrivial bar model carrying the full oscillator action. It is not the reduced bar coalgebra above.

For the Lie algebra $\mathfrak{h}_R$, the Chevalley–Eilenberg chains with trivial coefficients have $C_r = \Lambda_R^r\mathfrak{h}_R$, in degree $-r$. Choose the convention $d(u \wedge v) = [u, v]$. In particular,

$$d(a_n \wedge a_{-n}) = nK.$$

This differential uses the Lie bracket, whereas the associative bar uses multiplication. Antisymmetrization into the augmented bar of $U_R(\mathfrak{h}_R)$ is a chain map; on two inputs this follows from $uv - vu = [u, v]$. The level-one quotient $K = 1$ has no augmentation to R when R is nonzero: its relation $[a_1, a_{-1}] = 1$ would map to $0 = 1$. It therefore cannot replace this augmented enveloping algebra.

With Fock coefficients the full Lie complex has another decisive property. Write its chains as $\Lambda^r\mathfrak{h}_R \otimes_R P_R$, and take

$$\begin{aligned} d(u_1 \wedge \cdots \wedge u_r \otimes f) = &\sum_i (-1)^{i+1} u_1 \wedge \cdots \widehat{u}_i \cdots \wedge u_r \otimes u_i f \\ &+ \sum_{i<j} (-1)^{i+j+1}[u_i, u_j] \wedge u_1 \wedge \cdots \widehat{u}_i \cdots \widehat{u}_j \cdots \wedge u_r \otimes f. \end{aligned}$$

The module relation and Jacobi give $d^2 = 0$. Since K is central and acts as 1, the map $h(\omega \otimes f) = K \wedge \omega \otimes f$ satisfies $dh + hd = 1$. This Chevalley–Eilenberg complex is contractible. Already $d(K \otimes 1) = 1$. It cannot be identified with $B(P_R)$, whose degree-zero homology is R, or with the two-sided resolution, whose degree-zero homology is P_R.

Combining primes and preserving the central term

For a finite set of primes S, form $P_{S,R} = R[x_{p,n} : p \in S, n \geq 1]$. Different prime labels give independent oscillator families:

$$[a_{p,m}, a_{q,n}] = \delta_{pq}\, m \delta_{m+n,0} 1.$$

Adding a prime means tensoring with its vacuum polynomial representation. These inclusions define an algebraic restricted tensor product over all primes. Identifying every $a_{p,m}$ with the same a_m cannot preserve the relations: for $p \neq q$ the commutator on the left is zero, while $[a_1, a_{-1}] = 1$ in the proposed target.

There are nevertheless explicit level-one subrepresentations. Choose real numbers c_p with $\sum_{p \in S} c_p^2 = 1$, and set

$$X_n = \sum_{p \in S} c_p x_{p,n}, \qquad A_{\pm n} = \sum_{p \in S} c_p a_{p,\pm n}.$$

Then $[A_n, A_{-m}] = n\delta_{nm}$, and the polynomial map $x_n \mapsto X_n$ is injective and intertwines all oscillators. Indeed, $A_n X_m = n\delta_{nm}$, and the product rule gives the identity on every polynomial. Orthogonality of the prime families makes this map an isometry for the Hall form. In one mode,

$$\|X_n^m\|^2 = n^m m! \left(\sum_{p \in S} c_p^2 \right)^m = n^m m!,$$

by the multinomial formula; distinct modes are orthogonal. For two primes one can choose $c_p = 3/5, c_q = 4/5$; the construction then exists already over $\mathbb{Z}[1/5]$. The substitution $x_{p,n} \mapsto c_p x_n$ is a left inverse, since $\sum_p c_p^2 = 1$; this also proves injectivity over that coefficient ring. This left inverse is used only as a polynomial-algebra map for injectivity. The forward embedding $x_n \mapsto X_n$ preserves the formal current operations and the associative bar maps constructed above, since it preserves the vacuum, translation and modes. The orthogonal oscillator combinations remain in the larger representation.

For countably many primes, a square-summable sequence $c = (c_p)$ of norm one gives the same construction after real Hilbert completion. The one-particle space has orthonormal basis indexed by (p, n). On its symmetric Fock space, creation and annihilation with coefficient c are bounded between each pair of fixed particle-number sectors, with bounds $\sqrt{n(r+1)}\|c\|$ and $\sqrt{nr}\|c\|$. Thus finite prime sums converge on the domain of vectors with finitely many particle-number components. Their commutators converge there to the stated level-one relations. The induced single-species Fock space is a closed isometric subspace. This requires the choice of c. The Hilbert extension here concerns the oscillator representation and its isometric embedding. Formal vertex fields remain on the polynomial state space, or on a separately specified domain satisfying lower truncation. Finite particle number alone does not imply lower truncation: a one-particle Hilbert vector with nonzero components in arbitrarily large modes can have $a_n v \neq 0$ for arbitrarily large n. No vertex-algebra structure on the entire Hilbert completion is asserted. The unweighted sequence $c_p = 1$ is not square-summable and does not define a vacuum creation vector: its squared norm in mode n is $n \sum_p 1 = \infty$.

Let $e_{\mathbf{m}}$ be the normalized monomial basis with finite occupation numbers $m_{p,n}$. Define the logarithmic Hamiltonian by

$$E(\mathbf{m}) = \sum_{p,n} n \log p \, m_{p,n}, \qquad He_{\mathbf{m}} = E(\mathbf{m}) e_{\mathbf{m}},$$

$$\mathrm{Dom}(H) = \left\{ \sum_{\mathbf{m}} d_{\mathbf{m}} e_{\mathbf{m}} : \sum_{\mathbf{m}} E(\mathbf{m})^2 |d_{\mathbf{m}}|^2 < \infty \right\}.$$

It is the self-adjoint diagonal operator on this domain. It does not in general preserve the collective subspace. On its one-particle vectors,

$$HX_n|0\rangle = n \sum_p c_p \log p \, x_{p,n}|0\rangle.$$

This is defined when $\sum_p |c_p|^2 (\log p)^2 < \infty$. It equals $\lambda n X_n|0\rangle$ only when $(\log p - \lambda) c_p = 0$ for every p. A collective current involving two distinct primes therefore cannot intertwine the prime-energy operator with a single rescaled L_0. The coefficient comparison and the spectral comparison are different problems.

The arithmetic comparison still required

Theorem 55.6.5 *(integral oscillator comparison and its boundary).* The common integral polynomial representation has separate finite-place and real fibres preserving the oscillator operators, vacuum, central term, ordinary multiplication and the integral formal vertex operations. Its reduced associative bars commute with coefficient change. Its unnormalized two-sided bar resolution compares to the Fock module by an oscillator-equivariant quasi-isomorphism. A normalized finite collective current gives an isometric embedding into the representation with several prime labels. A square-summable choice extends that embedding to the real Hilbert completions on the specified domains.

Proof. The coefficient maps and operator identities follow from the integral polynomial formulas. The current fields have integral coefficients and satisfy the vertex identities before specialization. The bar comparison and its contraction are explicit above. The collective-current calculation preserves the central term by the equation $\sum c_p^2 = 1$. The operator bounds give convergence on each finite particle sector. □

Question 55.6.6 *(arithmetic and archimedean comparison).* Construct a common coefficient complex whose finite-place realizations are the specified arithmetic bar objects and whose real realization maps to a specified Heisenberg bar model. The comparison must identify the differential, central normalization and pairing. In particular, construct a square-zero arithmetic differential and maps comparing its Iwasawa and Gersten components with specified real operators. For a chiral or factorization comparison, specify the configuration spaces, restriction and collision maps, and their compatibility with these local current operations. To compare comodule and contramodule categories, specify the coefficient, completeness and duality hypotheses and construct the corresponding functors and pairing maps.

The integral oscillator and bar constructions above supply local coefficient data for this problem. They do not supply the common arithmetic complex or its Iwasawa–Gersten comparison. The residual-to-real tensor is zero, the Lie complex with Fock coefficients is contractible, and the logarithmic Hamiltonian need not preserve a collective current. These are separate constraints on the requested comparison.

55.7 C5: Functoriality under Λ-Coalgebra Morphisms

The Functoriality Statement

Definition 55.7.1 *(morphisms of abelian Λ-coalgebras with $\mu = 0$).* A morphism $f : C \to C'$ in $\mathrm{Coalg}^{\Lambda,\mu=0,\mathrm{ab}}$ is a Λ-linear morphism of dg coalgebras preserving the abelian Γ-action (trivial Γ-action on both sides) and the $\mu = 0$ structure (i.e., pseudo-isomorphism at level of Λ-modules).

Induced Pullback and Pushforward

Proposition 55.7.2 *(induced pullback on co-derived category).* Every morphism $f : C \to C'$ in $\mathrm{Coalg}^{\Lambda,\mu=0,\mathrm{ab}}$ induces a triangulated functor

$$f^* : \mathrm{D}^{\mathrm{co}}_{\Lambda}(C') \to \mathrm{D}^{\mathrm{co}}_{\Lambda}(C)$$

given by restriction of scalars: for $M \in C'\text{−comod}_\Lambda$, the C-comodule f^*M has underlying Λ-module M and C-coaction $M \xrightarrow{\Delta_{C'}} M \otimes_\Lambda C' \xrightarrow{\mathrm{id}\otimes f^{\mathrm{op}}} M \otimes_\Lambda C$ via the Λ-linear structure of f (Positselski 2011 arXiv:0905.2621 §6.3; for the Λ-coefficient extension, Lurie *Higher Algebra* 4.3.3).

Proof. For f a split injection, the splitting $g : C' \to C$ (as Λ-module, not as coalgebra) induces the restriction directly. For general f, the restriction is the derived left Kan extension along f: $f^* = \mathrm{LKan}_f$ on the abelian category of Λ-comodules.

Triangulated structure: f^* preserves co-fibrations and injective resolutions because the C-injective hull of a C-comodule is a Λ-module injective hull (by the abelian hypothesis), which is the same as the C'-module injective hull of the underlying C'-comodule (modulo the different coalgebra action, which does not affect the Λ-injective hull).

Compatibility with $\mu = 0$: for $M \in \mathrm{D}^{\mathrm{co}}_{\Lambda}(C')$ with $\mu(M) = 0$, f^*M has the same underlying Λ-module, hence $\mu(f^*M) = 0$. The Verdier quotient by acyclic injectives is preserved by f^* because Λ-injective resolution is preserved. □

Proposition 55.7.3 *(induced pushforward on contra-derived category).* The dual morphism $f^\vee : (C')^\vee \to C^\vee$ is a Λ-algebra morphism, and induces a triangulated functor

$$(f^\vee)_* : \mathrm{D}^{\mathrm{ctr}}_{\Lambda}((C')^\vee) \to \mathrm{D}^{\mathrm{ctr}}_{\Lambda}(C^\vee)$$

given by pushforward of contramodules along the Λ-algebra morphism $f^\vee$: for $N \in (C')^\vee\text{−contramod}_\Lambda$, the $C^\vee$-contramodule $(f^\vee)_*N$ has underlying Λ-module N and $C^\vee$-contramodule structure via $f^\vee$.

Proof. The dualization functor $(-)^\vee$ is contravariant on Λ-coalgebras (sends morphisms in one direction to morphisms in the other direction). Since $f : C \to C'$, $f^\vee : (C')^\vee \to C^\vee$ goes in the opposite direction. It is a Λ-algebra morphism because dualization sends coalgebra morphisms to algebra morphisms (Positselski 2011 §2). The pushforward $(f^\vee)_*N$ is the natural restriction of N from a $(C')^\vee$-contramodule to a $C^\vee$-contramodule via $f^\vee$ (standard: restrict the contra-action along a Λ-algebra morphism).

Triangulated structure and preservation of contra-derived classes follow by the dual argument to Chapter 55.7.2. □

Naturality of the Positselski Equivalence

Theorem 55.7.4 *(C5 closed: functoriality of arithmetic Positselski). (restricted to Λ-linear morphisms of abelian dg Λ-coalgebras with $\mu = 0$ and trivial Γ-action; see Chapter 55.7.1).* For every morphism $f : C \to C'$ in $\mathrm{Coalg}_\Lambda^{\Lambda,\mu=0,\mathrm{ab}}$, the diagram

$$\begin{array}{ccc} \mathrm{D}^{\mathrm{co}}_\Lambda(C) & \xrightarrow{\Psi_C} & \mathrm{D}^{\mathrm{ctr}}_\Lambda(C^\vee) \\ {\scriptstyle f^*}\uparrow & & \uparrow{\scriptstyle (f^\vee)_*} \\ \mathrm{D}^{\mathrm{co}}_\Lambda(C') & \xrightarrow{\Psi_{C'}} & \mathrm{D}^{\mathrm{ctr}}_\Lambda((C')^\vee) \end{array} \tag{55.3}$$

commutes up to natural isomorphism. Equivalently, the arithmetic Positselski equivalence Ψ is a natural transformation of 2-functors $\mathrm{Coalg}_\Lambda^{\Lambda,\mu=0,\mathrm{ab},\mathrm{op}} \to \mathrm{PrSt}^{\mathrm{tri}}$.

Proof. Unwind the definitions. For $M \in \mathrm{D}^{\mathrm{co}}_\Lambda(C')$,

$$\begin{aligned} \Psi_C(f^*M) &= \mathrm{Hom}_C(C, f^*M) \\ &\simeq \mathrm{Hom}_{C'}(C' \otimes_C C, M) && \text{(adjunction)} \\ &\simeq \mathrm{Hom}_{C'}(C', M) && \text{(since } C' \otimes_C C \simeq C' \text{ via } f) \\ &= \Psi_{C'}(M). \end{aligned}$$

On the other hand, the pushforward $(f^\vee)_* : \mathrm{D}^{\mathrm{ctr}}_\Lambda((C')^\vee) \to \mathrm{D}^{\mathrm{ctr}}_\Lambda(C^\vee)$ restricts the contra-action along $f^\vee$, so

$$\begin{aligned} (f^\vee)_* \Psi_{C'}(M) &= (f^\vee)_* \mathrm{Hom}_{C'}(C', M) \\ &\simeq \mathrm{Hom}_C(C, f^*M), \end{aligned}$$

where the identification uses the $f^\vee$-restriction of the $C^\vee$-contramodule structure on $\mathrm{Hom}_{C'}(C', M)$, which converts the $(C')^\vee$-action to a $C^\vee$-action via $f^\vee$ and yields the comodule f^*M.

The naturality in f follows because all steps are functorial: adjunction, the isomorphism $C' \otimes_C C \simeq C'$, and the $(f^\vee)_*$ pushforward are all natural in morphisms of coalgebras.

The statement "Ψ is a natural transformation of 2-functors" is the abstract reformulation: viewing $\mathrm{Coalg}_\Lambda^{\Lambda,\mu=0,\mathrm{ab}} \to \mathrm{PrSt}^{\mathrm{tri}}$ as 2-functors (one via $\mathrm{D}^{\mathrm{co}}_\Lambda$ co-derived, the other via $\mathrm{D}^{\mathrm{ctr}}_\Lambda$ contra-derived composed with $(-)^\vee$), Ψ is the natural transformation between them, with naturality squares (55.3). □

Corollary 55.7.5 *(functorial pullback of Positselski pairing).* For every morphism $f : C \to C'$ in $\mathrm{Coalg}_\Lambda^{\Lambda,\mu=0,\mathrm{ab}}$, the Positselski pairing $\langle \cdot, \cdot \rangle_{C'} : C' \otimes (C')^\vee \to \Lambda$ pulls back along f to the Positselski pairing $\langle \cdot, \cdot \rangle_C : C \otimes C^\vee \to \Lambda$:

$$\langle f(x), y \rangle_{C'} \;=\; \langle x, f^\vee(y) \rangle_C$$

for all $x \in C$, $y \in (C')^\vee$.

Proof. The Positselski pairing is the natural pairing of a coalgebra with its dual. Functoriality in f is the standard duality compatibility: $\langle f(x), y \rangle_{C'} = y(f(x)) = f^\vee(y)(x) = \langle x, f^\vee(y) \rangle_C$ by definition of dual map $f^\vee$. □

55.8 Consequence for the Arithmetic Mellin Comparison

Theorem 55.8.1 *(conditional arithmetic complementarity).* . Suppose the proposed arithmetic objects satisfy the C1–C5 comparison conditions and the coefficient and duality conditions of Remark 46.1.6. Suppose in addition that they supply the data V, J, v, w, E of Theorem 43.5.1, with

$$v - Jv = \big(\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}}\big)w, \qquad E(w) \neq 0,$$

and with $E(v) = \Lambda_\xi$ and $E(Jv)(s) = \Lambda_\xi(1-s)$. Then

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s).$$

Proof. Apply E to the central-defect identity. Its right-hand side vanishes exactly when the sum of levels is zero, since $E(w) \neq 0$. Its left-hand side is $\Lambda_\xi(s) - \Lambda_\xi(1-s)$. Multiplication by $s(s-1)/2$ gives the equivalent identity for ξ. □

The extra evaluation hypothesis is not a consequence of naturality of a pairing. For a coalgebra map $f : C \to C'$, naturality gives $\langle f(x), y\rangle = \langle x, f^\vee(y)\rangle$. It does not identify either side with a central level or a completed zeta function. The opposite oscillator weights in Section 46.5 likewise yield a local cancellation without constructing the arithmetic invariant maps.

The constructions in this chapter have distinct outputs. Theorem 55.4.2 gives an ordinary completed arithmetic comparison. The chiral differential in 55.4.3 requires further operations.

Question 55.5.3 asks for the arithmetic and BV state comparison beyond the Toeplitz product state. Theorem 55.6.5 gives local integral oscillator and bar models, while Question 55.6.6 asks for common arithmetic complexes and pairing maps. These outputs retain their own coefficient rings. No field-to-$\mathbb{Z}_p[[\Gamma]]$ base change is implicit.

Corollary 55.8.2 *(arithmetic level criterion).* Under all the hypotheses of Theorem 55.8.1, the scalar functional equation implies arithmetic level cancellation.

Proof. Use the reverse implication of that theorem. It is the detection condition $E(w) \neq 0$ that makes the implication valid. □

Remark 55.8.3 *(this corollary does not prove RH).* Chapter 55.8.1 and Chapter 55.8.2 identify the implication $\kappa + \kappa^! = 0 \Rightarrow \xi(s) = \xi(1-s)$ for the arithmetic Heisenberg under the stated hypotheses. They do not prove the Riemann hypothesis; the functional equation is a classical theorem of Riemann 1859, and RH is the separate assertion that the non-trivial zeros of ξ lie on the critical line. The conditional Mellin comparison relates level cancellation to the functional equation. A categorical equivalence alone does not.

The separate HP–Li implication of Chapter 44.3.10 uses the operator, determinant and trace identities of H-P^{Ar} (Chapter 44.3.2). It also assumes positivity of the regularized Li trace and the stated P2, P3, and positive-cone hypotheses. A self-adjoint Hilbert–Pólya realization with the specified determinant divisor already places the zeros on the critical line. The Li-trace implication gives a sufficient scalar criterion.

Its Li transforms of Θ_ξ are distinct from the Virasoro energy polynomials $p_n(L_0^{\mathrm{Vir}})$, where $p_n(x) = x^n - (x-1)^n$. Those polynomials fail positivity on the vacuum: $p_2(L_0^{\mathrm{Vir}})\Omega = -\Omega$. Chapter 51.2.10 constructs their maximal reducing positive spectral sector, which need not preserve the Virasoro action. A comparison from an arithmetic sector to the HP–Li trace remains Chapter 51.2.11; the Positselski reduction supplies neither that comparison nor the HP–Li hypotheses.

55.9 Residual Conditions

The Costello-refined Positselski reduction of C1–C5 addresses the abelian Heisenberg domain. Three residual items remain outside this domain:

(i) *Non-abelian Iwahori level.* The non-commutative Iwasawa $\Lambda_{GL_2} = \mathbb{Z}_p[[GL_2(\mathbb{Z}_p)]]$ Positselski is not addressed by this chapter; it requires the non-commutative Iwasawa framework of Fukaya–Kato 2006 and Coates–Fukaya–Kato–Sujatha–Venjakob 2005 Publ. IHES (the main conjecture for non-commutative Iwasawa theory). Residual form: conjectural (recorded as Chapter 46.7).

(ii) *Wildly-ramified primes $p = 2, 3$.* The Steinberg relation $\{p, 1 - p\} = 0$ holds for every prime, but does not construct a tame-weighted chiral operation. The ordinary residue complex in Section 55.4 includes all finite places, including those above 2 and 3, with an independently fixed odd coefficient prime ℓ. It does not construct the intended non-semisimple Iwahori category or its factorization maps. Any Ext^1-contributions in that category must be retained in a separate comparison; the ordinary bar calculation supplies no such comparison. Residual form: conjectural.

(iii) *Super Bethe-Hecke chain-level chiral coproduct.* The $\mu = 0$ hypothesis and the abelian domain exclude the super Bethe-Hecke sector where chain-level chiral coproduct computations are required; this sector is outside the abelian Heisenberg domain. Residual form: conjectural.

55.10 Refinement Boundary

(i) Five Costello-refined subconditions C1–C5 are recorded under their named hypotheses.
C1 (local-global factorization-coalgebra coherence): Theorem 55.3.3 constructs the filtered assembly from specified local coalgebras and compatible transition maps. Their arithmetic geometric realization and the adelic differential comparison remain the inputs of Question 55.3.4.
C2 (arithmetic differential and comparison): the exact residue squares and signed totalization give the ordinary completed model of Chapter 55.4.2. The tame-weighted local chiral operation and its comparison with that model remain Chapter 55.4.3.
C3 (renormalization / Euler-product convergence): recorded by Question 55.5.3: the compatible Toeplitz product state is constructed, while its arithmetic/BV comparison remains to be constructed.
C4 (integral and archimedean comparison): Chapter 55.6.5 constructs the common integral oscillator model, separate coefficient fibres, formal currents and bar comparisons. The arithmetic Iwasawa–Gersten and pairing maps remain the problem of Question 55.6.6.
C5 (functoriality): recorded by Chapter 55.7.4 via naturality of bar–cobar adjunction in Λ-linear coalgebra morphisms with parallel functor directions in the naturality square (pullback on comodules and pushforward on the dual side).

(ii) The P1 level criterion is conditional on the actual arithmetic objects, central-defect identity, Mellin evaluation, and detection condition of Theorem 55.8.1. C1–C5 and the coefficient comparison retain their own hypotheses. No categorical equivalence alone supplies that numerical criterion.

(iii) Three residual items remain outside the Costello-refined reduction: non-abelian Iwahori level, wildly-ramified primes $p = 2, 3$, super Bethe-Hecke chain-level chiral coproduct. Each is stated explicitly with its residual form in Chapter 55.9.

(iv) The relevant mathematical theories for Chapter 55.1 are: Costello–Gwilliam Vol. II for C1 and C3; Matsumoto's theorem and the localization and transfer identities in Weibel's *K-book* for the ordinary arithmetic model in C2; Macdonald's integral symmetric-function lattices and Frenkel's

Heisenberg vertex construction for the local models in C4; Positselski 2011 §6 plus Λ-linearity for C5. Secondary: Gelfand–Manin 1996 (general $d^2 = 0$ mechanism); Hinich 1997 (dg-operads); Costello 2011 (BV renormalization).

(v) The proposed arithmetic domain retains the C1–C5 and co–contra hypotheses. The implication $\kappa + \kappa^! = 0 \Rightarrow \xi(s) = \xi(1 - s)$ additionally requires the defect identity and evaluation of Theorem 43.5.1.
The HP–Li route requires the operator, determinant and trace data of H-P^{Ar}. Its regularized Li trace also requires the stated P2, P3 and positive-cone hypotheses. A route from Virasoro energy polynomials must specify a positive sector and construct its comparison with that trace. The vacuum obstruction in Chapter 51.2.10 excludes positivity on the entire Fock space. These arithmetic comparisons are additional to the co–contra criterion.

The arithmetic biconditional requires the central-defect identity and detecting Mellin evaluation of Theorem 43.5.1. The C1–C5 conditions and the co–contra requirements in Remark 46.1.6 specify additional structure on its intended arithmetic domain.

Chapter 56

Bernstein-Centre Descent and Local Pairing Normalization

The local-to-global problem requires coherent objects, compatible actions and effective descent. A separate local calculation compares weighted occupation vectors, diagonal Hilbert–Schmidt operators and radial functions. The spherical Whittaker norm is computed with its measure factor, and its unit normalization gives an explicit line isometry. These constructions isolate the actual maps still needed for arithmetic Koszul–Petersson compatibility.

56.1 Bernstein Gluing and Local Pairing Conditions

The BC-diamond-glue condition concerns local coherent Springer objects on the intended spectral carriers, their equivariant descent to a Selmer target, and identification of the descended central action with the global automorphic Bernstein centre. Coherent Springer theory on a Langlands-parameter stack does not itself construct the comparison to an Emerton–Gee stack.

For pairing compatibility, fix both carriers and the type of each form. Hermitian forms are linear in the first variable and conjugate-linear in the second; inserting an antilinear map into the second slot of a bilinear form produces this type. On the prime cyclic Gibbs carrier, $J\mu_{p^k}\Omega = p^{k/2}\mu^*_{p^k}\Omega$. Its arithmetic transport requires the action-compatible placement maps of Hypothesis 67.1.1.

56.2 Local Constructions and Comparison Data

Local Springer transport. The exact functor, support and action comparisons of Theorem 56.4.1 transport a constructed object to the intended local spectral carrier. The coefficient comparisons, including the $\ell = p$ case, must be constructed on their common carrier.

Effective equivariant descent. Theorem 56.5.4 applies to actual local objects, overlap maps and higher coherences in a specified effective descent model. Local flatness does not supply cross-prime transition maps or coherence of an arbitrary colimit.

Global centre comparison. Theorem 56.5.6 assembles supplied compatible actions over all finite sets of places. It also requires the separate identification with the actual global centre. An arithmetic AG equivalence alone does not identify its two actions.

Spherical norm. Lemma 56.7.4 gives $C_p = m_p(1 + p^{-1})L_p(1, \mathrm{Ad}\,\pi_p)$ for the specified unramified tempered representation. The unit-circle parameters make every local denominator at one nonzero. The norm is not the compact subgroup volume.

Local Hilbert maps. Theorem 56.7.5 constructs the occupation/diagonal/radial isometries and the normalized spherical line. Extending them to arithmetic pairing carriers with their Hecke actions is Conjecture 56.7.6.

Adelic normalization. Theorem 56.7.8 retains the continued value $c_\pi \neq 0$, actual placements and completed pairing maps. Common scalar rescaling preserves the supplied identity; it does not assert ordinary Euler-product convergence at one.

56.3 BC-Diamond-Glue: Decomposition

Definition 56.3.1 *(the three sub-operations of (BC-diamond-glue)).* (BC-diamond-glue) decomposes into three sub-operations:

(BCglue.local) *Local Ben-Zvi–Chen–Helm–Nadler construction.* At each finite prime p, construct a coherent Springer sheaf $\mathcal{F}_p \in \mathrm{Coh}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$ whose action on the local $\mathrm{IndCoh}_{\mathrm{Nilp}}$-category realises the local Bernstein centre $\mathcal{Z}_p$.

(BCglue.glue) *Cross-prime coefficient descent.* Construct a common coefficient carrier and actual transition correspondences for the local sheaves, with the support, filtration, and higher-coherence data of Hypothesis 56.5.2. Supply the effective coherent-descent model on the Selmer target required by Theorem 56.5.4. The global sheaf is obtained from that descent equivalence; a formal product across distinct primes or a filtered colimit of coherent sheaves does not supply it.

(BCglue.core) *Global Bernstein-centre compatibility.* The action of $\mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}$ on $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}})$ agrees, under the conjectural arithmetic AG equivalence of Theorem 38.4.2, with the global Bernstein-centre action on $\mathrm{D}^{\text{sph-fin}}([GL_2])$.

THEOREM 56.3.2 *(decomposition of (BC-diamond-glue)).* (BC-diamond-glue) is equivalent to the conjunction

$$\text{(BCglue.local)} \ \wedge \ \text{(BCglue.glue)} \ \wedge \ \text{(BCglue.core)}.$$

The core condition concerns the action on the object obtained from the first two constructions; no logical independence is asserted.

Proof. *Forward.* Suppose (BC-diamond-glue), i.e. Conjecture 48.5.4, holds. Then the local coherent Springer sheaves $\{\mathcal{F}_v\}_v$ exist (supplying (BCglue.local)), glue to $\mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}$ along the diagonal (supplying (BCglue.glue)), and the glued sheaf's action agrees with the global Bernstein centre (supplying (BCglue.core)).

Reverse. Suppose (BCglue.local), (BCglue.glue), (BCglue.core) all hold. Then (BCglue.local) gives the local sheaves; (BCglue.glue) assembles them into a global coherent sheaf; (BCglue.core) gives the Bernstein-centre compatibility. Together, these are exactly the content of Conjecture 48.5.4.

The equivalence separates the required data without constructing them. □

56.4 BC-Diamond-Glue: Local Construction (Ben-Zvi–Chen–Helm–Nadler)

THEOREM 56.4.1 *(Transport of a local coherent Springer object).* Fix a common coefficient category and a coherent Springer object S_p on a specified parameter carrier $\mathcal{Y}_p$. Supply an exact functor

$$T_p : \mathrm{Coh}(\mathcal{Y}_p) \longrightarrow \mathrm{Coh}(\mathcal{X}^{\mathrm{EG}}_p)$$

preserving the required singular support, together with compatible natural equivalences identifying its transported central action with the action on the stated local representation category. Then $\mathcal{F}_p = T_p(S_p)$ is a coherent object with that central action.

Proof. Preservation of coherence and support gives the object on the stated carrier. Apply T_p to the action morphisms. Functoriality preserves their unit and composition identities, and the supplied natural equivalences identify the resulting action with the required one. □

Remark 56.4.2 *(Local coefficient and spectral comparisons).* Ben-Zvi–Chen–Helm–Nadler construct the coherent Springer input on its Langlands-parameter carrier. Construct the functor T_p and the compatible representation-theoretic action comparison above. If several coefficient realizations are used, construct a common comparison carrier, the functors to it, and compatible isomorphisms between the resulting objects. In particular, the $\ell = p$ and cross-coefficient comparisons must be supplied; agreement of parameters or traces alone does not produce these isomorphisms.

56.5 BC-Diamond-Glue: Bernstein Centre Gluing

Prismatic Transition Maps

Definition 56.5.1 *(Nygaard-convention-aware transition map).* For distinct primes p, q and pairs $(R_p, \varphi_p, \Gamma_p)$, $(R_q, \varphi_q, \Gamma_q)$ of Emerton–Gee data (here R_p is the period ring, φ_p the Frobenius, $\Gamma_p = \mathrm{Gal}(\mathbb{Q}_p(\mu_{p^\infty})/\mathbb{Q}_p)$ the cyclotomic Galois group, as in Emerton–Gee arXiv:1908.07185 §2), the *Nygaard-convention-aware transition map* is a proposed comparison morphism

$$\mathcal{X}_{GL_2}^{\mathrm{EG},p} \times \mathcal{X}_{GL_2}^{\mathrm{EG},q} \;\to\; \mathcal{X}_{GL_2}^{\mathrm{EG},\{p,q\}}$$

where the target denotes a sought common moduli carrier for the rank-2 local data at p and q. Its construction and coefficient comparison are part of Hypothesis 56.5.2; a product of formal bases at distinct primes does not define it. The Nygaard filtration convention of Bhatt–Lurie arXiv:2201.06120 §8 is used to specify the expected comparison data. For $p \neq q$ this is a residual comparison correspondence, not a canonical fibre-product identity of formal bases.

Hypothesis 56.5.2 *(Cross-prime transition and descent data).* For the proposed comparison of Definition 56.5.1, supply a common coefficient category and actual transition correspondences. Assume their pullback functors preserve coherent objects and the specified nilpotent singular support, commute with the required colimits, and carry compatible Nygaard filtrations. Assume the comparison isomorphisms on double overlaps satisfy the triple cocycle and all higher coherences. These are cross-prime data, not consequences of separate theories over $\mathbb{Z}_p$ and $\mathbb{Z}_q$.

Remark 56.5.3 *(Flat base change and the missing arithmetic maps).* For a flat homomorphism of Noetherian rings $A \to B$, tensoring with B is exact and preserves finite presentation: a finite presentation $A^r \to A^s \to M \to 0$ becomes $B^r \to B^s \to B \otimes_A M \to 0$. Thus it sends coherent modules to coherent modules. This elementary calculation explains one required property once a common base and a flat map are given. It constructs neither a cross-prime map nor a singular-support comparison. A filtered colimit of coherent objects also need not be coherent: the increasing finite-dimensional subspaces of $\bigoplus_{n\geq 1} k$ are a counterexample over a field.

Effective Descent of the Local Sheaves

Theorem 56.5.4 *(Conditional coefficient descent).* Assume Hypothesis 56.5.2. Let $X = \mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$. Supply an effective descent diagram $U_\bullet \to X$ and an explicit equivalence

$$\mathrm{Coh}(X) \xrightarrow{\sim} \mathrm{Tot}\big(\mathrm{Coh}(U_\bullet)\big)$$

on the prescribed singular-support and coefficient subcategories. If the local coherent Springer sheaves and comparison isomorphisms form an object of the displayed totalization, they determine a coherent sheaf $\mathcal{F}_{\mathrm{glob}}^{\mathrm{prism}}$ on X, unique up to the equivalence of descent objects. Any archimedean factor requires its own compatible complex/Hodge comparison data.

Proof. The sheaves, overlap isomorphisms, and higher coherences define the stated descent object. Apply the inverse of the supplied descent equivalence. The resulting sheaf pulls back to each prescribed local object, and full faithfulness gives uniqueness and compatibility of its morphisms. Coherence follows from the target of that equivalence, not from an arbitrary filtered colimit in an ind-category. □

Question 56.5.5 *(Arithmetic cross-prime descent).* Construct the common coefficient carrier, transition correspondences, and effective descent equivalence in the preceding theorem for the specified Selmer problem, preserving its full Weil/(φ, Γ) data and Nygaard filtrations. Local prismatic constructions alone do not supply the first cross-prime morphisms. This is the remaining content of (BCglue.glue).

Reduction to core compatibility

THEOREM 56.5.6 *(Compatible finite-stage central actions).* Let $F : C \simeq \mathcal{D}$ be an equivalence of stable categories. Let (A_S) be a compatible diagram of commutative algebras indexed by all finite sets of places, with $A = \varinjlim_S A_S$. Suppose compatible actions

$$a_S : A_S \to Z^{\circ}(C), \qquad b_S : A_S \to Z^{\circ}(\mathcal{D})$$

are given, where $Z^{\circ}(C) = \mathrm{End}(\mathrm{Id}_{hC})$ is the ordinary centre of the homotopy category, consisting of ordinary natural transformations; similarly for $\mathcal{D}$. If $F(a_S(z)_M) = b_S(z)_{F(M)}$ for every S, z, M, then F intertwines the induced A-actions.

Proof. The compatible algebra maps factor uniquely through A. Every element of A comes from a finite stage, where the intertwining identity holds. Thus it holds for the induced actions. □

Remark 56.5.7 *(Coherent actions and the arithmetic centre).* For higher actions, the corresponding input is a compatible system of maps in the chosen category of derived algebras, with a coherent homotopy between the two systems. The colimit identity

$$\mathrm{Map}(\operatorname*{colim}_S A_S, Z) \simeq \lim_S \mathrm{Map}(A_S, Z)$$

assembles that supplied homotopy. Equalities in degree zero do not supply it. The index consists of all finite sets; the poset of pairs alone is not filtered.

For BCglue.core, one must further identify A with the actual global automorphic Bernstein centre, and b_S with the actions of the equivariantly descended coherent object. An equivalence of underlying categories does not do this. For example, on $C = \mathcal{D} = D(k)$, the identity equivalence fails to intertwine the two $k[t]$-actions $t \mapsto 0$ and $t \mapsto 1$: at the object k the required equation would be $0 = \mathrm{id}_k$.

The resulting implication uses the complete data:

$$\begin{array}{c}\text{local comparison and effective equivariant descent,}\\ \text{arithmetic AG and compatible global centre comparisons}\end{array} \quad\Longrightarrow\quad \text{BC-diamond-glue.}$$

The original cross-prime and global-centre constructions remain required, with their coherent equivariant descent data.

56.6 Consequence: L_{ACD} Final Residual Isolation

Corollary 56.6.1 *(Descent data for the categorical comparison).* Under the prior F1.a and F2.c comparison data, the BC-diamond-glue input to L_{ACD} requires all three constructions: local coherent transport, effective equivariant descent, and the compatible identification with the global automorphic centre. If these data are supplied, they give BC-diamond-glue.

Proof. The local theorem constructs the transported objects from its specified functors. The effective descent theorem assembles their coherent overlap data. The centre comparison identifies the resulting action, with finite-stage compatibility assembled by Theorem 56.5.6. These are the three parts of Definition 56.3.1. □

Remark 56.6.2 *(What remains after local transport).* A transported local object does not specify cross-prime overlap maps, and an effectively descended object does not identify its action with the global Bernstein centre. The original categorical construction requires both comparisons with their higher coherences.

56.7 K5: Spherical Whittaker Normalization

The Local Adjoint L-Factor

Definition 56.7.1 *(local adjoint L-factor $L_p(s, \mathrm{Ad})$).* For an unramified principal-series representation $\pi_p = \mathrm{Ind}_B^{GL_2}(\chi_1 \otimes \chi_2)$ at $GL_2(\mathbb{Q}_p)$ with Satake parameters $(\alpha_p, \beta_p) = (\chi_1(p), \chi_2(p))$ on the unit circle, the local adjoint L-factor is

$$L_p(s, \mathrm{Ad}(\pi_p)) \;:=\; \left(1 - \alpha_p \beta_p^{-1} p^{-s}\right)^{-1} \cdot (1 - p^{-s})^{-1} \cdot \left(1 - \alpha_p^{-1} \beta_p \, p^{-s}\right)^{-1}.$$

Reference: Jacquet 1979 Corvallis "Principal L-functions" §2, or Bump 1997 *Automorphic Forms and Representations* §3.2.

Lemma 56.7.2 *(Finite adjoint factor for an unramified tempered representation).* Fix an unramified tempered representation π_p of $GL_2(\mathbb{Q}_p)$, with unitary-normalized Satake parameters α_p, β_p satisfying $|\alpha_p| = |\beta_p| = 1$. Then the factor $L_p(1, \mathrm{Ad}\, \pi_p)$ of Definition 56.7.1 is finite and nonzero. This is a statement about the specified representation; its placement in an arithmetic Hochschild realization is separate comparison data.

Proof. The three denominator terms are

$$1 - \alpha_p \beta_p^{-1} p^{-1}, \qquad 1 - p^{-1}, \qquad 1 - \alpha_p^{-1} \beta_p p^{-1}.$$

Each is nonzero because the subtracted term has absolute value $p^{-1} < 1$. Their inverse product is therefore finite and nonzero. No inequality between α_p and β_p is needed. □

The Absorption Convention

Definition 56.7.3 *(Koszul-dual normalisation convention).* The *Koszul-dual normalisation convention* is the rescaling of the local Koszul pairing at a finite prime p, assuming $L_p(1, \mathrm{Ad})$ is finite and nonzero, by the local adjoint L-factor:

$$\langle \cdot, \cdot \rangle_p^{\mathrm{Koszul,Ad}} \;:=\; L_p(1, \mathrm{Ad})^{-1} \cdot \langle \cdot, \cdot \rangle_p^{\mathrm{Koszul}}.$$

The global normalized pairing is defined using the specified continued nonzero value $c_\pi = L(1, \mathrm{Ad}\,\pi)$, as $c_\pi^{-1}\langle\cdot,\cdot\rangle^{\mathrm{Koszul}}$, with the actual adelic extension and comparison maps of Hypothesis 67.1.1. It is not defined by an unproved ordinary product at $s = 1$.

LEMMA 56.7.4 *(Spherical Whittaker norm with specified measure).* Let π_p be normalized unramified tempered principal series, with $|\alpha| = |\beta| = 1$, and take an additive character of conductor $\mathbb{Z}_p$. Let $W(1) = 1$ be its spherical Whittaker function. Set $m_p = \mathrm{vol}_{d^\times a}(\mathbb{Z}_p^\times) > 0$. Its standard spherical formula is

$$W(\mathrm{diag}(p^j, 1)) = p^{-j/2} h_j(\alpha, \beta) \quad (j \geq 0), \qquad h_j = \sum_{r=0}^{j} \alpha^{j-r}\beta^r,$$

and it vanishes at negative valuations. For $\mathrm{Re}\, s > 0$,

$$Z_p(s) := \int_{\mathbb{Q}_p^\times} |W(a)|^2 |a|^{s-1}\, d^\times a = m_p \frac{L_p(s, \pi_p \times \widetilde{\pi}_p)}{\zeta_p(2s)}.$$

In particular

$$C_p := Z_p(1) = m_p(1 + p^{-1}) L_p(1, \mathrm{Ad}\,\pi_p) > 0.$$

For $d^\times a = da/|a|$ with additive unit volume, $m_p = 1 - p^{-1}$, so $C_p = (1 - p^{-2}) L_p(1, \mathrm{Ad}\,\pi_p)$.

Proof. Shell integration gives $Z_p(s) = m_p \sum_{j\geq 0} |h_j|^2 p^{-js}$, which converges absolutely since $|h_j| \leq j + 1$. With $r = \alpha/\beta$, summing geometric series gives

$$\sum_{j\geq 0} |h_j|^2 x^j = \frac{1 + x}{(1 - x)(1 - rx)(1 - r^{-1}x)}.$$

For $r \neq 1$, this follows by writing $|h_j|^2 = (2 - r^{j+1} - r^{-j-1})/|1 - r|^2$ and summing each term. The case $r = 1$ follows by continuity, or from $\sum (j + 1)^2 x^j = (1 + x)/(1 - x)^3$. The rank-four Rankin–Selberg factor has denominator $(1 - x)^2(1 - rx)(1 - r^{-1}x)$. Multiplication by $1 - x^2$ proves the displayed integral. Since $L_p(s, \pi_p \times \widetilde{\pi}_p) = \zeta_p(s) L_p(s, \mathrm{Ad}\,\pi_p)$, evaluation at one gives C_p. This is a positive norm; finiteness also follows directly from the convergent shell series. The measure normalization is the Kirillov normalization used by Blomer–Jana–Nelson, *Local Integral Transforms and Global Spectral Decomposition*, §2, (2.7), and §3.1. □

THEOREM 56.7.5 *(Occupation, diagonal Hilbert–Schmidt and radial function models).* Let $H_{\mathrm{occ}} = \ell^2(\mathbb{N}_0, p^{-j})$, with coordinate vectors δ_j, and let $E_j = p^j \mathbb{Z}_p^\times$. There are explicit isometries

$$T\delta_j = p^{-j/2} m_p^{-1/2} \mathbf{1}_{E_j}, \qquad D\delta_j = p^{-j/2} E_{jj}$$

onto, respectively, the closed radial subspace supported on nonnegative valuations in $L^2(\mathbb{Q}_p^\times, d^\times a)$ and the diagonal subspace of $\mathrm{HS}(\ell^2\mathbb{N}_0)$. They intertwine coordinate conjugation with function conjugation and $JX = X^*$. Thus, for all $v, w \in H_{\mathrm{occ}}$,

$$H_{\mathrm{occ}}(v, w) = H_{\mathrm{Whit}}(Tv, Tw) = \mathrm{Tr}(Dv(Dw)^*).$$

The spherical function is $W = T(\sqrt{m_p} \sum_{j\geq 0} h_j \delta_j)$. The map $a\Omega \mapsto aW/\sqrt{C_p}$ is an isometry from the unit prime Gibbs-vacuum line to the spherical Whittaker line.

Proof. The shells are disjoint, each of measure m_p, so the Gram matrix of $T\delta_j$ is $\delta_{jk}p^{-j}$. The matrix units are Hilbert–Schmidt orthonormal, giving the same Gram matrix for $D\delta_j$. Their finite spans are dense in the stated ranges, proving the extensions and surjectivity onto those ranges. Both displayed bases are fixed by their conjugations. The spherical expansion follows shell by shell and converges since $\sum p^{-j}|h_j|^2 < \infty$. Its norm is C_p, proving the normalized-line isometry. Notice that $W \neq T\delta_0$ in general; its coefficients depend on the representation. □

Conjecture 56.7.6 *(Arithmetic local pairing comparison).* Construct the arithmetic placement and action-intertwining maps from the actual bar–cobar carrier to the specified local representation and Whittaker models, with domains, Haar measure and spherical normalization fixed. Require them to transport the arithmetic bilinear pairing and its conjugation to the corresponding Hermitian form, compatibly with Hecke actions and the adelic extension in Hypothesis 67.1.1. The preceding radial and diagonal isometries are explicit bounded models; they do not construct this full arithmetic comparison.

Remark 56.7.7 *(Pairing type and normalization).* The Whittaker integral and the occupation Hilbert form are linear in the first variable and conjugate-linear in the second. An antilinear map cannot be inserted in their second slot without changing that type. If $B_{\mathrm{Whit}}(x, y) = H_{\mathrm{Whit}}(x, Jy)$ is the corresponding bilinear form, then $H_{\mathrm{Whit}}(x, y) = B_{\mathrm{Whit}}(x, Jy)$. This is the type required in an arithmetic Koszul comparison.

Adjoint rescaling alone changes the spherical norm to $m_p(1 + p^{-1})$, not to one. Unit normalization uses the full positive factor C_p. This scalar is distinct from $\mathrm{vol}(GL_2(\mathbb{Z}_p)) = (1 - p^{-1})(1 - p^{-2})$ for the standard additive-matrix Haar convention. Ramified and non-tempered representations require their own integral and domain calculation. The finite nonzero continued global value in Theorem 56.7.8 is a separate analytic input, not a proof of local denominator finiteness.

Adelic Consistency

Theorem 56.7.8 *(Conditional adelic normalization on the cuspidal sph-fin locus).* Fix a cuspidal representation π and the local comparison datum of Conjecture 56.7.6. Assume the placement and adelic pairing maps of Hypothesis 67.1.1 on the specified sph-fin core. Suppose the adjoint Euler product, initially defined in a half-plane of absolute convergence, has a specified holomorphic continuation to $s = 1$ with $c_\pi = L(1, \mathrm{Ad}\,\pi) \neq 0$. Then

$$\langle \cdot, \cdot \rangle^{\mathrm{Koszul,Ad}} := c_\pi^{-1} \langle \cdot, \cdot \rangle^{\mathrm{Koszul}}$$

is a well-defined rescaled pairing on that core. If the Petersson pairing is rescaled by the same scalar, the assumed pairing comparison is preserved. The value c_π is a continued value; no absolute convergence of $\prod_p L_p(1, \mathrm{Ad}\,\pi)$ is asserted.

Proof. Multiplication by the nonzero scalar c_π^{-1} defines the rescaled form. Multiplying the assumed identity $\langle v, w \rangle^{\mathrm{Pet}} = \langle v, \sigma^{\mathrm{BC}} w \rangle^{\mathrm{Koszul}}$ by that scalar gives the identity of reduced pairings on the same domain. It neither enlarges the domain nor constructs its placement.

The distinction between an Euler product and its continued value is already visible for tempered unramified local parameters. In that case the three adjoint parameters have absolute value one. For $\sigma = \mathrm{Re}(s) > 1$, the logarithmic series is bounded by

$$\sum_p \sum_{j \geq 1} \frac{3p^{-j\sigma}}{j} \leq \frac{3}{1 - 2^{-\sigma}} \sum_p p^{-\sigma} < \infty.$$

Finitely many ramified factors do not affect this estimate away from their poles. The bound establishes absolute convergence in this half-plane; it gives no convergence assertion at $s = 1$. For other local regimes one starts in a half-plane where the Euler product is known to converge. Analytic continuation and nonvanishing at one are separate analytic inputs, of the kind considered in Hoffstein–Lockhart 1994 and the Langlands–Shahidi theory; their applicability to the chosen representation is part of the hypothesis. □

Remark 56.7.9 *(Local and global normalization hypotheses).* Theorem 56.7.5 constructs specified local model isometries. Their arithmetic realization is the separate local comparison datum. The global assertion in Theorem 56.7.8 additionally requires the finite nonzero continued value c_π and the arithmetic placement and adelic pairing maps of Hypothesis 67.1.1. Neither the local datum nor the analytic continuation constructs those maps.

56.8 Consequence: K-P Compat, Conditional Domain

Corollary 56.8.1 *(K-P compat on the cuspidal sph-fin locus under the local comparison datum). (conditional on Conjecture 56.7.6, Hypothesis 67.1.1, the specified finite nonzero continued value $c_\pi = L(1, \mathrm{Ad}\,\pi)$, and domain-restricted to the cuspidal sph-fin locus).* The Koszul–Petersson compatibility (Theorem 47.9.1) holds on the cuspidal sph-fin locus of $\mathcal{V}^{\mathrm{prim}}$, with the Koszul pairing interpreted under the Koszul-dual normalisation convention of Definition 56.7.3 and the Petersson form rescaled by the same c_π^{-1}. The resulting equality is between these two rescaled forms. Full-sector extension further separates into the prime KMS_1/GNS cyclic-subspace comparison of Theorem 67.2.5 with the additional arithmetic maps of Hypothesis 67.1.1, and the ramified Rankin–Selberg and Eisenstein conditions of Remark 47.1.2.

Proof. The local comparison datum supplies the finite-place pairing match with its stated normalization. Hypothesis 67.1.1 additionally supplies the arithmetic placement, preserved pairings, archimedean comparison, and adelic extension on the specified domain. Theorem 47.9.1 therefore applies to these maps. Multiplying both forms by the same nonzero c_π^{-1} preserves their equality. The local normalization alone supplies neither the global placement nor this extension. The additional ramified and continuous comparisons remain those of Remark 47.1.2. □

Remark 56.8.2 *(impact on P3).* Corollary 47.10.1 stated P3 conditional on K-P compat, which was itself conditional on K5 (Theorem 51.2.9). The global pairing implication retains all hypotheses of Corollary 56.8.1. P3 concerns the original positive Petersson form; rescaling by an arbitrary nonzero complex c_π^{-1} preserves the pairing identity but need not preserve positivity. Under the arithmetic comparison hypotheses, the logical chain

$$\text{K5 (cuspidal sph-fin)} \;\Rightarrow\; \text{K-P compat (cuspidal sph-fin)} \;\Rightarrow\; \text{P3 (cuspidal sph-fin)}$$

is complete on the cuspidal sph-fin locus with the Koszul-dual normalisation convention explicit.

Remark 56.8.3 *(impact on sufficient RH path).* Corollary 47.10.3 retains the four-input conditional conjunction: arithmetic Positselski, Koszul–Petersson compatibility on its specified domain, $\mathrm{HP}^{\mathrm{Ar}}$, and VB^*. The pairing implication here requires the local comparison datum, the finite nonzero continued value c_π, and the arithmetic placement and adelic maps of Corollary 56.8.1. These assumptions do not prove the other three inputs or extend the pairing identity beyond its stated domain.

56.9 Remaining Arithmetic Constructions

The local objects and their comparison functors must be constructed on the chosen coefficient and spectral carriers. Their cross-prime assembly requires actual equivariant descent data, while the global centre identification remains separate from the underlying arithmetic AG equivalence.

Remark 56.9.1 *(The complete descent and pairing data).* After local transport and effective coherent descent are supplied, BCglue.core asks for the actual global-centre identification and its coherent action comparison. Pairwise statements alone do not supply this datum. The conditional composition theorem explains how a compatible system over all finite sets assembles once constructed.

The K5 calculation gives concrete local Hilbert-space maps and the spherical norm. Its arithmetic extension requires maps preserving Hecke actions, the bilinear pairing and conjugation. Adelic transport also requires its completed domains and normalization. These are not consequences of a finite nonzero adjoint factor.

56.10 Constructed Models and the Global Target

The local coherent transport theorem, finite-stage central-action composition, spherical integral and explicit Hilbert isometries are proved on their stated carriers. Effective coherent descent is applied only when its full diagram and equivalence are supplied.

Koszul–Petersson compatibility and P3 on the cuspidal sph-fin domain retain the actual arithmetic placement, pairing and adelic extension hypotheses of Corollary 56.8.1. The prime cyclic KMS construction does not identify a whole global GNS space with the automorphic carrier. Ramified, full archimedean and continuous comparisons remain part of the original target. Arithmetic Positselski, the Hilbert–Pólya realization and Li positivity also remain separate inputs to the sufficient RH implication.

Chapter 57

Arithmetic Hilbert–Pólya and the VB* Converse: Structural Analyses

Assume P1, P2, and P3 in the comparison form used in Chapter 44. The two additional arithmetic inputs are H-P^{Ar} and VB. H-P^{Ar} is the determinant-trace hypothesis: there is a self-adjoint operator A for which $\Theta_\xi = 1/2 + iA$ has determinant divisor* $\operatorname{div}\xi_{\mathbb{R}}$ *and Weil–Connes trace equal to the zero distribution. VB* adds positivity and Hamburger determinacy for the Fock-space moment measure. Connes' adelic trace formula and Deninger's regularised determinant give equivalent forms of the first input after the named intertwiners; de Branges positivity and Nyman–Beurling–Báez-Duarte decay give equivalent forms of the second. Zero-placement supplies support; it does not supply the unbounded moment theorem.*

57.1 The Analytic Splitting

Chapter 44 gives a sufficient implication to RH from four inputs: arithmetic Positselski, Koszul–Petersson compatibility, H-P^{Ar}, and VB*. The P1 input is the completed arithmetic Positselski comparison; its Tate-Poisson shadow is only the forward functional equation. The P3 input is the full Koszul–Petersson comparison; its proved sph-fin cuspidal core is only the Tamagawa normalisation. The last two inputs are the Hilbert–Pólya determinant-trace realisation and the Fock-space positivity-determinacy theorem.

The Asymmetry

Zero-placement and VB* have different strength. Three operator-theoretic facts account for the difference:

(i) Moment data for an unbounded operator do not determine the spectral measure without a determinacy theorem. Akhiezer–Glazman Ch. VI.3 supplies the classical obstruction.

(ii) The assertion that the normal zero-divisor operator has determinant divisor $\operatorname{div}\xi_{\mathbb{R}}$ and Weil–Connes zero trace is precisely H-P^{Ar} (Hypothesis 44.3.2).

(iii) A symmetric $L_{\mathrm{o}}^{\mathrm{Ar}}$ on the primary Fock is not automatically a self-adjoint Hilbert–Pólya operator; a domain and a self-adjoint extension must be specified.

Thus Theorem 44.3.10 gives the implication VB* $\Rightarrow$ zero-placement under P2, P3, and H-P^{Ar}. The converse implication needs spectral regularity: positivity of the regularised moment functional, Hamburger determinacy, and support compatibility for the Fock operator.

Analytic and Operator Inputs

For H-P^{Ar}:

Connes, arXiv:math/9811068 (1999). Trace formula on the adele class space $X_{\mathbb{Q}} = \mathbb{A}_{\mathbb{Q}}/\mathbb{Q}^{\times}$; absorption trace of the scaling action and the zero distribution of ζ. Selecta Math. 5 version with full technical details.

Connes–Consani–Marcolli 2007. Adele class space with quantum-statistical-mechanical structure; Bost–Connes equilibrium-state structure.

Deninger, Proc. Symp. Pure Math. 55.1 (1994). Motivic L-functions; formalism identifying $\xi(s)$ with a regularised determinant of a Frobenius operator on an arithmetic cohomology.

Deninger, Math. Nachr. 205 (2001). Motivic cohomology dynamical systems formalism.

Berry–Keating, SIAM Review 41 (1999). Proposal that $H = \frac{1}{2}(xp + px)$ on $L^2(\mathbb{R}_{>0}, dx/x)$ is the Hilbert–Pólya candidate; restriction to a Planck-cell cutoff gives the correct leading asymptotic zero density.

Akhiezer–Glazman *Theory of Linear Operators in Hilbert Space* Vol. II (Dover 1993 reprint). Ch. VI on unbounded self-adjoint operators, Friedrichs extensions, and moment problems; Ch. VI.3 is the Hamburger/Carleman determinacy criterion.

Reed–Simon *Methods of Modern Mathematical Physics* Vol. I (Academic Press 1980), Vol. II (1975). Ch. VIII (Vol. I) on unbounded operators; Vol. II on Fourier analysis and self-adjointness.

For the VB* converse:

de Branges *Hilbert Spaces of Entire Functions* (Springer 1968). Foundational theorem on reproducing-kernel Hilbert spaces of entire functions; Hermite–Biehler structure theorem.

Lagarias, Acta Arith. 89 (1999), 217–234. Reformulation of RH as Hermite–Biehler positivity for $E_\xi(z) = \xi_{\mathbb{R}}(\frac{1}{2} - iz) + \xi'_{\mathbb{R}}(\frac{1}{2} - iz)$.

Báez-Duarte, Adv. Math. 190 (2005), 315–320; arXiv:math/0202141. Quantitative strengthening of the Nyman–Beurling criterion.

Nyman *On Some Groups and Semigroups of Translations* (Uppsala 1950). Original criterion: RH equivalent to density of $\{\{\theta/x\} : \theta \in (0,1]\}$ translates in $L^2((0,1))$.

Beurling, Proc. Natl. Acad. Sci. 41 (1955). Beurling sequence space formulation of Nyman.

Burnol 2000. Hermite–Biehler refinement of Nyman–Beurling.

Simon, Adv. Math. 137 (1998), 82–203. Classical moment problem as self-adjoint finite difference operator; unbounded case treated via Jacobi matrix formalism.

Stein–Weiss *Introduction to Fourier Analysis on Euclidean Spaces* (Princeton 1971). Ch. V on Hardy spaces and boundary-value theorems governing Hermite–Biehler.

These analytic sources supply the external operator models for H-P^{Ar} and the VB* converse. P1, P2, and P3 enter only through their comparison hypotheses.

57.2 Structural Reductions

The assertions below separate domain, trace, determinant, and moment questions. Each assertion is an implication between named mathematical structures.

H-P^{Ar}: Operator-Theoretic Framework

On the finite-span core of the primary arithmetic Heisenberg Fock, the Sugawara operator is diagonal with real non-negative eigenvalues (Lemma 45.6.1). Reed–Simon Vol. I Thm. VIII.11 and the Friedrichs construction give a canonical self-adjoint non-negative extension from this semibounded quadratic form.

This removes the domain ambiguity in Hypothesis 44.3.2. It does not identify the resulting Bost–Connes partition trace with the Weil–Connes zero distribution; that identification is the spectral trace input of Proposition 57.3.3.

H-P^{Ar}: Connes Adele Class Space

Connes' adelic trace formula is a theorem on $X_{\mathbb{Q}} = \mathbb{A}_{\mathbb{Q}}/\mathbb{Q}^{\times}$. The comparison with H-P^{Ar} requires an intertwiner from the primary Fock space to the adele-class L^2-space which carries the zero-mode Bost–Connes monoid action to the idele-class scaling action. Under such an intertwiner, Connes' absorption trace and the regularised Fock trace are the same distribution. The displayed absorption-trace formula,

$$\sum_{\rho} h(\operatorname{Im}\rho) = h(0) + h(1) - \hat{h}(0)\log\pi - \sum_{v}{}' \int_{\mathbb{Q}_v^{\times}} \frac{h(\log|u|_v)}{|1-u|_v} d^{\times}u,$$

matches (as a distribution on the dual real line) the Li–Stieltjes moment generating function $\sum_{\rho} e^{-t\rho}$ through Mellin inversion $h(u) = e^{-tu/2}$, provided the embedding preserves the distributional trace.

H-P^{Ar}: Deninger Motivic Cohomology

Deninger's formalism postulates a cohomology $H^{\bullet}_{M}(\overline{\operatorname{Spec}\mathbb{Z}}, \mathbb{R}(\cdot))$ with Frobenius Φ and Lefschetz determinant formula. If that cohomology exists and is identified with the primary Fock by an intertwiner, then the determinant identity for $\xi_{\mathbb{R}}$ is the H-P^{Ar} determinant statement. The formal identity $\xi(s) = \det_{\infty}(s\cdot\mathrm{id} - L_0^{\mathrm{Ar}})$ holds under H-P^{Ar}: the regularised determinant is defined by $\log\det_{\infty}(A) = -\partial_s \operatorname{tr}(A^{-s})|_{s=0}$, and the determinant divisor is $\operatorname{div}\xi_{\mathbb{R}}$ after the trivial-zero and pole summands have been removed by the primary-sector restriction.

H-P^{Ar}: Necessary and Sufficient Conditions

The three formulations have one common mathematical core: a positive-definite Hilbert space $\mathcal{H}$, a densely-defined self-adjoint operator A, and an intertwiner $\pi : \mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}} \to \mathcal{H}$ such that $A\pi = \pi L_0^{\mathrm{Ar}}$, the normal operator $\frac{1}{2} + iA$ has regularised determinant divisor equal to the non-trivial zero divisor of $\xi_{\mathbb{R}}$, and its Weil–Connes trace is the corresponding zero distribution. This is classical Hilbert–Pólya inside the arithmetic-Fock framework.

VB Converse: Spectral Regularity Beyond RH*

Zero-placement gives the zeros on the critical line. VB* asks for positivity of the operators T_n on the Fock closure. Passing from the former to the latter is a Hamburger moment problem for an unbounded operator; in this setting moment positivity does not select a unique spectral measure. Carleman's criterion says that the Hamburger moment problem with moments $\{\mu_n\}_{n\geq 0}$ is determinate if $\sum_{n\geq 1} \mu_{2n}^{-1/(2n)} = +\infty$. For the proposed shifted-zero functional of Definition 62.4.1, constructing finite moments and proving positivity are separate requirements. The finite cutoff sums in Proposition 80.2.5 diverge; zero counting does not define their regularization. Once a positive functional has been constructed, the upper bound $\mu_{2n}^{1/(2n)} = O(n)$ suffices for Carleman determinacy.

VB Converse: de Branges and Báez-Duarte*

The de Branges operator comparison and the Nyman–Beurling approximation problem involve different data. The latter has the concrete Hilbert carrier $L^2((0,\infty), dx)$, fractional-part vectors $\rho_n(x) = \{1/(nx)\}$, and target $\chi = \mathbf{1}_{(0,1)}$. The classical Báez-Duarte criterion is convergence of the finite distances

to zero. A sharp two-sided rate, an arithmetic isometry, and its compatibility with the operator-positivity condition are additional questions. The finite distance and its exact transport are constructed in Proposition 57.4.13.

57.3 H-P^{Ar}: Structural Analysis

Operator-Theoretic Framework

Definition 57.3.1 *(candidate $L_{\mathrm{o}}^{\mathrm{Ar}}$ with explicit domain).* On the primary arithmetic Heisenberg Fock $\mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$, equipped with the Petersson inner product $\langle\cdot,\cdot\rangle^{\mathrm{Pet}}$ of Theorem 43.7.1, define:

- *Finite-span core* $\mathcal{D}_{\mathrm{o}} := \mathrm{span}_{\mathbb{C}}\{|\mathbf{n}\rangle \otimes \delta_m : \mathbf{n} \in \mathbb{Z}_{\geq 0}^{\oplus\mathbb{N}},\ m \in \mathbb{N}^{\times}\}$, the linear span of number-state/zero-mode-lattice basis vectors (Lemma 45.6.1, Definition 29.2.1).
- *Candidate operator* $L_{\mathrm{o}}^{\mathrm{Ar,\,symm}} : \mathcal{D}_{\mathrm{o}} \to \mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$ defined by

$$L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}\big(|\mathbf{n}\rangle \otimes \delta_m\big) = \Big(\sum_{i\geq 1} i\, n_i + \lambda(m)\Big)|\mathbf{n}\rangle \otimes \delta_m$$

  where $\lambda(m) \in \mathbb{R}$ is the Bost–Connes zero-mode weight corresponding to $m \in \mathbb{N}^{\times}$ (unspecified at this stage; the choice is constrained by the Bost–Connes KMS$_1$ state structure of Proposition 29.3.1).
- *Closure*: let $L_{\mathrm{o}}^{\mathrm{Ar}}$ denote the closure of $L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}$ with respect to the graph norm on $\mathcal{D}_{\mathrm{o}}$.

THEOREM 57.3.2 *(Friedrichs self-adjoint extension). Conditional statement.* Under the hypothesis that $\lambda(m) \geq 0$ for all $m \in \mathbb{N}^{\times}$ (non-negativity of the Bost–Connes zero-mode weights), the symmetric operator $L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}$ of Definition 57.3.1 admits a unique Friedrichs self-adjoint extension $L_{\mathrm{o}}^{\mathrm{Ar}} : \mathcal{D} \to \mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$ with $\mathcal{D} \supset \mathcal{D}_{\mathrm{o}}$ dense. On the Friedrichs extension, $L_{\mathrm{o}}^{\mathrm{Ar}}$ is essentially self-adjoint on the finite-span core $\mathcal{D}_{\mathrm{o}}$ and has non-negative spectrum.

Proof. Apply Reed–Simon Vol. II Thm. X.23 (Friedrichs extension of a non-negative symmetric operator). The quadratic form $q(\psi,\psi') = \langle L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}\psi, \psi'\rangle^{\mathrm{Pet}}$ is closable because $L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}$ acts diagonally on the orthonormal basis $\{|\mathbf{n}\rangle \otimes \delta_m\}$ with non-negative real eigenvalues. Reed–Simon Vol. I Thm. VIII.11 then gives essential self-adjointness on the finite-span core: a diagonal operator with real eigenvalues on a Hilbert space with eigenvector basis is essentially self-adjoint on the finite-span of eigenvectors. The Friedrichs extension is the unique self-adjoint extension dominated by the quadratic form (Akhiezer–Glazman Vol. II Thm. 123). Non-negativity of the spectrum follows from non-negativity of all eigenvalues. □

PROPOSITION 57.3.3 *(Bost–Connes trace compatibility is the HP input).* The Friedrichs extension of Theorem 57.3.2 constructs a self-adjoint non-negative Fock/BC Hamiltonian from the real weights $\lambda(m)$. It does not by itself construct the Hilbert–Pólya determinant-trace operator H_{HP}. H-P^{Ar} holds only after one supplies an additional distributional trace identification with the zero side. The formal heat-kernel expression is

$$\mathrm{tr}_{\mathrm{BC}}\big(e^{-tL_{\mathrm{o}}^{\mathrm{Ar}}}\big) = \sum_{\rho} e^{-t\rho} \qquad (t > 0) \tag{57.1}$$

but (57.1) is only symbolic notation. It means equality of Weil–Connes distributions on admissible Paley–Wiener tests, equivalently the trace identity of Hypothesis 44.3.2 for $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$. This trace compatibility is the Hilbert–Pólya determinant-trace input, not a consequence of the Friedrichs theorem.

Proof. Direct computation of $\mathrm{tr}(e^{-tL_0^{\mathrm{Ar}}})$ on the basis of $\mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}} = L \otimes \mathcal{H}^{(\infty)}$:

$$\mathrm{tr}\big(e^{-tL_0^{\mathrm{Ar}}}\big) \;=\; \Big(\sum_{m\geq 1} e^{-t\lambda(m)}\Big)\cdot\Big(\sum_{\mathbf{n}} e^{-t\sum_i i\,n_i}\Big) \;=\; \Big(\sum_{m\geq 1} e^{-t\lambda(m)}\Big)\cdot\prod_{i\geq 1}\frac{1}{1-e^{-ti}}.$$

For the Bost–Connes/KMS weight $\lambda(m) = \log m$, the zero-mode factor is $\zeta(t)$ for $\mathrm{Re}(t) > 1$, multiplied by the Dedekind-eta inverse from the Fock descendants. This is the Euler/partition side. It is not the zero distribution. Passing from this partition trace to the zero side requires the full Weil–Connes explicit-formula distribution and a positive trace realisation; that is exactly H-P^{Ar} in Hypothesis 44.3.2. Thus the proposition records an equivalence of formulations after the trace realisation is assumed, not a derivation of the trace realisation. □

Remark 57.3.4 *(what the Friedrichs construction buys).* Theorem 57.3.2 removes only one domain-specification ambiguity: a real non-negative diagonal Fock/BC Hamiltonian has a canonical self-adjoint extension. What remains is not an elementary choice of $\lambda(m)$. The KMS normalisation selects $\lambda(m) = \log m$, which gives the Bost–Connes partition trace $\zeta(t)$; the zero distribution of $\xi_{\mathbb{R}}$ (the completed xi function $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$, here denoting the restriction to the primary archimedean sector) is a different object. The Hilbert–Pólya content is the additional construction of H_{HP}, or an intertwiner carrying this Fock/BC Hamiltonian to the zero-divisor operator Θ_ξ, with the positive Weil–Connes trace preserved.

Connection to Connes Adele Class Space

Definition 57.3.5 *(Connes adele class space).* (Connes arXiv:math/9811068 §II). The *adele class space* is $X_{\mathbb{Q}} = \mathbb{A}_{\mathbb{Q}}/\mathbb{Q}^\times$, the quotient of the adeles by the multiplicative action of non-zero rationals. Its measure-zero part $X_{\mathbb{Q}}^0$ supports an L^2 space $L_0^2(X_{\mathbb{Q}}, d\mu)$ on which the idele class group $C_{\mathbb{Q}} = \mathbb{A}_{\mathbb{Q}}^\times/\mathbb{Q}^\times$ acts unitarily by multiplication. The absorption trace of this action is the content of Connes' realisation.

Theorem 57.3.6 *(Connes arXiv:math/9811068 Thm. 1).* For appropriate test functions h on $C_{\mathbb{Q}}$,

$$\mathrm{Tr}(\vartheta(h)) \;=\; 2h(1) + 2h(-1) - \hat{h}(0)\log\pi - \sum_v {\int_{\mathbb{Q}_v^\times}}' \frac{h(u)}{|1-u|}\,d^\times u - \sum_{\rho:\, L(\tilde{\rho},\chi)=0} \hat{h}(\chi,\rho), \qquad (57.2)$$

where $\vartheta(h)$ is the scaling operator on $L_0^2(X_{\mathbb{Q}})$, ρ ranges over zeros of Hecke L-functions $L(s,\chi)$, and the prime on the local integral denotes principal-value regularisation. The GL_1 case with trivial character recovers $\xi(s)$: the non-trivial zeros of ζ enter the absorption trace distribution.

Conjecture 57.3.7 *(intertwiner comparing H-P^{Ar} with Connes). Conjectural statement.* Let H_{HP} and $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$ be as in Hypothesis 44.3.2, and let D_{BC} denote the Friedrichs Fock/BC Hamiltonian of Theorem 57.3.2. Let ϑ be the scaling operator of Connes on $L_0^2(X_{\mathbb{Q}})$. The required comparison is the existence of an intertwiner

$$\pi : \mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}} \longrightarrow L_0^2(X_{\mathbb{Q}}, d\mu)$$

defined on $\mathcal{D}_0$ and extended by closure, such that

$$\pi \circ \Theta_\xi \;=\; \vartheta_0 \circ \pi$$

where ϑ_0 is the infinitesimal generator of the scaling action on the kernel of the idele-class scaling trace. The intertwiner π is $C_{\mathbb{Q}}$-equivariant on the sph-finite sector and identifies the positive Weil–Connes trace of Θ_ξ with the distributional trace in Connes' trace formula. Its restriction to the zero-mode

lattice must also explain how D_{BC}, whose partition trace is $\zeta(\beta)$, maps to the absorption trace without postulating the zero divisor.

Remark 57.3.8 *(open intertwiner).* The sph-finite sector of $\mathcal{V}^{\mathrm{prim}}$ embeds by restricted tensor product into a subspace of $L^2([GL_2(\mathbb{Q})]\backslash GL_2(\mathbb{A}))$ compatible with the adele class space image (Gelbart *Automorphic Forms on Adele Groups* §3.1). The zero-mode lattice $L \subset \mathcal{V}^{\mathrm{prim}}$ maps to the finite-adele part of $X^{\circ}_{\mathbb{Q}}$; the archimedean Heisenberg factor $\mathcal{H}^{(\infty)}$ maps to the archimedean-fibre Fock of $L^2_{\circ}(X^{\circ,\infty}_{\mathbb{Q}})$. The scaling action of $C_{\mathbb{Q}}$ on $L^2_{\circ}(X^{\circ}_{\mathbb{Q}})$ restricts on the sph-finite sector to the multiplicative action of $\mathbb{N}^{\times}$ on the Bost–Connes zero-mode lattice (Proposition 29.3.1), plus the real-parameter archimedean scaling on the Fock. The infinitesimal generator of this action is the Bost–Connes/Fock Hamiltonian on the chiral-algebra side, while the Connes trace formula sees the absorption trace. Constructing an isometric intertwiner from the former to the latter is exactly the determinant-trace problem.

COROLLARY 57.3.9 *(H-P^{Ar} and Connes have the same determinant-trace input). Conditional statement. (conditional on the intertwiner of Conjecture 57.3.7).* Under that intertwiner, the trace-compatibility condition (57.1), read as the distributional equality of Hypothesis 44.3.2, is equivalent to Connes' absorption-trace hypothesis: the $C_{\mathbb{Q}}$-scaling action on $L^2_{\circ}(X_{\mathbb{Q}})$ has zero distribution of ζ with correct multiplicity.

Proof. Given the conjectural intertwiner, applying π transports the regularised trace distribution of Θ_{ξ} to the Connes distributional trace. Conversely, on the sph-finite image of π, the Connes absorption-trace statement pulls back to the Hilbert–Pólya determinant and trace identities. The proof uses the intertwiner as an input; it does not construct it. □

Remark 57.3.10 *(form of Connes' trace formula).* Connes' trace formula (57.2) is proved in arXiv:math/9811068 Thm. 1. The identification of the absorption trace with the zero distribution of ζ with correct multiplicity is the content of Connes' RH-equivalent statement; it is *not* a theorem. Corollary 57.3.9 places H-P^{Ar} at the same level only after the intertwiner of Conjecture 57.3.7 is assumed. That intertwiner is part of the RH-equivalent determinant-trace problem. The chiral-algebra form replaces the adele-class-space L^2 setting by a Fock-space setting with Sugawara and free-boson operators.

Connection to Deninger Motivic Cohomology

Definition 57.3.11 *(Deninger axioms for motivic cohomology).* (Deninger Proc. Symp. Pure Math. 55.1, §1). A *Deninger motivic cohomology* is a conjectural functor

$$H^{\bullet}_M(-, \mathbb{R}(\cdot)) : \ \mathrm{Schemes}/\mathbb{Z} \longrightarrow \mathrm{Graded}\ \mathbb{R}\text{-vs}$$

equipped with an integral Frobenius endomorphism Φ satisfying:

(D1) *Lefschetz trace formula.* For every smooth arithmetic scheme X, $\zeta_X(s) = \prod_i \det_{\infty}(s \cdot \mathrm{id} - \Phi | H^i_M(X, \mathbb{R}(1)))^{(-1)^{i+1}}$.

(D2) *Purity.* The eigenvalues of Φ on $H^i_M(X, \mathbb{R}(1))$ all satisfy $\mathrm{Re}(\rho) = i/2$ (or a shifted variant).

(D3) *Regularised determinant.* The determinant $\det_{\infty}$ is the ζ-regularised determinant defined by $\log \det_{\infty}(A) = -\partial_s \mathrm{tr}(A^{-s})|_{s=0}$.

PROPOSITION 57.3.12 *(H-P^{Ar} $\Leftrightarrow$ Deninger formalism for $\overline{\mathrm{Spec}\ \mathbb{Z}}$). Conditional statement. (conditional on existence of Deninger cohomology for $\overline{\mathrm{Spec}\ \mathbb{Z}}$ and on an explicit Deninger–Fock intertwiner).* Assuming Definition 57.3.11 applies to $\overline{\mathrm{Spec}\ \mathbb{Z}}$ with $X = \overline{\mathrm{Spec}\ \mathbb{Z}}$ and $H^1_M(\overline{\mathrm{Spec}\ \mathbb{Z}}, \mathbb{R}(1))$ non-zero, the

Hilbert–Pólya zero-divisor operator Θ_ξ of Hypothesis 44.3.2 is identified with $\Phi|H^1_M(\overline{\mathrm{Spec}\,\mathbb{Z}},\mathbb{R}(1))^+$ (the + superscript denotes the primary $\mathrm{Gal}(\overline{\mathbb{Q}}/\mathbb{Q})$-invariant part), and H-P^{Ar} holds iff (D1), (D2), (D3) hold.

Proof. Under the Deninger axioms, the meromorphic Tate zeta surface is a cohomological superdeterminant: the even cohomology accounts for the Tate poles at 0 and 1, while the primary H^1 determinant is the entire factor $\xi_{\mathbb{R}}(s)$. The ordinary determinant target on the primary summand is

$$\xi_{\mathbb{R}}(s) = \det_\infty(s\cdot\mathrm{id} - \Phi|H^1_M(-,\mathbb{R}(1))^+).$$

The regularised determinant identity fixes the spectral divisor of the primary summand:

$$\operatorname{div}\det_\infty(s\cdot\mathrm{id} - \Phi|H^1_M(-,\mathbb{R}(1))^+) = \operatorname{div}\xi_{\mathbb{R}}(s).$$

By (D3), the trace of Φ is a distributional zero trace in the admissible Weil–Connes sense, not an ordinary heat trace. The identification is canonical only after composing the intertwiner of Conjecture 57.3.7 with the conjectural Deninger–Connes dictionary of Leichtnam. □

Remark 57.3.13 *(the three formalisms in alignment).* The three comparison formulations of H-P^{Ar}:

(i) *Fock/BC domain realisation*: the Friedrichs Hamiltonian of Theorem 57.3.2 supplies a self-adjoint Euler-side operator, but the passage to Θ_ξ is the determinant-trace realisation.

(ii) *Connes adele class space*: the scaling generator ϑ_0 on $L^2_0(X_{\mathbb{Q}})$ has the zero distribution as its absorption trace; this is Connes' RH-equivalent reformulation of the trace formula of arXiv:math/9811068 Thm. 1, not a formal consequence of it.

(iii) *Deninger motivic cohomology*: the Frobenius Φ on $H^1_M(\overline{\mathrm{Spec}\,\mathbb{Z}},\mathbb{R}(1))^+$ has determinant divisor $\operatorname{div}\xi_{\mathbb{R}}$ (Deninger 1994 axioms).

The equivalences among these formulations require the Connes/Fock and Deninger/Fock intertwiners. Without those intertwiners there is a comparison diagram, not a proof that the three operator models are the same object.

Necessary and Sufficient Conditions

Theorem 57.3.14 *(H-P^{Ar} is the determinant-trace realisation).* The following are equivalent after the explicit Connes/Fock and Deninger/Fock intertwiners named above are included as hypotheses:

(H-P^{Ar}) The arithmetic Hilbert–Pólya condition in Hypothesis 44.3.2.

(SP) *Determinant-trace condition:* there exists the self-adjoint operator A, the normal operator $\Theta_\xi = 1/2 + iA$, the determinant divisor, and the positive Weil–Connes trace required in Hypothesis 44.3.2.

(Connes) *Connes trace realisation:* the $C_{\mathbb{Q}}$-scaling action on $L^2_0(X_{\mathbb{Q}})$ has regularised trace distribution equal to the non-trivial zero distribution of ζ, with multiplicity.

(Deninger) *Deninger regularised-determinant condition:* the formal identity $\xi_{\mathbb{R}}(s) = \det_\infty(s\cdot\mathrm{id} - \Phi|H^1_{M,\mathbb{R}(1),+})$ holds with Φ a self-adjoint operator on a Hilbert space matching $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ via an explicit intertwiner.

Proof. (H-P^{Ar}) ⇔ (SP) is definitional after Hypothesis 44.3.2: SP is the statement that the self-adjoint operator, determinant divisor, and positive trace distribution exist. The Friedrichs theorem supplies a separate Fock/BC domain model; it is evidence for the analytic framework but is not identified with H_{HP} without an intertwiner.

(SP) ⇔ (Connes) is Corollary 57.3.9, conditional on the Connes/Fock intertwiner. (SP) ⇔ (Deninger) is Proposition 57.3.12, conditional on the Deninger/Fock intertwiner and on the Deninger cohomology. Under these named hypotheses, transitivity closes the comparison. □

COROLLARY 57.3.15 *(H-P^{Ar} reduces to determinant and trace).* H-P^{Ar} reduces to the determinant-trace condition (SP). The Friedrichs/KMS side fixes the natural Bost–Connes weight $\lambda(m) = \log m$ and gives the Euler partition trace; it does not give the zero trace. The required assertion is the construction of H_{HP}, Θ_ξ, and the positive Weil–Connes trace whose distribution is the non-trivial-zero distribution of $\xi_{\mathbb{R}}$. This is the Hilbert–Pólya content itself, not a routine weight choice (Remark 57.3.16).

Proof. Direct from Theorem 57.3.14. The trace-compatibility condition encodes the location of non-trivial zeros of $\xi_{\mathbb{R}}$; the Bost–Connes weight gives the Euler side, while the zero side is the determinant divisor together with the positive Weil–Connes trace distribution. □

Remark 57.3.16 *(Hilbert–Pólya factor).* The Friedrichs construction of Theorem 57.3.2 proves only the domain theorem. Given $\{\lambda(m)\} \geq 0$, the Friedrichs extension is unique, self-adjoint, and non-negative. H-P^{Ar} is the additional determinant-trace assertion: one must construct a zero operator with $\operatorname{div} \det_\infty(s - \Theta_\xi) = \operatorname{div} \xi_{\mathbb{R}}$ and trace distribution such that, in symbolic wave-kernel notation,

$$\mathrm{Tr}_{\mathrm{reg}}\left(e^{-t\Theta_\xi}\right) \;=\; \sum_{\rho} e^{-t\rho} \qquad (t > 0),$$

where the equality is read after admissible Weil–Connes regularisation and the sum is over non-trivial zeros of $\xi_{\mathbb{R}}$ counted with multiplicity. This is Hilbert's original eighth problem, not a corollary of the Friedrichs step. The determinacy comparison retains the domain theorem and leaves the Hilbert–Pólya determinant-trace realisation.

Remark 57.3.17 *(Berry–Keating candidate).* Berry–Keating SIAM Review 41 (1999) proposed $H = \frac{1}{2}(xp + px)$ on $L^2(\mathbb{R}_{>0}, dx/x)$ as a candidate Hilbert–Pólya operator, restricted to a Planck-cell cutoff. This operator has continuous spectrum on $\mathbb{R}$ and the Bohr-Sommerfeld quantisation of $xp = E$ gives the correct leading asymptotic zero density $N(T) \sim (T/2\pi)\log(T/2\pi)$. In the present framework, this candidate corresponds to a specific choice of $\{\lambda(m)\}_{m\in\mathbb{N}^\times}$: the prime-indexed weights $\lambda(p^k) = k \log p$ (Bost–Connes monoid generators), combined with the Fock archimedean spectrum $\{i\, n_i\}$, formally give the Berry–Keating spectrum structure. The Berry–Keating candidate is *not* rigorously known to have determinant divisor div $\xi_{\mathbb{R}}$; it reproduces the density but not the individual zero divisor. The rigorous identification requires a regularisation matching (57.1), which is the H-P^{Ar} content.

57.4 VB* CONVERSE: STRUCTURAL ANALYSIS

The Moment Problem in Hilbert Space

THEOREM 57.4.1 *(determinate vs. indeterminate Hamburger moment problem).* (Akhiezer 1965 §2.4; Shohat–Tamarkin 1943 Ch. III.5). Let $\{\mu_n\}_{n\geq 0}$ be a sequence of real numbers with Hankel matrices $H_n = (\mu_{i+j})_{0\leq i,j\leq n} \succeq 0$ for all n. The Hamburger moment problem is:

- *Solvable*: there exists a positive measure ν on $\mathbb{R}$ with $\mu_n = \int x^n \, d\nu(x)$.

- *Determinate*: the solution ν is unique.
- *Indeterminate*: multiple distinct positive measures share the moment sequence.

Carleman's sufficient criterion for determinacy: $\sum_{n\geq 1} \mu_{2n}^{-1/(2n)} = +\infty$. Non-sufficient examples (Stieltjes 1894): the lognormal moment sequence $\mu_n = e^{n^2/2}$ is indeterminate.

Theorem 57.4.2 *(Simon 1998: moment problem as Jacobi matrix).* (Simon Adv. Math. 137 (1998) §5). A Hamburger moment problem with $\mu_0 > 0$ and strictly positive Hankel forms on every nonzero polynomial is equivalent to the spectral theory of a Jacobi matrix

$$J = \begin{pmatrix} b_0 & a_0 & 0 & \cdots \\ a_0 & b_1 & a_1 & \cdots \\ 0 & a_1 & b_2 & \cdots \\ \vdots & \vdots & \vdots & \ddots \end{pmatrix}$$

on $\ell^2(\mathbb{Z}_{\geq 0})$, with $a_n > 0$ and $b_n \in \mathbb{R}$ determined recursively by the moment sequence via the Gram–Schmidt-orthonormalised polynomial basis $\{p_n(x)\}_{n\geq 0}$ with positive leading coefficient $p_n(x) = \kappa_n x^n + \text{lower}$, $\kappa_n > 0$, and $\int p_m p_n \, d\nu = \delta_{mn}$. With $p_{-1} = 0$, multiplication by x satisfies

$$x p_n = a_n p_{n+1} + b_n p_n + a_{n-1} p_{n-1}, \qquad a_n = \kappa_n/\kappa_{n+1} > 0.$$

The coefficient of p_j for $j < n-1$ vanishes because $\langle x p_n, p_j\rangle = \langle p_n, x p_j\rangle = 0$; comparison of leading terms gives the displayed a_n. A finite-support moment measure instead gives a terminating finite Jacobi matrix. In the stated nondegenerate infinite case, the moment problem is determinate iff J is essentially self-adjoint on c_{00}, and indeterminate iff J has deficiency indices $(1,1)$.

Proposition 57.4.3 *(VB* operator-positivity vs. moment positivity: the gap).* Let L be a specified positive Hamburger functional with finite moments, and let A be a self-adjoint realization on the stated arithmetic Hilbert space. Suppose the operator comparison identifies $T_n = p_n(A)$, where $p_n(t) = t^n - (t-1)^n$, on the maximal domains

$$D(T_n) = \left\{ v : \int_{\mathbb{R}} |p_n(t)|^2 \, d\langle E_A(t)v, v\rangle < \infty \right\},$$

and the trace comparison, wherever invoked, gives $\operatorname{tr}(T_n) = n\lambda_n$ with finite traces. Then:

(i) Positivity of all T_n implies Li positivity and hence RH.

(ii) All T_n are positive if and only if the spectral measure of A is supported in $[1/2, \infty)$.

(iii) Determinacy of L does not by itself construct this operator realization, trace comparison or support identification.

(iv) Positivity of a moment functional alone does not choose a self-adjoint realization in an indeterminate moment problem.

Proof. The first statement follows from positivity of the finite traces and Li's criterion. For the second, the real polynomial $t^n - (t-1)^n$ is nonnegative for $t \geq 1/2$: for odd n it is positive on all real t, and for even n compare $|t|$ and $|t-1|$. The spectral theorem gives positivity on the maximal polynomial domain. Conversely, positivity of $T_2 = 2A - I$ forces that support by the spectral theorem. The last two statements distinguish uniqueness of a representing measure from a specified realization; indeterminate Hamburger functionals admit different representing measures with the same moments. No claim about the off-line defect measure of Definition 45.4.1 is used. □

COROLLARY 57.4.4 *(the converse input is spectral regularity).* Assume a specified positive moment functional is identified with the arithmetic self-adjoint operator and has spectral support in $[1/2, \infty)$, with the polynomial operator comparison of Proposition 57.4.3. Then VB* holds. Determinacy supplies uniqueness of the representing measure when it is available; it does not construct these arithmetic identifications from zero placement.

Proof. Apply item 2 of the proposition on the stated spectral domains. □

PROPOSITION 57.4.5 *(A conditional Carleman construction).* For a specified positive Hamburger functional, the bound $\mu_{2n} \le C^n (n!)^2$ implies determinacy.

Proof. Its positive even moments satisfy $\mu_{2n}^{-1/(2n)} \ge C^{-1/2} (n!)^{-1/n} \ge C^{-1/2}/n$. Carleman's series diverges. If an even moment vanishes, the positive measure is supported at zero and is unique. No lower moment bound is required. □

Remark 57.4.6 *(Moment growth and the arithmetic construction).* A positive functional with moments $\mu_n = e^{n^2/2}$ has an indeterminate Hamburger problem, whereas the factorial upper bound above gives determinacy. These examples do not estimate the arithmetic moments. The finite-cutoff zero sums diverge, so a common linear regularization, positivity and the stated upper bound remain actual construction requirements.

Hermite–Biehler + de Branges

Definition 57.4.7 *(Hermite–Biehler function).* (de Branges 1968 Ch. II). An entire function $E(z)$ is *Hermite–Biehler* if $|E(z)| > |E^*(z)|$ for all z in the open upper half plane $\operatorname{Im} z > 0$, where $E^*(z) = \overline{E(\overline{z})}$. The *de Branges space* $\mathcal{H}(E)$ is the reproducing-kernel Hilbert space of entire functions f with $f/E, f^*/E \in H^2(\mathbb{C}_+)$ (upper-half-plane Hardy space) and reproducing kernel

$$K_E(w, z) \;=\; \frac{\overline{E(w)}E(z) - \overline{E^*(w)}E^*(z)}{2\pi i(\overline{w} - z)}.$$

THEOREM 57.4.8 *(de Branges structure theorem).* (de Branges 1968 Thm. 22). Every reproducing-kernel Hilbert space of entire functions $\mathcal{H}$ satisfying:

- $f, g \in \mathcal{H} \Rightarrow \overline{g(\overline{z})} \in \mathcal{H}$ (complex conjugate closure);
- for every non-real w, the point evaluation $f \mapsto f(w)$ is continuous;
- for every non-real w, $f \mapsto (f - \tilde{f})/(z - w)$ is bounded (where $\tilde{f}$ denotes a specific orthogonal projection);

is of the form $\mathcal{H}(E)$ for some Hermite–Biehler E.

THEOREM 57.4.9 *(The derivative kernel and zero placement).* Let $A(z) = \Xi(z) = \xi_{\mathbb{R}}(1/2 - iz)$ and

$$E_\xi(z) = A(z) + iA'(z) = \xi_{\mathbb{R}}(1/2 - iz) + \xi'_{\mathbb{R}}(1/2 - iz).$$

RH, strict Hermite–Biehler positivity of E_ξ, and positive semidefiniteness of K_{E_ξ} are equivalent.

Proof. Under RH the paired Hadamard product for the even function A has real zeros $\pm\gamma$ and

$$\frac{A'(z)}{A(z)} = \sum_{\gamma > 0} \left(\frac{1}{z - \gamma} + \frac{1}{z + \gamma} \right),$$

with multiplicities and locally uniform convergence off the real zeros, since $\sum \gamma^{-2} < \infty$. Each term has strictly negative imaginary part in the upper half-plane. Therefore $|A + iA'|^2 - |A - iA'|^2 = -4|A|^2 \operatorname{Im}(A'/A) > 0$, so E_ξ is strictly Hermite–Biehler. The standard Schur-kernel construction gives positive semidefiniteness of its de Branges kernel, as in Proposition 79.6.5. Conversely, positivity of the kernel forces strictness by Proposition 79.6.7. If the real part $A = (E_\xi + E_\xi^*)/2$ vanished in the upper half-plane, then $E_\xi = -E_\xi^*$ there, contradicting strictness. Reality excludes lower-half-plane zeros as well. Thus the zeros of A are real, which is RH. □

Proposition 57.4.10 *(Transport of the operator positivity predicate).* Let A be the specified self-adjoint arithmetic operator and $U : H_{\mathrm{Ar}} \to \mathcal{H}(E_\xi)$ a supplied unitary. Suppose a self-adjoint operator M on $\mathcal{H}(E_\xi)$ satisfies $U\,D(A) = D(M)$ and $UAU^{-1} = M$. With maximal polynomial domains, the following are equivalent:

(i) $p_n(A) \geq 0$ for every $n \geq 1$.

(ii) $p_n(M) \geq 0$ for every $n \geq 1$.

(iii) The spectral measure of M is supported in $[1/2, \infty)$.

The unitary and the self-adjoint realization are comparison inputs. No positivity assertion for arbitrary signed measures is required.

Proof. Unitary functional calculus gives $U\,p_n(A)U^{-1} = p_n(M)$, including their maximal domains, so the first two assertions are equivalent. The second and third are equivalent by the polynomial calculation in Proposition 57.4.3: sufficiency follows from $p_n(t) \geq 0$ on $[1/2, \infty)$, and necessity from $p_2(M) = 2M - I \geq 0$. □

The Báez-Duarte Refinement

Theorem 57.4.11 *(Nyman–Beurling criterion on the half-line).* Let $\rho(y) = y - \lfloor y \rfloor$, $\chi = \mathbf{1}_{(0,1)}$, and $H = L^2((0,\infty), dx)$. For real $a \geq 1$, put $\rho_a(x) = \rho(1/(ax))$. Then RH is equivalent to $\chi \in \overline{\operatorname{span}\{\rho_a : a \geq 1\}}$ in H. This is the half-line form of the Nyman–Beurling criterion.

Theorem 57.4.12 *(Báez-Duarte's discrete criterion).* With the same carrier and vectors, define

$$E_N = \operatorname{span}\{\rho_n : 1 \leq n \leq N\}, \qquad \epsilon_N^{\mathrm{BD}} = \operatorname{dist}_H(\chi, E_N).$$

Then RH is equivalent to $\epsilon_N^{\mathrm{BD}} \to 0$. Báez-Duarte, arXiv:math/0205003, Theorem 1.1, proves the discrete closure statement; it does not identify these spaces with an arithmetic Fock space or assert the sharp rate $\epsilon_N^{\mathrm{BD}} \asymp (\log N)^{-1/2}$.

Proposition 57.4.13 *(Finite-distance construction and conditional arithmetic transport).* Each E_N is a closed finite-dimensional subspace of H. Let P_N be its orthogonal projection. Then

$$\epsilon_N^{\mathrm{BD}} = \|\chi - P_N\chi\|_H.$$

For $G_{ij} = \langle \rho_j, \rho_i \rangle_H$ and $b_i = \langle \chi, \rho_i \rangle_H$, with inner products linear in the first variable, any solution of $Ga = b$ gives

$$P_N\chi = \sum_{j=1}^{N} a_j \rho_j, \qquad (\epsilon_N^{\mathrm{BD}})^2 = 1 - b^* a.$$

Now let K_{ar} be a specified Hilbert completion of an arithmetic pairing carrier. Suppose a linear map $U : H \to K_{\mathrm{ar}}$ satisfies $\langle Uf, Ug\rangle_{\mathrm{ar}} = c\langle f, g\rangle_H$ for a fixed real $c > 0$, and the arithmetic target and finite approximation spaces are $U\chi$ and UE_N. Then

$$\operatorname{dist}_{K_{\mathrm{ar}}}(U\chi, UE_N) = \sqrt{c}\,\epsilon_N^{\mathrm{BD}}.$$

The arithmetic carrier, U, and its compatibility with the intended operators remain specified comparison data.

Proof. The functions ρ_n are bounded near zero and equal $1/(nx)$ for $x > 1$, so they lie in H. Finite spans in a Hilbert space are closed. The projection equations are $Ga = b$. They are soluble even when the spanning list is dependent: the vector b is orthogonal to $\ker G$, since a vector in that kernel gives the zero linear combination of the ρ_j. Orthogonality gives $\|\chi - P_N\chi\|^2 = \|\chi\|^2 - \|P_N\chi\|^2 = 1 - b^*a$. Finally, for every $v \in E_N$, $\|U\chi - Uv\| = \sqrt{c}\,\|\chi - v\|$; taking infima proves the transport identity. This calculation constructs no rate of decay. □

Remark 57.4.14 *(The classical Mellin carrier).* The Mellin transform $\mathcal{M}f(t) = \int_0^\infty f(x)x^{-1/2+it}\,dx$, interpreted in the L^2 sense, is unitary from H to $L^2(\mathbb{R}, dt/(2\pi))$. Indeed, $x = e^u$ identifies f with $e^{u/2}f(e^u) \in L^2(du)$, and Fourier Plancherel applies. For $s = 1/2 + it$,

$$\mathcal{M}\chi(t) = \frac{1}{s}, \qquad \mathcal{M}\rho_n(t) = -\frac{\zeta(s)}{s}n^{-s}.$$

The second identity is the fractional-part Mellin identity and a change of variable (Báez-Duarte, arXiv:math/0205003, equation (2.6) and the identity immediately following it). This realizes the classical approximation problem on a spectral line. It does not place that line in the arithmetic Petersson carrier.

THEOREM 57.4.15 *(Conditional quantitative distance comparison).* Under the scaled-isometry hypotheses of Proposition 57.4.13, the arithmetic finite distances tend to zero if and only if RH holds. For any specified positive sequence r_N, they are $O(r_N)$, $\Omega(r_N)$, or $\asymp r_N$, respectively, if and only if ϵ_N^{BD} has the same property. The constants are multiplied by $\sqrt{c}$. In particular, transport of a sharp $(\log N)^{-1/2}$ rate requires that quantitative estimate as an additional input.

Proof. Use the exact distance identity and the discrete criterion. Multiplication by the fixed positive number $\sqrt{c}$ preserves each stated convergence or two-sided estimate and rescales its constants. No operator-positivity implication is used. □

Question 57.4.16 *(Sharp rate and operator comparison).* For the above concrete finite spaces, establish the two-sided estimate $\epsilon_N^{\mathrm{BD}} \asymp (\log N)^{-1/2}$ under precise analytic hypotheses, and determine any claimed leading constant. Construct the arithmetic map U with its normalization. To identify this quantitative condition with (Reg), or with the VB* converse, one must additionally prove an operator comparison relating these approximation projections to the specified positive, determinate spectral measure and its support. Neither convergence to zero nor the scaled isometry supplies that comparison. The classical lower-bound problem and the matching upper bound are distinct from the construction of U.

Remark 57.4.17 *(Convergence does not control its rate).* Let $E_N = \operatorname{span}(e_1, \dots, e_N) \subset \ell^2$. For any nonincreasing sequence $r_N \downarrow 0$ with $r_0 < \infty$, the vector with coefficients $x_j = (r_{j-1}^2 - r_j^2)^{1/2}$ has

$\operatorname{dist}(x, E_N) = r_N$, by telescoping the squared tail. Thus Hilbert-space density alone imposes no particular rate. This example makes no assertion about the zeta approximation spaces; it shows why the quantitative premise cannot be omitted from a formal distance-transport argument.

Remark 57.4.18 *(The forward arithmetic implication).* The distance comparison does not establish VB*, its converse, or the arithmetic Hilbert–Pólya construction. The sufficient path of Theorem 44.6.1 retains its arithmetic Positselski, pairing, determinant-trace, and positivity inputs. A classical criterion for RH does not construct those inputs.

Quantitative and Operator Inputs

Corollary 57.4.19 *(Transport of a supplied sharp rate).* Assume the map and positive scale of Proposition 57.4.13. If $A/\sqrt{\log N} \le \epsilon_N^{\mathrm{BD}} \le B/\sqrt{\log N}$ for all $N \ge N_0 > 1$, with $A, B > 0$, then the arithmetic distances satisfy the same bounds with constants $\sqrt{c}A$ and $\sqrt{c}B$. The converse follows by division by $\sqrt{c}$. Equivalence with VB*, (Reg), or (HB+) would require the separate operator comparison in Question 57.4.16.

Proof. Apply the exact finite-distance identity to each N. □

Remark 57.4.20 *(Distinct analytic requirements).* (Reg) requires a positive moment functional, determinacy, and the stated spectral support. (HB+) requires the specified de Branges operator comparison. The Báez-Duarte problem has the explicit fractional-part carrier and finite projections above. Their identification with the arithmetic operators is a construction problem; a common scalar norm or convergence assertion does not identify these structures.

Hypothesis 57.4.21 *(Arithmetic operator and quantitative comparison).* Fix the arithmetic Hilbert carrier, operators, and zero-moment functional used for VB*, together with the stated P2, P3 and H-P^{Ar} data. Supply the following additional comparisons on this same carrier.

(i) Prove that simultaneous positivity of the specified operators T_n is equivalent to (Reg): positivity and determinacy of the specified moment functional, with its required spectral support.

(ii) Supply a unitary to the specified de Branges carrier, intertwining all the T_n, including their domains. The target operator-positivity condition is denoted (HB+).

(iii) Supply the scaled isometry of Proposition 57.4.13, and prove that (Reg) is equivalent to (BD+): RH together with the specified sharp two-sided bound $\epsilon_N^{\mathrm{BD}} \asymp (\log N)^{-1/2}$. Any leading constant requires its own precise asymptotic statement.

These are construction hypotheses. In particular, item 3 is not a consequence of the scaled-isometry identity or the classical closure criterion. Question 57.4.16 retains the missing quantitative and operator construction.

Theorem 57.4.22 *(Conditional comparison of operator and approximation conditions).* Under Hypothesis 57.4.21, the predicates VB*, (Reg), (HB+), and (BD+) are equivalent. Consequently, in the RH sector their supply establishes the VB* converse. This is conditional transport of the supplied comparisons; it establishes neither item 1 nor item 3 of the hypothesis.

Proof. Item 1 supplies VB* if and only if (Reg). A unitary preserves the nonnegative quadratic forms of the intertwined operators on their transported domains, so item 2 identifies VB* with (HB+). Item 3 supplies the quantitative comparison with (BD+). Transitivity gives the asserted conditional equivalences. Merely assuming RH does not supply any of those comparison maps or estimates. □

COROLLARY 57.4.23 *(Conditional substitution of analytic inputs).* Under Hypothesis 57.4.21, any of (Reg), (HB+), or (BD+) can replace VB* in a conditional implication that uses only the stated operator positivity. The remaining hypotheses of that implication are retained.

Proof. Use the preceding conditional equivalence on the same carrier. □

57.5 RELATION BETWEEN H-P^{Ar} AND VB* CONVERSE

THEOREM 57.5.1 *(H-P^{Ar} and VB* reduce to RH plus regularity).* Under Hypothesis 57.4.21, H-P^{Ar}, and the Fock-space support identification, VB* is equivalent to RH *plus* the spectral-regularity condition of Corollary 57.4.4. Without H-P^{Ar}, the implication RH $\Rightarrow$ VB* is not meaningful, since VB* presupposes a self-adjoint $L_{\mathrm{o}}^{\mathrm{Ar}}$.

Proof. Direct from Theorem 57.4.22 combined with Theorem 57.3.14: once H-P^{Ar} is in place, $L_{\mathrm{o}}^{\mathrm{Ar}}$ has a well-defined spectral measure, and VB* $\Leftrightarrow$ RH plus spectral regularity reduces to the moment-problem equivalence with the support condition. □

PROPOSITION 57.5.2 *(H-P^{Ar} and regularity are separate data).* H-P^{Ar} (existence of a self-adjoint $L_{\mathrm{o}}^{\mathrm{Ar}}$ with prescribed determinant divisor and trace distribution) and the spectral-regularity condition (positivity, determinacy, and support of the spectral measure) are separate pieces of data:

- There exist indeterminate moment sequences with positive Hankel structure (Stieltjes' $e^{n^2/2}$ example); these admit multiple self-adjoint realisations. H-P^{Ar} asserts existence of one realisation with the right trace; regularity asserts uniqueness and support properties of the realisation.
- Conversely, a determinate moment sequence does not automatically admit a self-adjoint realisation that matches a specific target trace; the target trace (the Bost–Connes trace of Equation 57.1) is an additional constraint on the spectrum.

Proof. Akhiezer 1965 §2.4 and Simon 1998 Thm. 5.3 show that a moment sequence may admit several positive measures. Existence of one self-adjoint realisation and uniqueness of the realisation are therefore distinct assertions. The prescribed Bost–Connes trace is a further constraint. □

COROLLARY 57.5.3 *(separation of the two analytic inputs).* The two analytic inputs to VB* in the sufficient path of Theorem 44.6.1, H-P^{Ar} and the VB* converse, are not the same assertion. Hence both are required for the VB* input, and neither is redundant.

Proof. Proposition 57.5.2. □

Remark 57.5.4 *(the refined sufficient path).* The sufficient path to RH of Theorem 44.6.1 has four inputs: arithmetic Positselski, Koszul–Petersson compatibility, H-P^{Ar}, and VB*. The last two split as:

- H-P^{Ar}: existence of a self-adjoint operator obtained from $L_{\mathrm{o}}^{\mathrm{Ar}}$ by the required intertwiner, whose normal zero-divisor operator has determinant divisor div $\xi_{\mathbb{R}}$ and whose Weil–Connes trace is the corresponding zero distribution. Equivalent forms: Connes adele-class trace realisation; Deninger motivic regularised determinant with purity.
- VB*: RH *and* the spectral-regularity condition for the symmetrised zero moment sequence. The Hermite–Biehler formulation requires its operator comparison. The Báez-Duarte sharp-rate question is separate; a specified Petersson isometry transports distances but does not imply the rate or operator positivity.

Each of the two inputs is a single spectral condition. The Connes–Deninger and de Branges formulations require their stated comparison maps. The Nyman–Beurling distance problem has its separate quantitative and arithmetic comparison inputs.

57.6 Analytic Conditions

The two analytic conditions have the following forms:

(i) **(H-P^{Ar}, Friedrichs construction).** Construct the determinant-trace operator and the trace-compatible embedding for which condition (57.1) holds on the Friedrichs extension of Theorem 57.3.2. Equivalent forms:

- Connes: the $C_{\mathbb{Q}}$-scaling action on $L^2_0(X_{\mathbb{Q}})$ has absorption trace equal to the zero distribution of ζ, with correct multiplicity.
- Deninger: $\Phi|H^1_M(\overline{\mathrm{Spec}\,\mathbb{Z}}, \mathbb{R}(1))^+$ has determinant divisor div $\xi_{\mathbb{R}}$ with correct multiplicity.

(ii) **(VB* converse, regularity construction).** Establish positivity, Hamburger determinacy, and the support identification for the symmetrised zero moment sequence $\{\mu_n\}_{n\geq 0}$ of Definition 62.4.1. Proposed comparison forms:

- de Branges: operator-positivity of the reproducing kernel on $\mathcal{H}(E_\xi)$ beyond Hermite–Biehler.
- Báez-Duarte: construct the scaled arithmetic isometry and prove any proposed operator comparison; the sharp rate for ϵ_N^{BD} remains a separate quantitative question.

(iii) **(Combined VB* input).** Both (1) and (2) together supply the VB* input in the sufficient path of Vol IV. Neither alone suffices: (1) without (2) gives a specific self-adjoint operator but leaves T_n-positivity open; (2) without (1) gives abstract moment regularity without a Fock-space operator.

Remark 57.6.1 *(local form).* The Hilbert–Pólya condition is existence together with determinant divisor and trace distribution. The VB* converse is positivity, Hamburger determinacy, and support for the symmetrised zero moments. The Connes–Deninger and de Branges comparisons require their stated maps. The Báez-Duarte finite-distance construction is proved above; its arithmetic isometry, quantitative estimate, and operator comparison remain distinct inputs.

57.7 Spectral Boundary

(i) **H-P^{Ar} is determinant-trace realisation** (Theorem 57.3.14, Corollary 57.3.15): the Friedrichs extension of Theorem 57.3.2 closes the domain problem, but the determinant divisor div $\xi_{\mathbb{R}}$ and the matching Weil–Connes zero trace are the genuine Hilbert–Pólya content (Remark 57.3.16). The formulation is equivalent to Connes' adele-class trace realisation and to Deninger's motivic cohomology regularised-determinant condition.

(ii) **The proposed VB* converse requires spectral regularity and the stated Fock-space operator comparison**. Theorem 57.4.15 proves finite-distance transport, not that operator comparison. This regularity is not supplied by zero placement alone. The converse is an equivalence at the converse level only and does *not* close the forward direction VB* $\Rightarrow$zero-placement (Remark 57.4.18). Carleman's criterion remains an open possible construction (Proposition 57.4.5); abstract indeterminate moment problems show why this extra hypothesis cannot be suppressed. The de Branges operator comparison and the Báez-Duarte quantitative problem have their separate carriers and hypotheses; no sharp-rate equivalence is asserted here.

(iii) **The two analytic inputs are separate** (Proposition 57.5.2): H-P^{Ar} asserts existence of the operator; regularity asserts positivity, uniqueness, and support of the spectral measure. Both are required for the VB* input in the sufficient path; the other inputs of that path are not supplied here.

(iv) **Berry–Keating $H = \frac{1}{2}(xp + px)$ candidate** is a candidate choice of Bost–Connes zero-mode weights $\lambda(p^k) = k \log p$, reproducing the leading asymptotic zero density but not the individual zeros; rigorous identification requires the regularisation matching (57.1).

(v) **Stieltjes' example of an indeterminate moment sequence** ($\mu_n = e^{n^2/2}$) shows that the unbounded case admits genuine indeterminacy. A factorial upper bound on a specified positive functional, by contrast, implies determinacy by Carleman. Neither example constructs or estimates the arithmetic regularized functional (Remark 57.4.6).

(vi) **The refined sufficient path to RH** has four inputs (Remark 57.5.4): arithmetic Positselski, Koszul–Petersson compatibility, H-P^{Ar} with explicit Friedrichs domain and trace-compatibility, and VB* as RH plus spectral regularity. The last two are each reducible to single spectral conditions with classical comparison formulations.

(vii) **Independence of the two analytic inputs**: H-P^{Ar} does not imply the VB* converse, and the VB* converse does not construct the Hilbert–Pólya operator. The Connes, Deninger, de Branges, and Báez-Duarte formulations require their respective determinant, operator, or norm comparison maps. The distance identity supplies only the stated norm transport.

Chapter 58

The Platonic Variation and RH Completion

The arithmetic branch's correct geometric variation is an operadic adelic surface: holomorphic at ∞, Frobenius-oriented at finite primes, and glued by the pointed E_2 restricted tensor product of Iwahori Hecke categories: not a scheme-theoretic surface, not a literal almost-complex manifold at finite primes. The upgraded object $\mathfrak{S}_2^{\mathrm{Ar}}$ drives the Riemann Hypothesis completion inside Vol IV as a conditional theorem.

58.1 The Right Variation

Definition 58.1.1 *(Platonic 2-arithmetic surface).* A *Platonic 2-arithmetic surface* for the primary arithmetic branch is the stratified adelic-diamond factorisation datum

$$\mathfrak{S}_2^{\mathrm{Ar}} := \big(|\overline{C}|, \{S_v, \mathfrak{J}_v^{\mathrm{Ar}}, C_v, \eta_v, u_v\}_v, \bigotimes_{v\in|\overline{C}|}{}' (C_v, u_v)\big), \tag{58.1}$$

where:

- $|\overline{C}| = \mathbb{P} \sqcup \{\infty\}$ is the set of places of $\overline{\mathrm{Spec}\,\mathbb{Z}}$;
- $S_\infty = \mathbb{C}_\infty$, $\mathfrak{J}_\infty^{\mathrm{Ar}} = i$, and C_∞ is the archimedean holomorphic factorisation category with Harish–Chandra K_∞-spherical unit u_∞;
- for $p < \infty$, S_p is the Fargues–Scholze perfectoid-diamond Hecke chart, $\mathfrak{J}_p^{\mathrm{Ar}}$ is the Frobenius-semilinear untilt-orientation with Adams operation ψ_p and prismatic/Nygaard comparison datum, and $C_p = \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ is the full non-semisimple Iwahori Hecke category with spherical unit $u_p = |0\rangle_p$;
- $\eta_v\colon \mathrm{Sp} \to C_v$ is the pointed E_2-algebra map with image u_v; at almost every finite place u_v is the monoidal unit, and at the remaining places it is a compact central idempotent algebra object;
- the tensor product in (58.1) is the Tate restricted tensor product of pointed E_2-monoidal stable presentable ∞-categories in the sense of Section 50.1.1.

The word "surface" refers to the operadic dimension: the global category is E_2-monoidal, not a smooth scheme-theoretic surface over $\mathbb{Z}$.

Remark 58.1.2 *(almost complex versus arithmetic complex).* The symbol $\mathfrak{J}^{\mathrm{Ar}}$ is literal almost-complex geometry only on $S_\infty = \mathbb{C}_\infty$. At a finite prime it is the Frobenius-oriented substitute: a semilinear orientation of the diamond chart together with Adams and prismatic comparison data. The finite place supplies no tangent-bundle endomorphism satisfying $J^2 = -1$; its role is to make the E_2 Iwahori Hecke datum functorial. This convention governs every occurrence of $\mathfrak{J}^{\mathrm{Ar}}$ in the arithmetic branch.

Remark 58.1.3 *(source anchors and dependency separation).* The finite charts use Scholze diamonds and Fargues–Scholze local Langlands geometry as listed in Section A.8 and Section A.19. The archimedean factorisation D-module fibre is the Beilinson–Drinfeld/Francis–Gaitsgory/Costello–Gwilliam fibre of Section A.5 and Section A.7. The arithmetic $\mathcal{D}^\dagger$ and overconvergent F-isocrystal language is only a local

coefficient shadow, with primary sources recorded in Section A.6. The definition of $\mathfrak{S}_2^{\mathrm{Ar}}$ is complete on the data above; F3 and the wild-prime BZN comparison enter only when identifying $\mathcal{V}^{\mathrm{prim}}$.

Question 58.1.4 *(Comparison of arithmetic base data).* Construct a comparison from the base and coefficient system of Definition 41.6.1 to the specified datum $\mathfrak{S}_2^{\mathrm{Ar}}$, preserving the archimedean factorization, the finite-place collision maps and their Adams/Frobenius operations, and the global tensor structure.

The coefficient identity of Theorem 30.3.3 does not construct the finite-place maps. A pointing gives an E_0-datum; the failure of a prescribed unary vacuum to extend in Example 2.2.2 shows why its geometric extension requires further operations. Once the local E_2-monoidal categories and their compatible unital transitions are supplied, Corollary 50.8.3 transports that structure to their restricted tensor product. Its hypotheses remain part of the proposed arithmetic comparison.

58.2 Factorisable Arithmetic Modules

The local categories C_v of $\mathfrak{S}_2^{\mathrm{Ar}}$, when supplied, have a finite tensor assembly over the place labels. Their position diagrams and geometric comparison maps remain part of the local data.

Definition 58.2.1 *(factorisable arithmetic crystal).* A *factorisable arithmetic crystal* on $\mathfrak{S}_2^{\mathrm{Ar}}$ is a functor

$$\mathscr{D}^{\mathrm{Ar}} \colon \mathrm{Fin}^{u}(|\overline{C}|) \longrightarrow \mathrm{Alg}_{\mathcal{O}}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$$

such that

$$\mathscr{D}^{\mathrm{Ar}}(S) \simeq \bigotimes_{v \in S} C_v, \qquad \mathscr{D}^{\mathrm{Ar}}(S_1 \sqcup S_2) \simeq \mathscr{D}^{\mathrm{Ar}}(S_1) \otimes \mathscr{D}^{\mathrm{Ar}}(S_2)$$

for disjoint finite subsets $S_1, S_2 \subset |\overline{C}|$, with coherent transition maps given by insertion of the specified spherical units u_v. The category Fin^{u} is defined in Definition 50.7.2; its arrows add only places with supplied unit maps. An arithmetic realization also specifies a holomorphic factorization model at infinity and local geometric models at finite places, with maps to their coefficient categories. Proposed finite models include Iwahori Hecke categories on diamond charts and spectral ind-coherent categories with nilpotent singular support. An overconvergent F-isocrystal or arithmetic $\mathcal{D}^{\dagger}$ presentation on a chosen smooth formal chart requires its own comparison. The global identification with $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$ remains the F1/LACD/BC-diamond-glue comparison, not a definitional equivalence.

PROPOSITION 58.2.2 *(Finite tensor assembly).* Given the $\mathcal{O}$-monoidal coefficient categories and compatible unit maps of Setup 50.1.1, the assignment $S \mapsto \otimes_{v \in S} C_v$ has the discrete factorization and transition maps required in Definition 58.2.1.

Proof. Apply Theorem 50.7.3. Its tensor associators give the disjoint-set equivalences, and its covariant unit insertions give the required transitions. □

This construction does not identify a geometric factorization D-module with a finite-place coefficient category. The holomorphic, diamond, spectral and differential presentations require their stated comparison maps. At $p = 2, 3$ no semisimple truncation is intended. To include a wild contribution in C_p, the actual local category and trace comparison of Question 54.4.15 must be supplied. Over a common field, assembling the proposed local traces also includes the mixed degree-two term of Lemma 54.4.13; an additive degree-one formula alone is not the full tensor.

58.3 The Arithmetic-Chiral Bar Complex on the Variation

The ordinary arithmetic complexes of Theorem 55.4.2 have explicit square-zero differentials. The arithmetic-chiral comparison additionally requires common coefficients, local chiral operations and residue couplings.

Definition 58.3.1 *(Finite-stage bar data).* Fix a commutative ring R and a filtered poset $\mathcal{I}$ of finite sets of places containing ∞. For each $S \in \mathcal{I}$, give cochain complexes A_∞, G_S, A_p, $p \in S_f$, over R. Their intended chiral, residue and local arithmetic realizations are additional data. Use algebraic tensor products and direct-sum totalization:

$$M_S = A_\infty \otimes_R G_S \otimes_R \bigotimes_{p \in S_f} A_p.$$

Order the factors as ∞, PG, $p_1, \dots, p_r$. On a homogeneous tensor, let $\widetilde{d}_a$ apply the differential in factor a with sign $(-1)^{\sum_{b<a} |x_b|}$. Set

$$D_{0,S} = \sum_a \widetilde{d}_a, \qquad D_S = D_{0,S} + \tau_S,$$

where the specified degree-one operator $\tau_S \in \mathrm{End}^1_R(M_S)$ satisfies

$$D_{0,S}\tau_S + \tau_S D_{0,S} + \tau_S^2 = 0.$$

Require degree-zero transition maps j_{ST} with $j_{SS} = 1$, $j_{TU}\, j_{ST} = j_{SU}$, and

$$j_{ST} D_{0,S} = D_{0,T}\, j_{ST}, \qquad j_{ST}\tau_S = \tau_T\, j_{ST}.$$

The resulting algebraic finite-support complex is $B^{\mathrm{Ar}} = \mathrm{colim}_{S \in \mathcal{I}} (M_S, D_S)$. Its arithmetic-chiral interpretation requires identification of these carriers and operators with the intended arithmetic and chiral objects.

Lemma 58.3.2 *(Insertion of closed units).* If $G_S \to G_T$ is a cochain map and each new factor has $u_p \in A_p^0$ with $d_p u_p = 0$, insertion commutes with D_0. It commutes with D when it also intertwines τ.

Proof. An inserted factor contributes $d_p u_p = 0$, and its degree zero leaves the other tensor signs unchanged. The remaining difference is $D_T\, j_{ST} - j_{ST} D_S = \tau_T\, j_{ST} - j_{ST}\tau_S$. □

Proposition 58.3.3 *(Finite-stage differential).* The data of Definition 58.3.1 give $D_S^2 = 0$ and cochain transition maps over any commutative ring R, including rings in which 2 is not invertible.

Proof. Each $\widetilde{d}_a^2 = 0$. For $a < b$, the first differential increases by one the exponent in the sign of the second, so $\widetilde{d}_a\widetilde{d}_b + \widetilde{d}_b\widetilde{d}_a = 0$. Thus $D_{0,S}^2 = 0$, and expansion gives

$$D_S^2 = D_{0,S}^2 + D_{0,S}\tau_S + \tau_S D_{0,S} + \tau_S^2 = 0.$$

The two transition identities imply $D_T\, j_{ST} = j_{ST} D_S$. □

This operator identity involves every summand of D_0. Scalar reciprocity for residue homomorphisms does not establish it. No coalgebra structure, convolution product or degree-one tame twisting operator is implicit. The ordinary complexes $C_{r,s}$ of Theorem 55.4.2 give a concrete untwisted example: $D_0 = I + J + L$, $\tau = 0$. Their mixed-square identities, norm maps, coefficient reductions and completed exterior comparison are proved there; their identification with a tame-weighted chiral bar remains a separate construction.

PROPOSITION 58.3.4 *(Comparison of finite-stage systems).* Compatible cochain maps $q_S : N_S \to M_S$ between filtered systems of cochain complexes over R induce a cochain map on their colimits. If every q_S is a quasi-isomorphism, so is the induced map.

Proof. Transition compatibility defines the map. Exactness of filtered colimits of R-modules gives $H^n(\operatorname{colim} q_S) = \operatorname{colim} H^n(q_S)$. □

Application to Definition 33.8.1 requires actual common coefficient realizations and stage maps, differential and transition identities, and quasi-isomorphism proofs. Finite support alone does not identify a single Iwasawa action with the tensor of local Iwasawa actions.

THEOREM 58.3.5 *(Closure for specified arithmetic-chiral data).* Suppose the carriers, operators and transitions of Definition 58.3.1 are constructed on the intended arithmetic-chiral domain. Their algebraic finite-support colimit is a cochain complex. For a completed version, suppose complete Hausdorff filtrations are specified and the operators and transitions descend compatibly to every quotient. Their inverse-limit extensions also have square zero and commute with transitions.

Proof. Proposition 58.3.3 proves the finite-stage identities and hence the colimit assertion. The completed identities hold in each quotient and therefore in the separated inverse limit. □

The tame-weighted arithmetic realization is the construction problem of Question 55.4.3. The common arithmetic and real coefficient complex and its comparison maps are requested in Question 55.6.6; the analytic carrier and state comparison are requested in Question 55.5.3. The ordinary bar and integral oscillator models supply local constructions for these questions. An algebraic colimit is not thereby identified with a completed restricted tensor product.

58.4 RH COMPLETION

Definition 58.4.1 *(RH completion hypothesis).* The *RH completion hypothesis* is the conjunction of:

- the Platonic surface $\mathfrak{S}_2^{\mathrm{Ar}}$ of Definition 58.1.1;
- an arithmetic-chiral realization of Definition 58.3.1, including common coefficients, degree-one operators, transition identities and the required completed comparison maps;
- the arithmetic Heisenberg Koszul biconditional, conditional on the arithmetic Positselski completion input of Corollary 55.8.2;
- the arithmetic Petersson positive-form condition, conditional on the restricted Koszul–Petersson compatibility input recorded in Corollary 47.10.1;
- H-P^{Ar} in the equivalent determinant-trace form of Theorem 57.3.14;
- VB* on the specified arithmetic carrier. It may be supplied by (Reg), meaning positivity, determinacy and the required spectral support of the identified arithmetic moment functional, together with item 1 of Hypothesis 57.4.21. Substitution of (HB+) or (BD+) additionally requires the corresponding operator or quantitative comparison from that hypothesis.

THEOREM 58.4.2 *(Platonic RH completion, conditional).* Conditional on the RH completion hypothesis of Definition 58.4.1, the Riemann Hypothesis holds.

Proof. The surface $\mathfrak{S}_2^{\mathrm{Ar}}$ and the bar complex $B^{\mathrm{Ar}}(\mathcal{V}^{\mathrm{prim}})$ of Definition 58.3.1 place $\mathcal{V}^{\mathrm{prim}}$ (a Hochschild trace class; see Remark 44.1.2) in the correct arithmetic-chiral bar framework. The conditional Koszul

input gives P1 in the abelian Heisenberg domain (Corollary 55.8.2); P2 is Tate's functional-equation/Zhu-modularity input from Theorem 43.6.1; the conditional Petersson condition supplies the positive Hermitian form needed for P3 in the restricted arithmetic branch Corollary 47.10.1. H-P^{Ar} supplies the self-adjoint operator, the zero-divisor determinant, and the required Bost–Connes trace. The specified (Reg) condition and operator comparison give VB* on the primary Fock; positivity, determinacy and the required support are all retained. Theorem 44.3.10 gives the zero-placement clause of F-RH. By Remark 44.1.2, this clause is RH. □

Corollary 58.4.3 *(A determinant–positivity sufficient condition for RH).* Assume P1, P2 and P3 on their stated domains, together with the specified H-P^{Ar} determinant–trace realization. Assume its arithmetic moment functional is positive and determinate, its representing measure has the support required by (Reg), and item 1 of Hypothesis 57.4.21 identifies (Reg) with VB* on this operator domain. Then RH holds. RH by itself is not asserted to construct this realization, support identification, or comparison.

Proof. The positive determinate moment functional and supplied support give (Reg). The assumed operator comparison gives VB*. The remaining P1–P3 and determinant–trace hypotheses now permit Theorem 58.4.2 to be applied. □

Chapter 59

Conditional Hypotheses for F1–F3 Arithmetic

Several F1–F3 arithmetic reductions are correct as equivalences, but some component subconditions require open inputs: the Fargues–Scholze-to-Emerton–Gee categorical equivalence (F1.a, an unproved comparison hypothesis), the arithmetic Arinkin–Gaitsgory conjecture ($\mathrm{L}_{\mathrm{ACD}}.1$–$\mathrm{L}_{\mathrm{ACD}}.3$), and the formal-Noetherian extension of Gaitsgory–Rozenblyum (R1.formal). The exact logical form is the conditional system determined by Section C.2, Chapter 58, and Chapter 44.

59.1 Conditional Statements

For each reduction the displayed hypothesis is part of the theorem, not an afterthought to the proof.

F1–F3 in Chapter 43

F1.a domain: Fargues–Scholze local geometrisation versus categorical equivalence. Theorem 43.2.1 requires an unproved comparison hypothesis for F1.a, the local categorical equivalence

$$\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$$

(where $\mathcal{X}^{\mathrm{EG},p}_{GL_2}$ is the Emerton–Gee moduli stack at the prime p, $\mathrm{IndCoh}_{\mathrm{Nilp}}$ denotes ind-coherent sheaves with nilpotent singular support in the sense of Arinkin–Gaitsgory, and $\mathrm{D}^{\text{sph-fin}}$ the spherical-finite derived category of smooth $GL_2(\mathbb{Q}_p)$-representations). Fargues–Scholze arXiv:2102.13459 supplies the local geometrisation, spectral action, and Langlands-parameter structure for GL_2; the displayed categorical equivalence is not contained there. Dotto–Emerton–Gee arXiv:2603.26887 gives a fully-faithful-only, fixed-central-character functor for $GL_2(\mathbb{Q}_p)$ at $p \geq 5$. The authoritative reference for the current F1.a form is Section C.2 and Theorem 43.2.1.

Emerton–Gee deformation stack. Emerton–Gee arXiv:1908.07185 constructs the deformation-theoretic setting (*Moduli stacks of étale (φ, Γ)-modules and the existence of crystalline lifts*, Annals of Mathematics Studies). See App. A §A.8.

Coherent Springer theory. Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321 treats coherent Springer theory (*Coherent Springer theory and the categorical Deligne–Langlands correspondence*, Invent. Math. 235 (2024)). See App. A §A.20.

Adelic Categorical Descent

Function-field transport and (L_2). Theorem 48.2.3 requires an unproved comparison hypothesis. The assertion (L_1) follows from Raskin's ∞-categorical construction independently of function-field Langlands; the assertion (L_2) requires the local categorical comparison F1.a (an unproved comparison hypothesis via Dotto–Emerton–Gee) and Bernstein-centre diamond gluing.

(L_2) *reduction: Fargues–Scholze domain.* Theorem 48.4.1 requires an unproved comparison hypothesis. The comparison functors Φ_v^{loc} identifying $\mathcal{C}_v$ with $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},v}_{GL_2})$ are not supplied by Fargues–Scholze arXiv:2102.13459; that source gives the local geometrisation and spectral action. The local categorical comparison is the residual open input.

F1 reduction: two open inputs. Theorem 48.9.1 conditionally states that F1 reduces to F1.a plus (BC-diamond-glue). Since F1.a remains an unproved comparison hypothesis, the reduction leaves F1 conditional on two independent open inputs: F1.a and (BC-diamond-glue).

Arithmetic Ben-Zvi–Nadler

F3.BZN^{Ar}: procyclic shadow versus full Weil parameter stack. Conjecture 49.1.1 is conjectural. The comparison target for F3.BZN^{Ar} is the full Weil/(φ, Γ) parameter stack $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$, not the procyclic shadow $\mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}})$, which forgets Frobenius and unramified data. The theorem is conditional on F1 and F2. Proposition 49.4.6 carries an unproved comparison hypothesis; the closed-immersion property of Proposition 49.4.9 is conjectural, since the closed-immersion property is unavailable on the inertia-only shadow.

Structural Reduction Theorems

$\mathrm{L}_{\mathrm{ACD}}$ *equivalence and subcondition forms.* Theorem 51.2.4 is proved under its stated hypotheses: the adelic categorical descent condition $\mathrm{L}_{\mathrm{ACD}}$ is equivalent to the conjunction of subconditions $\mathrm{L}_{\mathrm{ACD}}$.1 through $\mathrm{L}_{\mathrm{ACD}}$.4. The equivalence itself is a logical factorisation. The subconditions $\mathrm{L}_{\mathrm{ACD}}$.1–$\mathrm{L}_{\mathrm{ACD}}$.3 remain conjectural; $\mathrm{L}_{\mathrm{ACD}}$.4 is the combination of Kneser's strong approximation theorem for SL_2 and Tate's determinant idele-class quotient for GL_2. The residual content is recorded in the subcondition forms.

F3.BZN^{Ar} equivalence via Gaitsgory–Rozenblyum. Theorem 51.2.5 is proved under its stated hypotheses: F3.BZN^{Ar}, assembled through Gaitsgory–Rozenblyum DAG Vol. II, is equivalent to the conjunction of R1, R2, and R3. The equivalence is a valid logical factorisation. R1 holds as a theorem for smooth finite-type stacks (Gaitsgory–Rozenblyum) and is conjectural for the formal-Noetherian Emerton–Gee setting (R1.formal); R2 is an unproved comparison hypothesis; R3 is definitional. The R1 fine structure and the honest residual are recorded in Chapter 53 and Corollary 53.5.1.

Arithmetic Positselski C1–C5. Chapter 44 treats the arithmetic Positselski equivalence C1–C5 as five subconditions, of which C1–C4 are conditional on explicit hypotheses and C5 (functoriality) is the named residual. The arithmetic Heisenberg equivalence is restricted to the abelian-Heisenberg sector; C5 is the functoriality condition for the full claim.

$\mathrm{L}_{\mathrm{ACD}}$ *Subconditions*

$\mathrm{L}_{\mathrm{ACD}}$.0*: archimedean stratum construction.* Theorem 52.3.3 is proved under its stated hypotheses: the archimedean local category $\mathcal{C}_\infty$, distinguished unit, and Langlands–Vogan classification are constructed from the theorems of Harish-Chandra (1966), Vogan (1981), and Wallach (1988). Thus $\mathrm{L}_{\mathrm{ACD}}$.0 is independent of the global $\mathrm{L}_{\mathrm{ACD}}$ comparison.

L_{ACD}.1*: the F2.c hypothesis.* Theorem 52.4.1 is conditional on F2.c: the assertion L_{ACD}.1 uses the restricted tensor theorem Theorem 50.1.3 on the central idempotent pointed-unit E_2 domain. Hence Theorem 52.4.1 is conditional, with F2.c as its displayed hypothesis.

L_{ACD}.2*: local Hecke commutativity, not global functoriality.* Theorem 52.5.1 is proved under its stated hypotheses: formal tensor-factor commutativity of local Hecke endofunctors, once the restricted tensor product is constructed. The domain remark Remark 52.5.2 records that global Hecke functoriality is not part of the statement; the L_{ACD}.2 label refers to the local commutativity subcondition only.

L_{ACD}*: Bernstein-centre compatibility.* Corollary 52.7.1 assumes F2.c, the ∞-categorical Bernstein lift, the finite-prime local categorical comparison, the archimedean boundary datum, and the global identification with the automorphic category. Under these hypotheses, the remaining Bernstein-centre condition is (BC-diamond-glue). Its local construction, cross-prime gluing, and global action compatibility are the three requirements in Theorem 56.3.2. The local categorical comparison F1.a remains an input. Bernstein-centre gluing alone does not supply the other hypotheses.

BZN Formal Noetherian and EG Derived

R2: the Selmer-derived target and its formal geometry. Fix a residual representation $\bar{\rho}$, determinant, finite ramification set, and local deformation conditions $\mathcal{L}$. Chapter 53.3.5 defines the Selmer-derived stack $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ as a derived fibre product of global and local deformation functors. Linearization gives its Selmer tangent complex. The local conditions must be derived formal algebraic substacks of the full $\mathrm{Weil}/(\varphi,\Gamma)$ parameter stacks. Formal Noetherianness, quasi-smoothness, and compatibility of nilpotent singular support with the Selmer cotangent complex remain hypotheses for the chosen deformation problem. A product or colimit presentation alone does not establish them.

R1: extension of the finite-type trace theorem. The Gaitsgory–Rozenblyum trace theorem for smooth finite-type stacks is the finite-type input R1.fin-type. Its extension to the Selmer-derived target requires R1.formal, including formal-loop continuity and the flat-locus comparison. Chapter 53.4.1 states this conditional reduction. The formal-Noetherian hypotheses on the arithmetic target remain separate from the finite-type theorem.

Loop Convention and Wild Primes

R3: comparison of arithmetic loop spaces. Let $\mathcal{X}$ be a formal Noetherian derived algebraic stack with cotangent complex of finite Tor-amplitude and a t-bounded Postnikov tower. Chapter 54.3.4 compares its three loop constructions under three additional assumptions: $B\widehat{\mathbb{Z}}$-mapping stacks are computed by the profinite limit of finite cyclic mapping stacks, formal completion commutes with the relevant derived tensor products, and the perfect locus generates the same loop object after ind-completion. These assumptions give the comparison equivalences. They do not identify the inertia shadow with the full $\mathrm{Weil}/(\varphi,\Gamma)$ parameter stack.

R4: large-prime wild Hochschild vanishing. For $p \geq 5$, Corollary 54.4.12 gives positive-degree vanishing only under Hypothesis 54.4.10, which specifies an actual local arithmetic trace equivalent to a module in degree zero. Semisimplicity of an unspecified category or a numerical prime threshold does not supply this comparison. At two and three, the arithmetic local models and Ext-to-trace maps remain open; their full assembly must respect the four-term tensor formula of Lemma 54.4.13.

BC-Diamond-Glue Decomposition

Local construction, gluing, and global action. The construction data in Chapter 56.3.2 give

$$\text{(BC-diamond-glue)} \iff \text{(BCglue.local)} \wedge \text{(BCglue.glue)} \wedge \text{(BC-diamond-glue.core)}.$$

This equivalence unpacks the required sheaves, gluing maps, and action compatibility. It does not construct any of them. The local comparison must connect the Ben-Zvi–Chen–Helm–Nadler construction at $\ell \neq p$ with the Emerton–Gee target at $\ell = p$, including the required coefficient comparison. The cross-prime construction requires prismatic transition maps, their triple-overlap cocycle, and continuity of the induced IndCoh construction. These data remain conjectural in Chapter 56.5.4.

Global Bernstein-centre compatibility. The core condition compares the glued action with the global Bernstein-centre action under the arithmetic Arinkin–Gaitsgory identification. That identification is itself a hypothesis. The reduction of Chapter 56.6.1 also retains F2.c, the Bernstein lift, local categorical comparison, the archimedean boundary datum, and global identification from Chapter 52.7.1. Supplying the local and cross-prime data leaves the core action compatibility to be established under those hypotheses.

Primary Source Identifiers in App. A

Local geometric and categorical inputs. Emerton–Gee arXiv:1908.07185 constructs the local moduli stacks. Ben-Zvi–Chen–Helm–Nadler arXiv:2010.02321 supplies coherent Springer theory, and Fargues–Scholze arXiv:2102.13459 supplies local geometrization and spectral actions. Dotto–Emerton–Gee arXiv:2603.26887 supplies the fully faithful, fixed-central-character functor at $p \geq 5$ used in the F1.a comparison of Chapter 43.2 and Chapter 42.1. The full local categorical equivalence requires further input.

59.2 Logical Form for F1–F3 Arithmetic

The local categorical comparison F1.a requires more than the fully faithful, fixed-central-character functor at $p \geq 5$. F1.c defines the Selmer target using the chosen local deformation conditions. Its derived and Noetherian properties remain conditional on those local conditions, as in Chapter 43.2.1.

The formal descent arguments require F2.c and the ∞-categorical Bernstein lift. Local categorical comparison, the archimedean boundary datum, and global identification with the automorphic category are additional inputs to Chapter 52.7.1. The three Bernstein-centre requirements are local construction, cross-prime gluing, and compatibility of the global action. The core action comparison also assumes arithmetic Arinkin–Gaitsgory.

The structural splits in Chapter 51.2.4 and Chapter 51.2.5 organize these comparison problems. The conditional implications above use their specified construction data. A converse identifying the original global assertions with only the abbreviated lists of subconditions requires additional comparison maps and hypotheses. The strong-approximation input for SL_2 and the determinant idele-class quotient for GL_2 remain distinct from these categorical comparisons.

For the arithmetic trace comparison, the Selmer fibre product and its tangent complex specify R2. The required formal geometry and nilpotent-support compatibility remain hypotheses. R1.formal supplies the extension beyond the finite-type trace theorem. The loop comparison R3 additionally requires the three completion and generation assumptions stated above. It leaves the full $\mathrm{Weil}/(\varphi, \Gamma)$ target comparison separate. R4 includes the wild-prime contributions, with large-prime vanishing conditional

on the arithmetic semisimplicity datum. Together with F1 and F2, these are the inputs to the conditional arithmetic Ben-Zvi–Nadler construction.

59.3 Open Conditions for F1–F3 Arithmetic

The remaining F1–F3 conditions are as follows, consistent with the running list Chapter C.2 and the RH completion conjunction Chapter 58.4.1.

- F1.a (local categorical equivalence $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$): via Dotto–Emerton–Gee arXiv:2603.26887 (fully-faithful-only, $p \geq 5$, fixed central character). Fargues–Scholze arXiv:2102.13459 supplies the local geometrisation, spectral action, and Langlands-parameter structure; the categorical equivalence is the residual.
- F1 is conditional on F1.a and $\mathrm{L}_{\mathrm{ACD}}$; $\mathrm{L}_{\mathrm{ACD}}$ requires F2.c tightened, (BCglue.local), (BCglue.glue), and (BC-diamond-glue.core).
- F3.BZN^{Ar} requires F1, F2, R1.formal.b (profinite formal-loop continuity), R1.formal.c (flat-locus pullback), R4 (wild-prime $\mathrm{Ext}^{\mathrm{I}}$ refinement, domain beyond the explicit computation already stated), and the full-target Weil/(φ, Γ) comparison.
- Chapter 58.4.1 is the sufficient set for RH, with VB^* operator positivity as a forward positivity residual, $H\text{-}P^{\mathrm{Ar}}$ as a separate spectral hypothesis, and the arithmetic Positselski C1–C5 plus Koszul–Petersson compatibility as the four-input RH form conditions.

Chapter 60

Sharp Hypotheses for the Four-Input RH Form

The six comparisons below have different mathematical inputs. P1 requires an arithmetic evaluation, while P3 compares arithmetic and Petersson pairings. K5 supplies a spherical Whittaker normalization, and C1–C5 specify additional algebraic and analytic operations. The Hilbert–Pólya and positive-trace questions concern the spectral realization.

Tate's Poisson formula gives the scalar functional equation. The arithmetic P1 interpretation needs its defect and evaluation maps. The local Whittaker norms and occupation/radial isometries retain their arithmetic placement and adelic transport hypotheses. The Friedrichs construction supplies an operator domain. Identifying its determinant and trace with the required spectral object is a further comparison.

60.1 Six Sharp Forms

The six assertions have the following logical form.

The same list appears in Section C.10. The Platonic capstone is Theorem 58.4.2. Its sufficient arithmetic path is the four-input conjunction in §60.3.

60.2 Local Forms

Zero-Placement

Proposition 60.2.1 *(one-sided zero-placement). Conditional statement.* Assume P2, full P3, the H-P^{Ar} determinant-trace realisation, and the positive VB* trace form. Then Theorem 44.3.10 gives the zero-placement clause of F-RH. The reverse implication is not a consequence of RH; it asks for spectral regularity of the operator model.

Proof. The implication used in Theorem 44.3.10 is the positive quadratic form statement on the Bost–Connes regularised trace. P2 and P3 identify the test vectors and the Petersson form with the arithmetic trace form. H-P^{Ar} identifies the zero divisor and the Weil–Connes trace distribution. Positivity then forces the ordinates entering the Weil form to be real, hence the zeros lie on the critical line. None of these steps constructs the converse positive form from zero-placement alone. □

Arithmetic Positselski

Proposition 60.2.2 *(two arithmetic comparison criteria).* Suppose the arithmetic comodule and contramodule recipients, exact adjunction, and complete unit and counit cofibers satisfy Theorem 46.1.5. Then the adjunction is an equivalence.

Suppose also that the arithmetic central classes have the common defect and Mellin evaluation of Theorem 43.5.1, and that the evaluation detects that defect. Then their cancellation is equivalent to the completed scalar functional equation.

Proof. The first assertion is the stated completion criterion applied to the actual unit and counit. The second follows by evaluating $v - Jv = (\kappa + \kappa^!)w$ with $E(w) \neq 0$. The two assertions require different

No.	Assertion	Established domain	Additional hypothesis
1	P1 level criterion (Theorem 55.8.1)	Tate–Poisson gives the scalar functional equation.	Actual arithmetic objects, a central-defect identity, and a Mellin evaluation detecting that defect.
2	P3 Koszul–Petersson (Corollary 47.10.1, Theorem 47.9.1)	Segal form, normalized vacuum-line and occupation/radial isometries.	Arithmetic placement, action-compatible pairing maps and adelic extension, including the remaining spectral sectors.
3	K5 absorption (Theorem 56.7.5, Theorem 56.7.8)	Specified tempered spherical Whittaker norm and local Hilbert models.	Arithmetic and Hecke comparisons, continued global normalization and full-sector placement.
4	Costello refinements C1–C5 (Theorem 55.3.3, Remark 55.4.3, Question 55.5.3, Question 55.6.6, Theorem 55.7.4)	Restricted abelian-primary, $\mu = 0$, pointed E_2, and Λ-linear domains specified below.	The five Positselski hypotheses and the five Costello hypotheses.
5	H-P^{Ar} (Theorem 57.3.14)	Friedrichs self-adjoint domain.	Determinant divisor and Weil–Connes trace distribution for the scaling action.
6	VB* $\Rightarrow$ zero-placement (Theorem 44.3.10, Theorem 57.4.22 under Hypothesis 57.4.21)	One-sided implication after P2, P3, H-P^{Ar}, and positive Bost–Connes trace.	Forward positivity; the converse is only a spectral-regularity comparison.

TABLE 60.1: Sharp domains for the four-input RH form.

maps. Faithfulness of reduction modulo p is not used. It fails already on the nonzero endomorphism p of $\Lambda/(T)$. □

Koszul–Petersson Compatibility

PROPOSITION 60.2.3 *(Conditional transport of P3).* Assume the arithmetic placement, pairing maps and completed adelic extension of Hypothesis 67.1.1 on the specified normalized sph-fin cuspidal core. The transported positive Petersson form then agrees with the arithmetic bilinear pairing composed with its specified conjugation.

Proof. The model identities are $H(v, w) = B(v, Jw)$. The occupation, diagonal Hilbert–Schmidt and radial-function maps in Theorem 56.7.5 verify these identities on their local carriers. Theorem 47.5.3 constructs their normalized restricted tensor form. The assumed arithmetic maps identify that form on the stated completed domain. No equality of local scalar factors alone supplies those maps. □

Remark 60.2.4 *(The full pairing construction).* The normalized archimedean vacuum line and prime cyclic Gibbs model are genuine local constructions. Their full arithmetic realization, ramified factors and continuous-spectrum transport remain required. The restriction to a cuspidal sph-fin core does not remove the placement and pairing hypotheses even there.

Costello Refinements C1–C5

Proposition 60.2.5 *(Costello refinements).* Assume the integral co–contra comparison, the central-defect identity, and the detecting Mellin evaluation of Theorem 55.8.1. Then the P1 biconditional holds on any common arithmetic domain also satisfying the following C1–C5 requirements:

(i) C1: local factorization coalgebras, compatible unital transitions and the collision functors satisfy Theorem 55.3.3; the adelic differential comparison of Question 55.3.4 is supplied. Any required E_2-monoidal coefficient structures are specified before taking their pointed colimit;

(ii) C2: the tame-weighted chiral carriers and degree-one operators of Question 55.4.3 are constructed, with their full square-zero, norm and transition identities and comparison maps. Theorem 55.4.2 supplies a proved ordinary local model;

(iii) C3: the completed arithmetic carrier and arithmetic/BV comparison maps of Question 55.5.3 are constructed, preserving the observables, state and dynamics; any pro-nilpotent presentation has the specified filtration and compatible transition maps;

(iv) C4: the common coefficient complex and finite-place and real realization maps of Question 55.6.6 are constructed, identifying the differential, central normalization and pairing, including the real operators corresponding to the Iwasawa and Gersten components;

(v) C5: the morphism class is Λ-linear with trivial Γ-action.

Proof. The P1 conclusion follows from the explicitly assumed evaluation and defect identity by Theorem 55.8.1. C1 supplies the local coalgebras, their compatible assembly, and the required coefficient structures. C2 supplies the arithmetic-chiral differential and comparison identities. C3 supplies the completed carrier and state comparison. C4 identifies arithmetic and real realizations through a common coefficient complex. C5 specifies the allowed morphisms.

The integral co–contra criterion in Section 60.2 requires its own adjunction, complete cofibers, and reduced equivalences. □

K5 Godement–Jacquet Normalisation

Proposition 60.2.6 *(Local factors and the global continued value).* For a specified unramified tempered representation, $L_p(1, \mathrm{Ad}\,\pi_p)$ is finite and nonzero, and the spherical norm is $m_p(1 + p^{-1})L_p(1, \mathrm{Ad}\,\pi_p)$. The global continued value $c_\pi = L(1, \mathrm{Ad}\,\pi) \neq 0$ and the arithmetic pairing comparisons are separate inputs to the adelic normalization theorem.

Proof. The unit-circle parameters make each local denominator nonzero because $p^{-1} < 1$; the shell-series proof computes the norm in Lemma 56.7.4. Neither assertion uses global nonvanishing. Theorem 56.7.8 rescales two already compared forms by the common supplied scalar c_π^{-1}. Finiteness of local factors supplies neither that continued global value nor a projection excluding continuous spectrum. □

Remark 60.2.7. The propagation of K5 to full Koszul–Petersson compatibility is therefore the full P3 problem of §60.2.

H-P^{Ar} *and the* VB* *Converse*

Proposition 60.2.8 *(Friedrichs domain and determinant divisor). Conditional statement.* The Friedrichs construction of Theorem 57.3.2 gives a self-adjoint operator on its quadratic-form domain. The Hilbert–Pólya input is the further assertion that the associated normal zero-divisor operator has

determinant divisor div $\xi_{\mathbb{R}}$ and Weil–Connes trace equal to the zero distribution. This assertion is not a choice of zero-mode weights.

Proof. The Friedrichs theorem starts from a lower-semicontinuous positive form and produces a self-adjoint operator. It does not determine the regularised determinant or the Weil–Connes trace of the scaling action. The Connes and Deninger forms have the required Lefschetz shape only when the determinant divisor and the trace distribution are the non-trivial zero divisor and distribution of $\xi_{\mathbb{R}}$. Thus the operator-domain theorem and the determinant-trace theorem are distinct statements. □

PROPOSITION 60.2.9 *(Conditional operator comparisons).* Under Hypothesis 57.4.21, Theorem 57.4.22 compares the predicates VB*, (Reg), (HB+) and (BD+). (Reg) includes positivity and the specified spectral support as well as determinacy. In the RH sector, supplying one of these predicates with the comparison data establishes the VB* converse; the implication "RH implies VB*" is not itself one of the four equivalent predicates.

Proof. Item 1 of the stated hypothesis identifies operator positivity with (Reg). Item 2 transports the operators and their domains by a unitary, so that positivity is equivalent to (HB+). Item 3 supplies the separate comparison of (Reg) with (BD+). Applying these three comparisons gives the asserted equivalences. RH alone supplies none of these comparison maps or the sharp approximation bound. □

Primary-Source Anchors

Remark 60.2.10. Li–Weil positivity, Connes' trace formula, Deninger's cohomological form, and the Bost–Connes scaling action are four shadows of the same problem only after the determinant divisor and trace distribution have been specified. The symmetrised zero measure gives the VB* converse shadow; the self-adjoint scaling operator with determinant divisor div $\xi_{\mathbb{R}}$ gives the H-P^{Ar} shadow. Their coincidence is the Hilbert–Pólya content.

60.3 THE FOUR-INPUT CONDITIONAL CONJUNCTION

THEOREM 60.3.1 *(the four-input conditional conjunction). Conditional statement.* Assume the following four statements.

(i) $\mathrm{P}_1^{\mathrm{ArPos}}$: arithmetic Positselski for the specified arithmetic domain, together with the central-defect identity, Mellin evaluation, and detection condition of Theorem 43.5.1.

(ii) $\mathrm{P}_3^{\mathrm{KP}}$: full-sector Koszul–Petersson compatibility, extending the normalized sph-fin cuspidal identity by the three spectral hypotheses of §60.2.

(iii) $\mathrm{HP}^{\mathrm{Ar}}$: the H-P^{Ar} determinant-trace realisation, including determinant divisor div $\xi_{\mathbb{R}}$ and the Weil–Connes zero trace distribution.

(iv) VB_+^*: the positive Bost–Connes regularised trace form giving the forward VB* $\Rightarrow$ zero-placement implication.

Together with the Tate-Poisson direction, P2, and Hamburger determinacy, these four statements imply the zero-placement clause of F-RH. Hence the arithmetic branch implies RH under precisely this four-input conjunction.

Proof. The first hypothesis includes the evaluation and defect identity needed for Theorem 43.5.1, so it supplies P1 on that arithmetic domain. Full P3 identifies the adelic Petersson form with the arithmetic trace form on the whole primary space. $\mathrm{HP}^{\mathrm{Ar}}$ supplies the zero divisor and Weil–Connes trace

distribution attached to that trace. The positive VB_+^* form is then the Weil-positive form on the zero distribution. By the Platonic completion theorem Theorem 58.4.2, P1, P2, P3, $\mathrm{HP}^{\mathrm{Ar}}$, VB_+^*, and Hamburger determinacy imply F-RH, hence RH. □

Remark 60.3.2 *(independence of directions).* The theorem is a sufficient implication. It does not assert that RH recovers arithmetic Positselski, full Koszul–Petersson compatibility, the Hilbert–Pólya determinant-trace realisation, or the positive VB* trace form. The H-P^{Ar} and VB* residuals are separated by Proposition 57.5.2; the Positselski and Koszul–Petersson residuals are separated by Section 46.7 and Remark 47.10.4.

Remark 60.3.3 *(hypothesis support).* The P1 input is an arithmetic central-defect identity and an equivariant Mellin evaluation. A converse additionally requires detection of the specified defect vector. The coefficient and co–contra hypotheses are separate requirements. The P3 support is the KMS_1/GNS identification, the full Rankin–Selberg extension, and the Eisenstein-sector calculation. The $\mathrm{HP}^{\mathrm{Ar}}$ support is the determinant divisor div $\xi_{\mathbb{R}}$ and the Weil–Connes trace distribution. The VB_+^* support is positivity of the regularised Bost–Connes trace.

60.4 Logical Form of the Essential Biconditional

The essential biconditional

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \iff \xi(s) = \xi(1-s)$$

(Theorems 41.2.1 and 43.5.1) holds under its specified arithmetic evaluation and central-defect hypotheses. Tate's Poisson formula proves the scalar functional equation. The forward arithmetic implication follows by evaluating the defect identity. The reverse implication additionally requires that evaluation detect the defect. It does not reconstruct an entire co–contra equivalence from a scalar equality.

In $\mathbb{C}^2$, swapping coordinates preserves their sum, although it does not fix $(1, 0)$. This is the kernel example following Theorem 43.5.1.

60.5 Consequences

(i) The scalar Tate identity is unconditional. Its arithmetic interpretation requires the defect and evaluation maps. The converse also requires detection.

(ii) P3 on the normalized sph-fin cuspidal core retains its actual arithmetic placement, pairing and adelic extension hypotheses.

(iii) K5 has explicit local Hilbert models and a computed spherical norm; the arithmetic action-compatible comparison remains to be constructed.

(iv) C1–C5 are sufficient Costello refinements on their common restricted domain and inherit the arithmetic-Positselski hypotheses.

(v) The Friedrichs theorem gives the operator domain for H-P^{Ar}; the determinant divisor and trace distribution are the Hilbert–Pólya content.

(vi) The VB* converse is a spectral-regularity comparison and is logically distinct from the positive forward implication to zero-placement.

Chapter 61

The Local Categorical Comparison and the DEG Essential Image

F1.a asks for the specified local categorical comparison at every prime, with its coefficient category, spectral support and Hecke actions. The Dotto–Emerton–Gee theorem constructs a fully faithful functor on its p-power-torsion representation carrier at $p \geq 5$. Its essential image is proper in its stated target. The arithmetic comparison therefore requires a geometric identification of the relevant image and comparison carriers, not an assertion that this existing functor is surjective onto its whole target.

61.1 Representation and Spectral Carriers

Fargues–Scholze geometrization and spectral actions concern their own sheaf and parameter categories. The intended F1.a equivalence

$$\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG},p})$$

requires specified comparisons with these carriers. The coefficient regime, the meaning of the sph-finite realization, and the nilpotent-support restriction are part of the construction. They cannot be substituted into a fully faithful theorem on different categories without a comparison functor.

61.2 The Local and Family Construction Problems

At $p \geq 5$, the problem is to relate the actual DEG image to the chosen arithmetic spectral category, construct action-compatible functors and identify lifted generators. At two and three, the wild-enhanced carrier, the block functors and their exhaustion are separate data (H2)–(H4). Finite extension calculations can constrain these data but do not construct the functors. The three-vertex model of Question 54.4.9 retains its separate arithmetic realization problem.

Varying a central character requires effective category-valued descent on a specified parameter site, including nonreduced families and higher overlap maps. Point-character comparisons do not suffice. Even complete local comparisons leave the cross-prime and global centre maps required for adelic descent.

61.3 Dotto–Emerton–Gee Recalled

The DEG result, stated precisely, is the theorem on which the rest of the argument builds.

The Proven Coefficient and Spectral Carriers

Fix $p \geq 5$, the ring of integers $\mathcal{O}$ of a finite extension of $\mathbb{Q}_p$, and a central character $\zeta : \mathbb{Q}_p^\times \to \mathcal{O}^\times$. Let $\mathcal{A}$ be smooth $\mathcal{O}$-representations on which p acts locally nilpotently, with central character ζ. Let X be the formal stack of rank-two projective étale (φ, Γ)-modules of determinant $\zeta\varepsilon^{-1}$, where ε is the cyclotomic character.

Theorem 61.3.1 *(Dotto–Emerton–Gee, Theorem 1.1.1).* There is an $\mathcal{O}$-linear fully faithful exact functor $D^b_{\mathrm{fp}}(\mathcal{A}) \to D^b_{\mathrm{coh}}(X)$. It extends to a colimit-preserving fully faithful functor

$$F^{\mathrm{DEG}} : D(\mathcal{A}) \longrightarrow \mathrm{Ind}\, D^b_{\mathrm{coh}}(X).$$

Reference. Dotto–Emerton–Gee, arXiv:2603.26887, Theorem 1.1.1 and the paragraph following it. The extension uses their compact generation statement for $D(\mathcal{A})$. □

Remark 61.3.2 *(The essential-image boundary).* Remark 1.1.2 of that paper states that this functor is not an equivalence. Thus exhaustion of its entire displayed target is not an unproved consequence to be appended to this theorem. The geometric description of its proper essential image, its relation to a specified nilpotent-support category, and changes of coefficient or representation carrier are separate comparisons. The theorem also does not supply the wild-prime or varying-character construction.

Proposition 61.3.3 *(The constructed essential-image carrier).* Let $\mathcal{I}_{p,\zeta}$ be the full essential image of F^{DEG} in its actual target. Then $D(\mathcal{A}) \simeq \mathcal{I}_{p,\zeta}$, and $\mathcal{I}_{p,\zeta}$ is closed under small colimits.

Proof. Full faithfulness identifies the source with this full subcategory. Every diagram in it lifts to the source; preservation of colimits places its colimit back in the image. This categorical construction does not identify the image with a specified support condition or with a category generated by named cycle sheaves. □

For the F1.a comparison below, use the notation $\Phi^{\mathrm{cmp}}_{p,\chi}$ for a chosen functor on the specified arithmetic representation and nilpotent-support carriers. Constructing these carriers, the functor, and its relation to the actual F^{DEG} is part of (H1). It is not a coefficient substitution in the preceding theorem.

Why Essential Surjectivity is Subtle

Remark 61.3.4 *(intuition for obstruction (a)).* The sub-∞-category $\mathrm{IndCoh}^{\text{BM-image}}_{\mathrm{Nilp}}$ is only a test subcategory generated by Breuil–Mezard cycles. A possible obstruction to essential surjectivity is the structure sheaf of an intersection of two such cycles which is not itself a named Breuil–Mezard cycle. Whether every such object lies in the triangulated colimit closure of the test generators is the block-exhaustion question.

61.4 Obstruction (a): Essential Surjectivity at $p \geq 5$

The Colmez–Paskunas Block Decomposition

Theorem 61.4.1 *(Componentwise functors on specified stable blocks).* Suppose presentable stable categories and compatible decompositions $\mathcal{C} \simeq \prod_\rho \mathcal{C}_\rho$, $\mathcal{D} \simeq \prod_\rho \mathcal{D}_\rho$ are specified. A family of fully faithful exact colimit-preserving functors $\Phi_\rho : \mathcal{C}_\rho \to \mathcal{D}_\rho$ gives a functor with these properties on the products.

Proof. Mapping spectra and colimits in a product are computed componentwise. Apply the given properties in every component. □

The Required Spectral Block Models

Proposition 61.4.2 *(Image support under a categorical block comparison).* Suppose the chosen comparison functor is identified with the componentwise functor under specified equivalences

$$C \simeq \prod_{\rho} C_{\rho}, \qquad \mathcal{D} \simeq \prod_{\rho} \mathcal{D}_{\rho}, \qquad \mathcal{D}_{\rho} = \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi,\rho}_{GL_2}).$$

Then $\Phi(C_{\rho}) \subseteq \mathcal{D}_{\rho}$. These are categorical decomposition and support hypotheses; a formal stack is not thereby identified with a deformation ring.

Proof. An object of one component is the tuple whose other components are zero. The componentwise functor preserves this property. □

Corollary 61.4.3 *(Reduction to the specified stable blocks).* Under these supplied decompositions, Φ is essentially surjective if and only if every Φ_{ρ} is essentially surjective.

Proof. Choose preimages componentwise in one direction. In the other, apply essential surjectivity to a target tuple supported in one component. Its preimage gives the required component preimage. □

The Block-Exhaustion Question

Definition 61.4.4 *(Block exhaustion for the chosen comparison).* For the specified stable categories $C_{\rho}, \mathcal{D}_{\rho}$, a block is exhausted if the chosen $\Phi^{\mathrm{cmp}}_{p,\chi,\rho}$ is essentially surjective. A cycle class alone supplies neither an object of the target nor its preimage through this functor.

Conjecture 61.4.5 *(The arithmetic block comparison datum).* For $p \geq 5$, construct the common coefficient carriers, the specified stable block decompositions and image-support comparisons for F1.a. Construct exact colimit-preserving fully faithful $\Phi^{\mathrm{cmp}}_{p,\chi,\rho}$ with the required Hecke compatibilities, and actual lifts of a localizing generating family of $\mathcal{D}_{\rho}$. Identify their relation to the proper essential image of F^{DEG}. This does not assert that the latter functor is an equivalence onto its whole target.

Remark 61.4.6 *(Objects and their lifts).* A Breuil–Mezard construction must provide actual spectral objects Q_i, their nilpotent singular support and generation, together with objects P_i and equivalences $\Phi(P_i) \simeq Q_i$. Generation by target objects alone is insufficient. Matching degree-one extensions also does not prove full faithfulness on mapping spectra.

Proposition 61.4.7 *(Exhaustion by lifted generators).* Let $F : C \to \mathcal{D}$ be fully faithful, exact and colimit-preserving between presentable stable categories. If Q_i generate $\mathcal{D}$ as a localizing subcategory and specified equivalences $F(P_i) \simeq Q_i$ exist, then F is an equivalence.

Proof. Full faithfulness lifts diagrams in the image; preservation of colimits puts their colimits in the image. Exactness gives closure under shifts and cones. Thus the image is a localizing subcategory containing the generators, and is the whole target. □

For example, $D(k) \to D(k) \times D(k)$, $M \mapsto (M, 0)$, is fully faithful, exact and colimit-preserving, but misses $(0, k)$. The two component structure sheaves $(k, 0)$, $(0, k)$ generate the target; only one is in this functor's image. When full faithfulness also needs proof, the compact-generator criterion of Theorem 70.4.1 requires equivalences on the full mapping spectra, not just $\mathrm{Ext}^{\mathrm{I}}$.

THEOREM 61.4.8 *(conditional essential surjectivity at $p \geq 5$).* Assume all the carrier, functor and lifted-generator data of Conjecture 61.4.5. Then for every $p \geq 5$ and every central character χ, the functor $\Phi^{\mathrm{cmp}}_{p,\chi}$ is an equivalence

$$\Phi^{\mathrm{cmp}}_{p,\chi} \colon \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big)_{\chi} \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}\big).$$

Proof. The lifted-generator proposition makes each chosen block functor an equivalence. The supplied categorical decompositions assemble them componentwise. The full faithfulness used here is part of the chosen comparison datum, not an unproved identification of its carriers with those of the DEG theorem. □

The Coefficient and Support Comparison

The arithmetic block datum includes its common coefficients, presentable stable realizations, categorical decompositions, Hecke compatibilities and actual lifted generators. The proven DEG functor supplies none of these identifications by a change of notation. Its proper image is a concrete categorical starting point; a geometric description of that image and the intended nilpotent support category is the remaining comparison.

61.5 OBSTRUCTION (B): EXTENSION TO $p = 2, 3$

Why DEG Does Not Extend Directly

At $p \in \{2, 3\}$ the obstructions to DEG are multiple:

PROPOSITION 61.5.1 *(Data required at the wild primes).* The theorem for $p \geq 5$ supplies no functor at two or three. A wild comparison requires its own spectral carrier, exact colimit-preserving fully faithful block functors, and their support and family compatibilities. A list of types or finite extension dimensions does not specify these categorical maps.

Proof. These primes are outside the proven theorem's hypotheses. Constructing a functor requires its action on objects and mapping spectra, with composition and higher coherences. Neither a type label nor an extension dimension gives these data. The following hypotheses retain the actual required constructions. □

The Wild-EG Enhancement Programme

The reduction is two-step: (i) construct a wild-block DEG functor via Bushnell–Henniart types and local Langlands normalisations; (ii) pair it with an enhanced Emerton–Gee stack incorporating the wild inertia data absent from the fixed-character setup.

Definition 61.5.2 *(wild-enhanced Emerton–Gee comparison datum).* For $p \in \{2, 3\}$ and central character χ, a *wild-enhanced Emerton–Gee comparison datum* consists of a derived formal algebraic stack $\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$, a map to $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$, and specified comparisons of its tangent and trace complexes with the corresponding arithmetic block data, respecting the chosen coefficients and local Langlands normalizations. Existence is an additional hypothesis. Adding a vector space of a prescribed dimension does not construct this datum.

Remark 61.5.3 *(the proposed degree-one datum at two).* The intended local degree-one contribution is a line, as in Question 54.4.8. Its identification with a derived fibre requires an actual comparison map. In characteristic two, trivial and sign characters coincide. The dual-number model has a one-dimensional

self-extension but also has nonzero extensions in every higher degree; it does not prove that the arithmetic derived fibre is concentrated in degree one.

Remark 61.5.4 *(the proposed degree-one datum at three).* The intended local degree-one contribution is the sum of two lines, as in Question 54.4.9. In the explicit right-module three-vertex model these are $\mathrm{Ext}^1(L_0, L_1)$ and $\mathrm{Ext}^1(L_1, L_2)$; their Yoneda product gives a nonzero degree-two class. A comparison with an arithmetic block and a spectral derived fibre must account for this product and specify the actual relations, rather than discard the higher degree.

Construction of the Wild DEG Functor

Conjecture 61.5.5 *(wild block functor datum).* For $p \in \{2, 3\}$ and fixed χ, construct presentable stable representation blocks C_τ^{BH}, their common coefficient category, and compatible categorical block decompositions on both sides. Construct exact, colimit-preserving, fully faithful functors

$$\Phi^{\mathrm{wild}}_{p,\chi,\tau} : C_\tau^{\mathrm{BH}} \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG,wild},p,\chi,\tau}_{GL_2})$$

with the stated type and Hecke compatibilities, assembling under those decompositions. Type labels alone do not construct these maps.

Theorem 61.5.6 *(existence of wild DEG functor at $p = 2, 3$).* Fix $p \in \{2, 3\}$ and the common coefficient ring R of the wild comparison datum, with its stated coefficient comparisons. Fix a central character $\chi : \mathbb{Q}_p^\times \to R^\times$. Assume Conjecture 61.5.7 below (existence of the wild-enhanced EG stack with the stated structural properties) and Conjecture 61.5.5. Then there exists a fully faithful functor

$$\Phi^{\mathrm{wild}}_{p,\chi} : \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big)_\chi \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}\big)$$

extending DEG to the wild primes, compatible with the Bushnell–Henniart fiber correspondence on each block.

Proof. The wild-enhancement hypothesis supplies the spectral carrier. The wild block functor datum supplies compatible stable block decompositions and component functors. Form their componentwise functor and transport it through the supplied equivalences. Mapping spectra and colimits in a product are computed componentwise, so full faithfulness, exactness and colimit preservation follow. The type and Hecke compatibilities are those of the supplied datum. □

Conjecture 61.5.7 *(wild-EG enhancement).* Conjectural statement. For $p \in \{2, 3\}$ and a central character χ, there exists a derived formal algebraic stack $\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$ with the following properties:

(i) The truncation $\tau_{\leq 0}\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$ equals the classical Emerton–Gee stack $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$.

(ii) A specified cotangent complex and deformation comparison, including infinitesimal automorphisms of the unframed stack. At a field-valued point x, its positive cohomological degree must retain $H^1(\mathbb{L}_x) = \mathrm{Lie}(\mathrm{Aut}(x))^\vee$. A two-term amplitude for a framed or relative chart requires that chart and its comparison map; it is not an absolute amplitude claim. Any proposed degree-one block dimensions must be established by the actual arithmetic class comparison, not prescribed uniformly by $p = 2$ or $p = 3$.

(iii) There is a fiber correspondence, compatible with local Langlands, between the wild components of $\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$ and the Bushnell–Henniart wild types of $GL_2(\mathbb{Q}_p)$.

(iv) Ind-coherent sheaves with nilpotent singular support on $\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi}$ are generated under colimits and shifts by the derived structure sheaves of the Bushnell–Henniart-indexed closed points.

LEMMA 61.5.8 *(A split-point automorphism direction).* At a split rank-two point $M_1 \oplus M_2$ with fixed determinant, the unframed deformation stack has a nonzero infinitesimal automorphism direction. Its absolute cotangent complex cannot have amplitude contained in $[-1, 0]$.

Proof. The automorphisms $\mathrm{diag}(t, t^{-1})$ preserve the summands and determinant. Over $k[\epsilon]/(\epsilon^2)$, putting $t = 1 + \epsilon a$ gives $1 + \epsilon\,\mathrm{diag}(a, -a)$, a nonzero direction also in characteristic two. In cohomological conventions, infinitesimal automorphisms are $H^{-1}(T_x)$; dualizing gives a nonzero $H^1(\mathbb{L}_x)$. For instance $\mathbb{L}_{B\mathbb{G}_m}|_x = \mathfrak{g}_m^*[-1]$, which is concentrated in degree $+1$. Retaining the classical unframed stack retains this direction. □

Remark 61.5.9 *(inputs to the wild-EG comparison).* The intended comparison combines smooth representation blocks, Galois deformation data and an arithmetic trace construction. Questions 54.4.8 and 54.4.9 ask for the coefficient-compatible local maps. The explicit finite-algebra resolutions establish possible extension patterns, including higher Ext; they do not establish the arithmetic fibre dimensions. The existence of a single derived formal stack with these maps, and compact generation by the proposed closed-point objects, remain parts of the wild-EG hypothesis.

Remark 61.5.10 *(domain of the wild-EG conjecture).* The wild-EG conjecture requires a derived enhancement and actual comparison maps with arithmetic block data. The classical stack and the finite-algebra examples do not by themselves construct that enhancement. In particular, the local resolutions in Chapter 54 neither determine the arithmetic derived fibres nor identify their trace classes.

BH-Block Exhaustion and Essential Surjectivity at Wild Primes

Conjecture 61.5.11 *(BH-block exhaustion at wild primes). Conjectural statement.* For $p \in \{2, 3\}$, every central character $\chi : \mathbb{Q}_p^\times \to R^\times$, and every Bushnell–Kutzko type τ (tame or wild) in the support of $\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi}$, the pair

$$\left(\mathrm{Block}_\tau^{\mathrm{BH}},\ \mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi,\tau}\right)$$

is exhausted in the sense of Definition 61.4.4: the chosen $\Phi_{p,\chi,\tau}^{\mathrm{wild}}$ is essentially surjective. A sufficient construction lifts actual target generators through this exact colimit-preserving fully faithful functor, as in Proposition 61.4.7. Generation by named spectral objects without these image identifications is not an equivalent condition.

COROLLARY 61.5.12 *(wild essential surjectivity, conditional).* Assume Conjectures 61.5.7, 61.5.5, and 61.5.11. Then $\Phi_{p,\chi}^{\mathrm{wild}}$ of Theorem 61.5.6 is an equivalence

$$\mathrm{D}^{\text{sph-fin}}\left([GL_2(\mathbb{Q}_p)]\right)_\chi \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\left(\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi}\right).$$

Proof. Fully-faithfulness is Theorem 61.5.6. Essential surjectivity follows block-by-block from the BH-block analogue of Corollary 61.4.3 plus Conjecture 61.5.11. □

Categorical Hypotheses for Obstruction (b), $p \in \{2, 3\}$

Local algebra and arithmetic comparison. The finite-algebra calculations of Section 54.4 use explicit resolutions. Their arithmetic realization requires the coefficient-compatible block and trace maps in the two local comparison questions. A bibliography of local representation constructions does not supply these maps.

Conventions. Bushnell–Henniart type conventions match those of Emerton–Gee arXiv:1908.07185 via the standard dictionary (Bushnell–Henniart §18 Thm A). $\mathrm{Ext}^{\mathrm{I}}$ conventions follow Jantzen 2003 Ch. II §8.

Ambient categories. Wild-enhanced EG stack sits in derived formal algebraic stacks; $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on a derived formal stack is computed via the Gaitsgory–Rozenblyum ind-completion. The LHS of (61.5.6) is the same as before.

Hypotheses. The three wild inputs are Conjecture 61.5.7 (H2), Conjecture 61.5.5 (H3), and Conjecture 61.5.11 (H4). They specify the enhanced stack, the actual block functor, and its essential surjectivity, respectively.

Functoriality. Hecke compatibility and the maps between blocks are part of the functor datum (H3). Orthogonality controls cross-block morphisms once those categories and functors exist; a type classification alone does not construct the Hecke intertwiners.

Remaining constructions. All three inputs (H2)–(H4) are retained. Constructing the target stack or naming its types does not by itself construct the functor or prove its essential surjectivity.

61.6 Obstruction (c): Central Character Variation

The Central-Character Parameter and Its Families

A fixed central character is a continuous homomorphism $\chi : \mathbb{Q}_p^\times \to k^\times$. To vary it, fix a coefficient regime and a parameter site $\mathcal{T}_p^{\mathrm{cent}}$ for the intended character families, including any nonreduced coefficient algebras. Its topology and representability are part of the family construction; a list of point-valued characters is not a descent model.

Throughout this family construction, write $\mathcal{X}_p^{\mathrm{fam}}$ for the chosen spectral carrier: the classical Emerton–Gee carrier for $p \geq 5$, and the chosen wild-enhanced carrier of (H2) for $p \in \{2, 3\}$. In the latter case its fixed-character carriers and functors are the data of (H2) and (H3), with block exhaustion as in (H4). The family carrier and its base-change identifications are part of the descent model below; they are not inferred from point-valued characters. The chosen fixed-character functors are the chosen arithmetic comparison functors of (H1), related to the actual DEG image by their supplied maps, and the wild block functors at two and three. Denote their sought family extension by Φ_p^{fam}.

Definition 61.6.1 *(Central-character descent model).* A central-character descent model consists of a specified cover $U \to \mathcal{T}_p^{\mathrm{cent}}$, its Čech diagram $U_\bullet$, and compatible diagrams of presentable stable categories $\mathcal{C}(U_\bullet)$, $\mathcal{D}(U_\bullet)$, with equivalences

$$\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \simeq \mathrm{Tot}\,\mathcal{C}(U_\bullet), \qquad \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_p^{\mathrm{fam}}) \simeq \mathrm{Tot}\,\mathcal{D}(U_\bullet).$$

The models must realize the stated fixed-character categories under the chosen base-change operations. Equivalence must be detected on this conservative descent cover, not merely on its point characters.

Remark 61.6.2 *(Generalized central characters).* Smooth representations need not split into a direct sum of strict central-character subrepresentations. For an explicit example, let k have characteristic different from two and let $N \neq 0$ on k^2 satisfy $N^2 = 0$. The formula

$$g \longmapsto (1 + N)^{v_p(\det g)} = 1 + v_p(\det g)N$$

defines a smooth representation of $GL_2(\mathbb{Q}_p)$: the valuation is additive and locally constant. The central element pI acts by $1 + 2N$, which is not scalar and is not semisimple. Its two composition factors have the trivial central character, but the extension is not a direct sum of strict-character objects. A family model must retain this extension data.

Conjecture 61.6.3 *(Central-character family comparison datum).* Construct the descent models of Definition 61.6.1 and a morphism $\Phi_\bullet : C(U_\bullet) \to \mathcal{D}(U_\bullet)$ extending these chosen fixed-character functors. Prove that each Φ_n is an equivalence on the specified conservative cover and all its higher overlaps, compatibly with the descent maps, Hecke actions, coefficient changes and central/determinant twists. Naturality at point characters alone is not this datum.

Assembly of the Family Functor

Theorem 61.6.4 *(Central-character variation by effective descent).* Assume the actual models and levelwise equivalences of Conjecture 61.6.3, with the fixed-character block comparisons on their stated domains. Then their totalization gives an equivalence

$$\Phi_p^{\mathrm{fam}} : \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)]) \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_p^{\mathrm{fam}}),$$

compatible with the supplied family and Hecke data.

Proof. A natural transformation of diagrams that is an equivalence at every level is an equivalence in the functor category. Applying the limit functor preserves equivalences. Compose $\mathrm{Tot}\,\Phi_\bullet$ with the two specified descent model equivalences to obtain the displayed functor. Its compatibilities follow from those of the diagram. The proof uses actual overlap data; pointwise equivalences do not replace them. □

Remark 61.6.5 *(Fixed characters and families).* Fixed-character block exhaustion is only one input to the family problem. The coefficient extensions, conservative cover, overlap comparisons and descent models remain the construction required by Conjecture 61.6.3.

Categorical Hypotheses for Obstruction (c)

Local representation-theoretic inputs. The central-character-variation argument uses Gaitsgory–Rozenblyum Vol. I Ch. 9–10 (fibrations of categories) plus DEG arXiv:2603.26887. The passage from fixed-character functors to a family requires the effective descent and conservative-cover datum stated above.

Conventions. The determinant-fibration convention on the classical Emerton–Gee carrier follows Emerton–Gee arXiv:1908.07185 §2.2; its wild-enhanced analogue and compatibility are part of the chosen family datum. The sheaf-of-categories convention follows Gaitsgory–Rozenblyum Vol. I Ch. 10 Thm 10.3.2.1.

Ambient categories. Sheaves of presentable stable ∞-categories over $\mathcal{T}_p^{\mathrm{cent}}$; the totalisation equivalence is an equivalence in this ambient.

Hypotheses. The effective descent models and compatible equivalences over the conservative cover are not imported from the fixed-character theorem. They form the separate hypothesis Conjecture 61.6.3. The fibre-to-total passage is formal only after that hypothesis is in place.

Functoriality. The twisting morphism $\chi' \to \chi$ is compatible with both sides only under Conjecture 61.6.3.

Unproved comparisons. The actual cover-level equivalences, including coefficient extensions and higher overlaps, remain to be constructed as part of the family datum. The totalization theorem is conditional on them.

The central-character family datum is a genuine residual.

61.7 Fi.a Reduction

Assembly of (a), (b), (c)

Theorem 61.7.1 *(Fi.a at all primes, conditional).* Assume:

(H1) Conjecture 61.4.5 at every $p \geq 5$ and every central character χ.

(H2) Conjecture 61.5.7 at $p \in \{2, 3\}$ and every χ.

(H3) Conjecture 61.5.5 at $p \in \{2, 3\}$ and every χ.

(H4) Conjecture 61.5.11 at $p \in \{2, 3\}$ and every χ.

(H5) Conjecture 61.6.3 at every p.

Then for every prime p and every continuous central character χ there exists an equivalence

$$\Phi_{p,\chi}^{\mathrm{LocCat}} \colon \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big)_{\chi} \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}_{GL_2}^{\mathrm{EG,wild\text{-}enhanced},p,\chi}\big),$$

where the spectral side is the classical Emerton–Gee stack for $p \geq 5$ and its wild enhancement for $p \in \{2, 3\}$, and the family over χ assembles to the displayed Fi.a equivalence

$$\Phi_{p}^{\mathrm{LocCat}} \colon \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big) \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}_{GL_2}^{\mathrm{EG,wild\text{-}enhanced},p}\big).$$

Local Hecke-functoriality at the place p is part of the local categorical input; it is not inferred from full faithfulness alone.

Proof. Assemble Theorem 61.4.8 (valid for $p \geq 5$ under (H1)), Corollary 61.5.12 (valid for $p \in \{2, 3\}$ under (H2), (H3), and (H4)), and Theorem 61.6.4 (assembles the family under (H5)). Per-χ equivalences (from (H1)+(H2)+(H3)+(H4)) combine with the family decomposition to produce the total equivalence (61.7.1). □

Unconditional DEG Full Faithfulness

Theorem 61.7.2 *(The proven fixed-character embedding).* On the exact coefficient and spectral carriers of Theorem 61.3.1, F^{DEG} is fully faithful and colimit-preserving. It is not an equivalence onto its entire displayed target.

Proof. The theorem and Remark 1.1.2 of the cited paper give these assertions. □

Corollary 61.7.3 *(Equivalence onto the actual essential image).* For the same data, $D(\mathcal{A}) \simeq \mathcal{I}_{p,\zeta}$.

Proof. Apply Proposition 61.3.3. □

Remark 61.7.4 *(The arithmetic carrier remains to be identified).* The equivalence onto this proper image does not identify the sph-finite arithmetic carrier with a nilpotent-support category. That geometric comparison is part of (H1), and the wild and family constructions remain (H2)–(H5).

Residuals

R1a: the arithmetic comparison at $p \geq 5$. Hypothesis (H1) requires common coefficients and support, the chosen functor and actual lifted generators. It does not assert essential surjectivity of the known DEG functor onto its entire target.

R1b: the wild spectral carrier. Hypothesis (H2) requires the stacky deformation comparison and its geometric carrier. It supplies no wild representation functor alone.

R1c: the wild functor and its image. Hypotheses (H3) and (H4) require the exact colimit-preserving fully faithful functor, its categorical decomposition and lifted target generators. The wild equivalence uses (H2), (H3) and (H4) together.

Central-character variation (c) requires the family datum of Conjecture 61.6.3. Per-χ equivalences do not supply their naturality or descent as χ varies.

61.8 Consequence for F1 and $\mathrm{L}_{\mathrm{ACD}}$

Local F1.a Closed at Every Prime Suffices for Adelic F1

Theorem 61.8.1 *(Adelic F1 from local comparison and descent).* Conditional statement. Assume the conditional closure of F1.a at every prime p of Theorem 61.7.1 (i.e. assume (H1)–(H5)), together with the specified adelic descent data. Then the F1 obstruction is reduced to the current $\mathrm{L}_{\mathrm{ACD}}$ table of Corollary 43.2.3:

$$\mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A}_{\mathbb{Q}})]\big) \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}\big).$$

Proof. Apply Corollary 43.2.3: F1 holds given (F1.a) and $\mathrm{L}_{\mathrm{ACD}}$. Our Theorem 61.7.1 reduces (F1.a) under (H1)–(H5), up to the wild-enhancement of the local conditions at $p \in \{2, 3\}$. These wild conditions must be inserted into the Selmer-derived stack as modified factors $\mathcal{X}^{\mathrm{EG,wild\text{-}enhanced},p}_{GL_2}$ in the local condition $\mathcal{L}_p$. The global equivalence (61.8.1) therefore uses the Selmer-derived target on the right-hand side; it is not an ind-Noetherian product of local stacks. □

Remark 61.8.2 *(three local pieces).* Under the assumptions (H1)–(H5) of Theorem 61.7.1 plus $\mathrm{L}_{\mathrm{ACD}}$, F1 holds. The assumptions (H1)–(H5) are the local-categorical-comparison residuals of the DEG reduction; $\mathrm{L}_{\mathrm{ACD}}$ is the adelic-categorical-descent residual of Remark 43.2.4. The F1 obstruction set therefore has six items: (H1)–(H5) and $\mathrm{L}_{\mathrm{ACD}}$.

Refined Chapter 43 Reduction

Proposition 61.8.3 *(Local comparison inputs and adelic descent).* The sufficient input set for the stated F1 comparison consists of (H1)–(H5) from Theorem 61.7.1 and the adelic descent datum $\mathrm{L}_{\mathrm{ACD}}$. Here (H3) constructs the wild block functor, (H4) requires its block exhaustion, and (H5) supplies the central-character family comparison. These are distinct requirements.

$$\mathrm{Inputs}(F1) = \{\mathrm{H1}, \mathrm{H2}, \mathrm{H3}, \mathrm{H4}, \mathrm{H5}, \mathrm{L}_{\mathrm{ACD}}\}.$$

This is a sufficient construction route, not a proof that each input is logically necessary for every possible F1 equivalence.

Proof. Under (H1)–(H4), the specified block functors give the per-character local comparisons in the stated coefficient categories. Hypothesis (H5) supplies their compatible family as the character varies.

The adelic descent datum then assembles these local comparisons on the specified Selmer target, as in Theorem 61.8.1. Neither a family of unrelated equivalences nor essential surjectivity without a constructed functor performs these steps. □

Global Assembly and Its Hypotheses

The global comparison uses the local categorical comparisons together with the F1 reduction of Corollary 43.2.3. Its inputs are (H1)–(H5) and L_{ACD}. The spectral geometry is formulated in ind-Noetherian formal algebraic stacks over Spec $\mathbb{Z}$, while the automorphic geometry uses the adelic double coset. The comparison concerns their associated presentable ∞-categories.

The global Emerton–Gee construction uses the ind-Noetherian limit of Emerton–Gee, §2.3. Incorporating the proposed wild enhancements at the two small primes requires compatibility with that limit. Assembly over primes is a restricted tensor product, and its compatibility with cross-prime Hecke functoriality is part of L_{ACD}. Thus the global consequence retains the local, wild-functor, family, and adelic descent hypotheses.

61.9 Residual Conditions

Residual Conditions for the DEG Extension

The DEG extension has five residual inputs:

(i) Conjecture 61.4.5 (**R1a/F1.a.1**): the specified arithmetic comparison functor, common coefficients and support, and actual lifts of spectral generators at $p \geq 5$. This is not essential surjectivity of the known DEG functor onto its entire target; that functor has a proper image.

(ii) Conjecture 61.5.7 (**R1b/F1.a.2**): existence of a derived formal algebraic wild-enhanced EG stack at $p \in \{2, 3\}$ with four structural properties.

(iii) Conjecture 61.5.5 (**R1b'**): existence of the Bushnell–Henniart-compatible per-block fully faithful functor at $p \in \{2, 3\}$.

(iv) Conjecture 61.5.11 (**R1c/F1.a.3**): the wild-block analogue of Conjecture 61.4.5; essential surjectivity per Bushnell–Kutzko type at $p \in \{2, 3\}$.

(v) Conjecture 61.6.3 (**R1d**): effective descent of the specified comparison functors over the central-character family.

What is Unconditional

The established fixed-character theorem and the conditional assembly have different scopes:

(i) The fixed-χ, $p \geq 5$, fully faithful DEG embedding (Theorem 61.7.2): no residual needed. This is the strongest unconditional DEG input toward F1.a.

(ii) The conditional global F1 reduction (Proposition 61.8.3), with all the explicitly named local, family, and L_{ACD} inputs.

Out of Domain

Three items are outside the stated domain:

(i) *Langlands functoriality at the global level.* Deferred to the adelic categorical descent L_{ACD}.

(ii) *Higher GL_n for $n \geq 3$.* The chapter focuses on $GL_2(\mathbb{Q}_p)$; DEG's technology generalises under significant additional input (Emerton–Helm–Paskunas for GL_n), not in domain here.

(iii) *Number fields beyond* $\mathbb{Q}$. The chapter focuses on $\mathbb{Q}_p$; extension to K_v for $K/\mathbb{Q}$ a finite extension requires additional considerations at primes ramified in K.

61.10 DEG Extension Boundary

(i) Dotto–Emerton–Gee arXiv:2603.26887 supplies the stated embedding on its integral coefficient and formal spectral carriers: *fully-faithful, fixed central character,* $p \geq 5$ *only* (Theorem 61.3.1).

(ii) Three obstructions separate DEG from F1.a: (a) essential surjectivity; (b) extension to $p \in \{2, 3\}$; (c) central-character variation (Remark 61.3.2).

(iii) Obstruction (a) reduces to Conjecture 61.4.5 (F1.a.1): block exhaustion per residual Galois representation. Theorem 61.4.8 closes (a) under this conjecture.

(iv) Obstruction (b) reduces to Conjecture 61.5.7 (F1.a.2: existence of wild-enhanced EG stack), Conjecture 61.5.5, plus Conjecture 61.5.11 (F1.a.3). Theorem 61.5.6 and Corollary 61.5.12 close (b) under these conjectures.

(v) Obstruction (c) is the family datum Conjecture 61.6.3. It is not a consequence of the fixed-character DEG theorem.

(vi) Full conditional closure of F1.a at all primes: Theorem 61.7.1, conditional on (H1)–(H5).

(vii) Unconditional partial closure: the fixed-χ, $p \geq 5$, fully faithful DEG embedding (Theorem 61.7.2, Corollary 61.7.3). No family statement is asserted.

(viii) Global assembly check: F1 follows from F1.a (at every prime, including wild) plus $\mathrm{L}_{\mathrm{ACD}}$ (Theorem 61.8.1); total F1 residual table is six items (Proposition 61.8.3).

The fixed-character DEG functor has the proper image specified in Corollary 61.7.3. The proposed arithmetic equivalence requires different comparison data: the actual coefficient and support maps, lifted generators, wild functors, family descent and centre compatibility. The conditional assembly proves what these maps would imply; their construction remains the arithmetic target.

Chapter 62

H-P^{Ar} Determinant-Trace Matching and Hamburger Determinacy

Chapter 57 reduces the arithmetic Hilbert–Pólya hypothesis H-P^{Ar} to a determinant-trace realisation (SP) equivalent to the Connes adele-class-space absorption-trace conjecture and to the Deninger regularised-determinant axioms. Its conditional operator comparison uses (Reg), including positivity, determinacy and spectral support on an identified arithmetic carrier, with explicitly supplied comparison data. Chapter 58 uses the conditional RH completion hypothesis and isolates the positivity/determinacy input. The H-P^{Ar} side separates the Bost–Connes zero-mode weight-selection *problem from the trace-matching problem: the logarithmic Berry–Keating weight is the only survivor among a small canonical test family, and is unique under an explicit KMS/zeta-partition normalisation, but existence of the required trace identity is the H-P^{Ar} obstruction. The VB* side tests the Carleman construction: the Bombieri–Lagarias Li-coefficient bounds do not imply the Carleman estimate for the shifted-zero moments. The sufficient analytic residual is* ($\mathrm{R}_{\mathrm{analytic}}$)*: a linear upper-growth bound for $\mu_{2n}^{1/(2n)}$, or equivalently a positive regularised moment measure with Carleman divergence.*

62.1 Determinacy Comparison

Residual Splitting

The residual splitting structural analysis of Chapter 57 gives four structural inputs:

(i) *Domain theorem for $L_{\mathrm{o}}^{\mathrm{Ar}}$.* Theorem 57.3.2: on the primary arithmetic Heisenberg Fock, under non-negativity of the Bost–Connes zero-mode weights $\lambda(m) \geq 0$, the symmetric operator $L_{\mathrm{o}}^{\mathrm{Ar,\,symm}}$ admits a unique Friedrichs self-adjoint extension $L_{\mathrm{o}}^{\mathrm{Ar}}$, essentially self-adjoint on the finite-span core $\mathcal{D}_{\mathrm{o}}$, with non-negative spectrum.

(ii) *Three-way equivalence for H-P^{Ar}.* Theorem 57.3.14: H-P^{Ar} (in the determinant-trace form SP) is equivalent to the Connes absorption-trace conjecture and to the Deninger regularised determinant condition.

(iii) *Conditional operator comparison.* Under Hypothesis 57.4.21, Theorem 57.4.22 compares VB*, (Reg), (HB+) and (BD+). Bare determinacy is only one component of (Reg); the sharp BD rate also requires the specified quantitative comparison.

(iv) *Separation of the two residuals.* Proposition 57.5.2: H-P^{Ar} (existence of a self-adjoint $L_{\mathrm{o}}^{\mathrm{Ar}}$ with prescribed trace) and spectral regularity of the moment problem are separate assertions.

The determinacy calculation adds weight selection and Carleman analysis to these structural inputs.

Two Analytic Tests

(A) *Zero-mode weight selection for H-P^{Ar}.* Corollary 57.3.15 names the single residual as "the choice of Bost–Connes zero-mode weights $\{\lambda(m)\}_{m\in\mathbb{N}^\times}$ such that the combined trace matches the zero generating

function''. Four canonical weight systems against the arithmetic Koszul self-duality (P1), the completed-zeta character and explicit formula (P2), and Bost–Connes rigidity at $\beta = 1$ are considered. This is a finite test family, not a classification of all additive functions on $\mathbb{N}^\times$. A genuine uniqueness theorem requires the extra KMS/zeta-partition normalisation stated below.

(B) *Hamburger determinacy obstruction on the symmetrised shifted-zero measure.* Proposition 57.4.5 proves that a factorial upper bound on a specified positive functional gives Carleman determinacy. The finite cutoff sums diverge; their arithmetic regularization and positivity must first be constructed. An upper bound $\mu_{2n}^{1/(2n)} \leq Cn$ then suffices, without a matching lower bound.

The single positivity corollary Corollary 58.4.3 is sufficient for RH after the conditional hypothesis of Chapter 58 is supplied. The resulting residual is $(\mathrm{R}_{\mathrm{analytic}})$.

Analytic Inputs

Chapter 57 used: Connes arXiv:math/9811068, Deninger 1994, Berry–Keating 1999, Reed–Simon, Akhiezer–Glazman, de Branges 1968/1994, Báez-Duarte 2003, Burnol 2000. The present determinacy argument uses a complementary list:

Akhiezer, *The Classical Moment Problem* (Oliver & Boyd 1965). Definitive monograph on the Hamburger, Stieltjes, Hausdorff moment problems; §2.4 Carleman's criterion; §2.5 Nevanlinna parametrisation of indeterminate solutions; §3.1 Jacobi-matrix formalism; §5.6 exponential-moment estimates.

Shohat–Tamarkin *The Problem of Moments* (AMS 1943). The American companion to Akhiezer; Ch. III.5 classical determinacy, Ch. III.2 Hankel determinants as sufficient tests, Ch. VI bounded-case theorems.

Conrey, J. Reine Angew. Math. 399 (1989) 1–26. Zero-density theorem: at least 40% of the non-trivial zeros of ζ lie on the critical line. Unconditional.

Selberg, Arch. Math. Naturvid. 48 (1946) 89–155. Positive proportion of zeros on the critical line, first unconditional zero-density result.

Levinson, Adv. Math. 13 (1974) 383–436. 1/3 of zeros on the line via Levinson's method.

Odlyzko, 2001 (unpublished note). Numerical computation of 10^{13} non-trivial zeros on the critical line.

Bombieri–Lagarias, J. Number Theory 77 (1999) 274–287. Unconditional upper bound $\lambda_n \leq n(c_0 + \log n)/2$, $c_0 = 2 - \log(4\pi) + \gamma$, and a matching lower bound $\lambda_n \geq -(n/2)\log n - O(n)$.

The zero-counting and Li-coefficient estimates do not by themselves supply a positive moment functional or its Carleman upper-growth bound.

62.2 Weight Selection and Moment Determinacy

The weight problem concerns logarithmic generators and a prescribed trace. The moment problem requires a positive regularised interpretation and a sufficient upper-growth estimate.

Zero-Mode Weights and the Trace Condition

Problem. Does the Berry–Keating ansatz $\lambda(p^k) = k \log p$ (Remark 57.3.17) constitute the unique natural Bost–Connes zero-mode weight?

Argument. The Berry–Keating ansatz reproduces the leading asymptotic zero density $N(T) \sim (T/2\pi)\log(T/2\pi)$ (Bohr–Sommerfeld quantisation of $xp = E$) but does not reproduce the individual spectrum; three independent competitors exist among finite canonical tests.

Sources. Bost–Connes 1995 §2.2 (Hecke algebra structure); Connes–Marcolli 2008 Ch. 3 (KMS_β classification); Laca 1998.

Conclusion. Four candidate weight systems are enumerated as Definition 62.3.1; pairwise P1+P2 compatibility is proved as Theorem 62.3.5. The $\mathrm{KMS}_{\beta=1}$ state of the Bost–Connes system is unique in the symmetric normalisation, but that rigidity alone does not classify arbitrary additive prime-weight systems. Trace-compatibility (57.1) for each candidate is equivalent to H-P^{Ar} for that candidate; no combination gives an unconditional trace identity.

Uniqueness under KMS and Zeta Normalisation

Problem. Does at most one weight system satisfy simultaneous compatibility with P1, P2, and the H-P^{Ar} trace condition?

Argument. Existence is not assumed (it is H-P^{Ar} itself); uniqueness holds conditionally on existence, via Connes–Marcolli rigidity.

Sources. Connes–Marcolli, AMS Colloq. Publ. 55 (2008), Thm 4.15 (uniqueness of symmetric KMS$_{\beta=1}$ state); Connes–Marcolli–Ramachandran arXiv:math/0501424 (explicit form).

Conclusion. The KMS$_{\beta=1}$ state on $C^*_{\mathbb{Q}}$ is unique among symmetric states (invariant under $\mathrm{Gal}(\mathbb{Q}^{\mathrm{ab}}/\mathbb{Q})$) by Connes–Marcolli 2008 Thm 4.15. The compatibility theorem identifying the partition function and prime-generator expectations with the canonical zeta normalisation forces the logarithmic weight under that hypothesis; see Theorem 62.3.7. Existence of the weight system with the required zero trace is precisely the H-P^{Ar} assertion.

The Determinant-Trace Hierarchy

Problem. Does the Berry–Keating weight $\lambda(p^k) = k \log p$ reproduce the H-P^{Ar} trace identity?

Argument. The Berry–Keating partition function $\sum_{n\geq 1} e^{-t\log n} = \sum_{n\geq 1} n^{-t} = \zeta(t)$, multiplied by the Dedekind-eta inverse, does not equal the zero wave-kernel distribution; the two sides match only after the archimedean Euler factor is subtracted and the logarithmic-derivative expansion is inverted.

Sources. Edwards, *Riemann's Zeta Function* (Academic Press 1974) §§1.13 and 3.3, Mellin inversion of ξ via the logarithmic derivative.

Conclusion. The trace-compatibility condition is an infinite hierarchy of constraints, not a single scalar equation. By Mellin inversion, the hierarchy is an equality of distributions for the normal zero operator Θ_ξ, equivalently $\det_\infty(s\,\mathrm{id} - \Theta_\xi) = \xi_{\mathbb{R}}(s)$. The Friedrichs Fock/BC Hamiltonian supplies the Euler partition side, not this determinant identity. The hierarchy is identified with a regularised Weil/Connes explicit-formula extension only after the admissibility of the test family is supplied; see Theorem 62.3.10. No weight system is known to close the trace identity.

Carleman's Criterion and Moment Growth

Problem. Does Carleman's criterion $\sum_{n\geq 1} \mu_{2n}^{-1/(2n)} = +\infty$ hold for the symmetrised shifted-zero moment sequence $\{\mu_{2n}\}$?

Finite calculation. Proposition 80.2.5 computes the cutoff sums and proves their divergence. There is no finite unregularized saddle from which to infer a factorial law. For a specified finite positive functional, the upper bound $\mu_{2n}^{1/(2n)} = O(n)$ implies Carleman by harmonic comparison. The arithmetic task is to construct that functional and estimate it; see Theorem 62.4.5.

Li Coefficients and Absolute Moments

Problem. Can the unconditional Bombieri–Lagarias bound $\lambda_n \leq n(c_0 + \log n)/2$ be converted into an unconditional estimate on μ_{2n} sufficient for Carleman?

Argument. The Li coefficients are oscillatory sums over zeros, whereas μ_{2n} is a positive regularised moment. The unconditional bound on λ_n does not transfer to μ_{2n} without a separate positivity/domination theorem.

Sources. Bombieri–Lagarias J. Number Theory 77 (1999) 274–287, Theorem 2; Voros 2003 Ann. Inst. Fourier (refinements); Coffey 2005 Math. Phys. Anal. Geom.

Conclusion. Bombieri–Lagarias Thm 2 bounds the Li sum $\lambda_n = \sum_\rho (1 - (1 - 1/\rho)^n)$ (Li 1997). This is a highly oscillatory zero sum. It is not a bound on the absolute moments μ_{2n}, and cancellations in the Li sum cannot be reversed into Carleman control without an additional positivity and regularisation theorem; see Proposition 62.4.3. An independent construction of a positive regularised shifted-zero moment measure with upper-growth estimate $\mu_{2n}^{1/(2n)} \le Cn$ is the analytic residual.

Positivity and Growth of the Regularised Moments

The positivity input in Chapter 58 requires a positive regularised interpretation of the formal shifted-zero moments

$$\mu_{2n} = \sum_\rho (1/4 + |\gamma_\rho|^2)^n.$$

A sufficient growth estimate for Carleman's criterion is $\mu_{2n}^{1/(2n)} = O(n)$. Positivity and this upper bound are the analytic data required in Theorem 62.4.7; the other hypotheses remain the conditional inputs of the residual splitting and Chapter 58.

The classical formulations through Carleman's criterion, Nevanlinna parametrisation and Akhiezer–Krein theory concern this same moment problem. Their sources are Akhiezer, Shohat–Tamarkin, Carleman, Krein and Nevanlinna, together with the sources for the residual splitting cited above.

62.3 H-P^{Ar} Spectral Matching: Bost–Connes Zero-Mode Weight

Candidate Weights

The residual splitting candidate weight system stated was the Berry–Keating ansatz $\lambda(p^k) = k \log p$ extended multiplicatively to $\lambda(m) = \log m$ (Remark 57.3.17). We compare it with three nearby weights. This is not an exhaustive classification of all maps $\mathbb{N}^\times \to \mathbb{R}$: additive weights are determined by arbitrary prime values $\{\lambda(p)\}_p$. The point is to separate the canonical BC/zeta generator from common false substitutes.

Definition 62.3.1 *(four canonical zero-mode weight tests).* Let $C^*_{\mathbb{Q}}$ be the Bost–Connes algebra of Definition 29.1.1. Four canonical weight tests $\{\lambda_\star(m)\}_{m\in\mathbb{N}^\times}$ are available, each arising from a distinct structural interpretation of the Hecke action on the zero-mode lattice:

(BK) *Berry–Keating / logarithmic*: $\lambda_{\mathrm{BK}}(m) := \log m$. Extended multiplicatively: $\lambda_{\mathrm{BK}}(p^k) = k \log p$. This is the Euler-product generator; yields the BC KMS$_\beta$ partition function $\zeta(\beta)$ at $\beta = 1$.

(Li-shift) *Li spectral translation*: $\lambda_{\mathrm{Li}}(m) := \log m$ as a semigroup weight, with the critical-line translation $s \mapsto s - \frac{1}{2}$ applied to the spectral parameter rather than inserted as a constant shift in the semigroup homomorphism. A literal formula $\log m - \frac{1}{2}$ is not additive on $\mathbb{N}^\times$ and is therefore not a BC weight.

(vM) *von Mangoldt / Weil*: $\lambda_{\mathrm{vM}}(m) := \Lambda(m) \log m$ where $\Lambda(m)$ is the von Mangoldt function ($\Lambda(p^k) = \log p$, zero otherwise). This is logarithmic derivative data, not a multiplicative semigroup weight.

(FS-quad) *quadratic finite-place weight*: $\lambda_{\mathrm{FS}}(p^k) := k^2 \log p$ and $\lambda_{\mathrm{FS}}(m) := \sum_{p^{k_p} \| m} k_p^2 \log p$. This records the quadratic-exponent alternative suggested by finite-place Hecke powers on perfectoid Iwahori charts (Definition 58.1.1 finite-place orientation). It agrees with (BK) on squarefree integers and differs on higher prime powers.

Remark 62.3.2 *(domain of the four tests).* Under the $\mathbb{Q}$-positive-semigroup action of $\mathbb{N}^\times$ on the zero-mode lattice, a weight system $\lambda : \mathbb{N}^\times \to \mathbb{R}$ is compatible with the Bost–Connes Hecke action $\mu_n \mu_m = \mu_{nm}$

only when $\lambda(nm) = \lambda(n) + \lambda(m)$. The additive case reduces to specifying $\lambda(p)$ for each prime p, hence contains infinitely many choices. The zeta partition normalisation

$$\sum_{m\geq 1} e^{-\beta\lambda(m)} = \zeta(\beta)$$

for all $\mathrm{Re}(\beta) > 1$ forces $e^{-\lambda(p)} = p^{-1}$ prime-by-prime, and therefore forces (BK). Without that normalisation there is no uniqueness theorem. The four tests above only record the canonical logarithmic, translated, logarithmic-derivative, and quadratic finite-place possibilities used in the obstruction comparison.

Pairwise Compatibility with P1 and P2

Lemma 62.3.3 *(P1 compatibility within the four tests).* Within Definition 62.3.1, the additive Berry–Keating weight is compatible with the formal $m \leftrightarrow m^{-1}$ functional-equation involution. The Li-shift test is the same additive weight together with an external critical-line translation. The von Mangoldt and quadratic finite-place tests are not multiplicative semigroup weights and therefore do not define BC zero-mode weights satisfying P1.

Proof. For (BK), $\lambda_{\mathrm{BK}}(m) + \lambda_{\mathrm{BK}}(m^{-1}) = 0$ after formal extension of log to $\mathbb{Q}_{>0}$. The Li shift is not the map $\log m - \frac{1}{2}$ on $\mathbb{N}^{\times}$, since such a map fails $\lambda(nm) = \lambda(n) + \lambda(m)$. It is the same additive weight with the spectral parameter translated by $1/2$. The von Mangoldt test is supported on prime powers and the FS-quad test satisfies $\lambda_{\mathrm{FS}}(p^{a+b}) \neq \lambda_{\mathrm{FS}}(p^a) + \lambda_{\mathrm{FS}}(p^b)$ for general a, b. Hence neither is a BC semigroup weight. □

Lemma 62.3.4 *(P2 compatibility within the four tests).* Within Definition 62.3.1, the Berry–Keating weight is the only additive weight whose partition function is the classical zeta partition function. The Li shift changes only the external critical-line normalisation. The von Mangoldt and FS-quad tests do not give the ζ-partition function and hence do not satisfy the P2 completed-zeta character condition.

Proof. (BK) gives

$$\sum_{m\geq 1} e^{-t\log m} = \sum_{m\geq 1} m^{-t} = \zeta(t).$$

The Li-shift convention leaves this semigroup partition function unchanged and moves the $1/2$ into the spectral variable. For (vM) one obtains logarithmic-derivative data supported on prime powers, not a Dirichlet series with the ξ-functional equation. For (FS-quad) one obtains

$$\prod_{p}\sum_{k\geq 0} p^{-tk^2},$$

not the Euler product for $\zeta(t)$. These two tests therefore fail the P2 partition-function test. □

Theorem 62.3.5 *(four-test filter under P1+P2).* Among the four tests of Definition 62.3.1, simultaneous P1+P2 compatibility leaves only the Berry–Keating semigroup weight $\lambda(m) = \log m$, with the Li convention understood as the same weight after external critical-line translation. This is a finite filter, not a classification of all possible prime-weight systems.

Proof. Lemma 62.3.3 and Lemma 62.3.4 eliminate the von Mangoldt and FS-quad tests as BC semigroup weights. The Li convention does not produce a new additive weight; it is the Berry–Keating weight with the spectral parameter centred at $1/2$. Thus the only surviving semigroup weight in the four-test family is (BK). □

Remark 62.3.6 *(what the filter proves).* Theorem 62.3.5 proves only the finite-filter statement just stated. Full uniqueness requires the zeta partition normalisation or an equivalent KMS compatibility condition; without such a condition, arbitrary prime weights $\{\lambda(p)\}_p$ remain possible.

Uniqueness under KMS/Zeta Normalisation

The surviving canonical weight is (BK). Existence with the trace-compatibility condition is the H-P^{Ar} assertion. Uniqueness after the partition function is fixed is unconditional.

Theorem 62.3.7 *(uniqueness under zeta partition normalisation).* Suppose $\lambda : \mathbb{N}^\times \to \mathbb{R}_{\geq 0}$ is additive and has zeta partition function

$$\sum_{m\geq 1} e^{-\beta\lambda(m)} = \zeta(\beta)$$

for all $\mathrm{Re}(\beta) > 1$, with Euler factors matched prime-by-prime to the Bost–Connes Hecke generators. Then $\lambda(m) = \log m$. Consequently any H-P^{Ar} realisation satisfying this KMS/zeta normalisation uses the Berry–Keating weight.

Proof. Additivity gives $\lambda(p^k) = k\lambda(p)$, so the partition function factors as

$$\prod_p (1 - e^{-\beta\lambda(p)})^{-1}.$$

Prime-by-prime equality with $\zeta(\beta) = \prod_p (1 - p^{-\beta})^{-1}$ gives $e^{-\lambda(p)} = p^{-1}$, hence $\lambda(p) = \log p$ for every prime. Additivity then gives $\lambda(m) = \log m$. □

Remark 62.3.8 *(relation to Connes–Marcolli rigidity).* Connes–Marcolli rigidity at $\beta = 1$ is the conceptual source of this normalisation. Identifying an arbitrary weight with the unique symmetric KMS state requires the prime-generator and partition-function bridge proved in the theorem. The theorem records the exact conditional uniqueness available on the arithmetic path. H-P^{Ar} is the Bost–Connes/Dedekind-eta trace identity, the unresolved determinant-trace matching problem.

The Hierarchy Condition

Lemma 62.3.9 *(admissible Weil–Connes wave-kernel regularisation).* Let $\xi = \xi_{\mathbb{R}}$ and write each non-trivial zero as $\rho = \beta_\rho + it_\rho$, and set $z_\rho := -i(\rho - \frac{1}{2})$. Use the Fourier convention

$$h(r) = \int_{\mathbb{R}} \widehat{h}(u) e^{-iru}\, du.$$

Let

$$\mathsf{PW} := \{h = \mathcal{F}^{-1}\psi : \psi \in C_c^\infty(\mathbb{R})\}$$

with the LF topology transported from $C_c^\infty(\mathbb{R})$. For $h \in \mathsf{PW}$, the Weil–Connes explicit formula gives

$$\sum_\rho h(z_\rho) = \int_{\mathbb{R}} h(r)\, dW_\infty(r) - 2\sum_{n\geq 1} \frac{\Lambda(n)}{\sqrt{n}} \widehat{h}(\log n),$$

in the normalisation of (62.1); the prime sum is finite because $\widehat{h}$ has compact support. The replacement $z_\rho = t_\rho$ is equivalent to RH.

For $\phi \in C_c^\infty((0,\infty))$, set

$$h_\phi(r) := \int_0^\infty e^{-u/2}\phi(u)e^{-iru}\,du.$$

Then $h_\phi \in \mathsf{PW}$, and

$$\langle \mathcal{W}_\xi, \phi\rangle := \sum_\rho h_\phi(z_\rho)$$

defines a distribution $\mathcal{W}_\xi \in \mathcal{D}'((0,\infty))$. Consequently the symbolic kernel $\sum_\rho e^{-t\rho}$ is a distributional wave kernel, not an ordinary heat trace.

Proof. This is the standard Paley–Wiener form of the Weil explicit formula: compact support of $\widehat{h}$ makes the prime sum finite and the archimedean term is the distribution W_∞. The second statement is obtained by substituting the compactly supported function $u \mapsto e^{-u/2}\phi(u)$ into the same formula. Approximation of the point kernel uses mollifiers $\widehat{h}_{t,\epsilon}(u) = e^{-u/2}\epsilon^{-1}\eta((u-t)/\epsilon)$; the convergence is in $\mathcal{D}'((0,\infty))$, not pointwise heat trace convergence. □

Theorem 62.3.10 *(trace-compatibility as regularised Weil/Connes hierarchy). (conditional on the H-P^{Ar} trace realisation).* Let $\lambda = \lambda_{\mathrm{BK}}$ be the Berry–Keating weight of Definition 62.3.1. The trace-compatibility condition (57.1) is the regularised Weil/Connes trace hierarchy

$$\sum_\rho{}^{\mathrm{reg}} h_t(z_\rho) \;=\; \int_{-\infty}^{\infty} h_t(r)\,dW(r) \;-\; 2\sum_{n\ge 1}\frac{\Lambda(n)}{\sqrt{n}}\widehat{h}_t(\log n) \tag{62.1}$$

for the wave-kernel test family associated to $e^{-t\Theta_\xi}$, after the admissible regularisation of Lemma 62.3.9 is supplied. The admissibility and regularisation are the trace-realisation bridge required for H-P^{Ar}; the classical Weil formula applies only to admissible test functions. Under the full H-P^{Ar} determinant condition, $z_\rho = t_\rho$ and the trace becomes the ordinate trace.

Proof. Under the BK weight system, the Friedrichs operator acts on δ_m by eigenvalue $\log m$. The regularised trace of $e^{-tL_0^{\mathrm{Ar}}}$ on the zero-mode lattice is $\sum_{m\ge 1} e^{-t\log m} = \sum_{m\ge 1} m^{-t} = \zeta(t)$, convergent for $t > 1$ and meromorphically continued.

Combining with the archimedean Dedekind-eta inverse product $\prod_{i\ge 1}(1-e^{-ti})^{-1}$ and subtracting the archimedean descendant contribution (Tate-pole and archimedean terms) via the Bost–Connes regularisation (Proposition 57.3.3), one obtains

$$\mathrm{tr}_{\mathrm{BC}}(e^{-tL_0^{\mathrm{Ar}}}) = \zeta(t)\cdot\eta(it)^{-1}\cdot(\text{regularisation}),$$

with the archimedean terms removed by the Bost–Connes/Dedekind-eta prescription. The Hadamard product for $\xi_{\mathbb{R}}$ rewrites the zero side as a regularised zero trace. The classical Weil explicit formula supplies this identity for the admissible Paley–Wiener test spaces of Lemma 62.3.9. The Vol IV condition is the additional assertion that the Bost–Connes/Fock trace is carried to that distributional extension. Therefore the theorem is a reformulation of the trace-compatibility hierarchy under H-P^{Ar}, not a proof of H-P^{Ar}. □

Corollary 62.3.11 *(the hierarchy is the Connes absorption-trace bridge). (conditional on the H-P^{Ar} trace realisation).* Under the BK weight selection, the H-P^{Ar} trace-compatibility condition is the

Connes–Meyer–Weil absorption-trace bridge for the Bost–Connes/Weil wave-distribution family. The classical Weil explicit formula applies to admissible Paley–Wiener test functions; the admissibility and trace-identification of the BC heat-trace family is the additional content.

Proof. The previous theorem identifies the needed equality with the regularised explicit-formula extension for the BC/Weil wave family. By Corollary 57.3.9, this is the same structural condition as the Connes absorption-trace realisation. The admissibility and trace-identification step is precisely what H-P^{Ar} asserts. □

Remark 62.3.12 *(weight selection and H-P^{Ar}).* Theorem 62.3.7 and Corollary 62.3.11 together state: if H-P^{Ar} holds, the weight is uniquely Berry–Keating under the zeta/KMS normalisation. Whether the Berry–Keating weight satisfies the trace compatibility is the regularised Connes absorption-trace problem. The reduction is tight: the canonical weight is determined under explicit normalisation, while the trace identity is the classical absorption-trace problem.

62.4 Hamburger Determinacy Obstruction

The Symmetrised Shifted-Zero Measure

Definition 62.4.1 *(symmetrised shifted-zero moment sequence).* For a non-trivial zero ρ of ξ, put

$$z_\rho := -i(\rho - \tfrac{1}{2}), \qquad x_\rho := \rho(1-\rho) = \tfrac{1}{4} + z_\rho^2.$$

The number z_ρ is real for every zero exactly under RH. The *symmetrised shifted-zero moment sequence* is

$$\mu_{2n} := \sum_{\rho}^{\mathrm{reg}} x_\rho^n$$

with odd moments zero, provided a specified common linear regularization makes every displayed value finite. The notation $\sum^{\mathrm{reg}}$ is this additional datum, not a summation procedure furnished by zero counting. Under RH the finite-cutoff terms are nonnegative but their sums diverge. Positivity of the regularized functional must therefore be proved separately.

Remark 62.4.2 *(relation to the symmetrised zero measure of the residual splitting).* The off-line defect measure of Definition 45.4.1 is not the shifted-zero moment measure defined here. For the latter, a positive representing measure is sought only after finite moments have been supplied. Under a common linear regularization of the unshifted powers, $\mu_{2n} = \sum_{k=0}^{n} \binom{n}{k} 4^{-(n-k)} M_{2k}$. This polynomial identity fixes the required compatibility but does not construct the regularization or its positive representing measure.

Li-Coefficient Bounds Do Not Give Carleman Moments

Proposition 62.4.3 *(Li-coefficient bounds do not imply Carleman moments).* The Bombieri–Lagarias bounds for Li coefficients do not imply the Carleman estimate for the regularised moments μ_{2n} in this argument. An estimate of the form $|\lambda_n| = O(n \log n)$ would not by itself imply

$$|\lambda_n| = O(n \log n) \quad \not\Longrightarrow \quad \mu_{2n}^{1/(2n)} = O(n) :$$

a separate positivity and domination theorem is required.

Proof. The Li coefficient is the oscillatory zero sum

$$\lambda_n = \sum_{\rho} \left(1 - \left(1 - \frac{1}{\rho} \right)^n \right).$$

The shifted-zero moment relevant to Carleman is instead the positive regularised quantity

$$\mu_{2n} = \operatorname*{reg}_{\rho} \left(\frac{1}{4} + \gamma_\rho^2 \right)^n.$$

An estimate for the oscillatory Li sum gives no bound on the absolute or positive regularised $2n$-th moment without a separate positivity and domination theorem. Reversing the cancellations in the Li sum would itself be a new spectral-positivity input. Hence the Bombieri–Lagarias theorem is evidence for the Li/RH reformulation but not a Carleman proof. □

Remark 62.4.4 *(direction of the Carleman bound).* A lower bound on μ_{2n} would give an upper bound on $\mu_{2n}^{-1/(2n)}$, not the lower bound on $\mu_{2n}^{-1/(2n)}$ that Carleman's divergence criterion requires. Carleman's criterion is driven by upper growth of the moments, together with positivity of the representing measure.

Tightest Conditional Reduction

THEOREM 62.4.5 *(Hamburger determinacy from linear upper growth).* Suppose the symmetrised shifted-zero moments come from a positive regularised Hamburger moment functional and there is a constant $C > 0$ such that

$$\mu_{2n}^{1/(2n)} \leq Cn$$

for all sufficiently large n. Then Carleman's criterion holds:

$$\sum_{n \geq 1} \mu_{2n}^{-1/(2n)} = +\infty.$$

Consequently the associated Hamburger moment problem is determinate.

Proof. The upper-growth hypothesis gives

$$\mu_{2n}^{-1/(2n)} \geq \frac{1}{Cn}$$

for all large n. The harmonic series diverges, so Carleman's criterion applies. By the classical Carleman theorem for Hamburger moments, the positive moment functional is determinate. □

COROLLARY 62.4.6 *(unconditional inputs and the Carleman gap).* The unconditional inputs used here do not imply the hypotheses of Theorem 62.4.5: the required positive regularised moment functional and the linear upper-growth estimate $\mu_{2n}^{1/(2n)} = O(n)$ are additional analytic inputs.

Proof. Proposition 62.4.3 blocks the only candidate unconditional shortcut above. The Riemann–von Mangoldt counting formula controls the distribution of zeros by height, but by itself it does not define the required positive regularised moment functional nor bound the regularised moments after off-line and archimedean terms are included. □

Theorem 62.4.7 *(A sufficient determinacy estimate and its arithmetic use).* Let L be a specified positive Hamburger moment functional with moments $\mu_n = L(x^n)$, including the chosen symmetrization and regularization. Suppose

$$(\mathrm{R}_{\mathrm{analytic}}) \qquad \limsup_{n\to\infty} \frac{\mu_{2n}^{1/(2n)}}{n} < \infty.$$

Then its representing measure is determinate. To conclude arithmetic VB*, additionally assume that this is the moment functional of the specified arithmetic operator, that its measure has the spectral support required in (Reg), and that the operator-positivity comparison in item 1 of Hypothesis 57.4.21 holds on the stated domains. Under these additional assumptions, (Reg), hence VB*, holds.

Proof. For some $C > 0$, eventually $\mu_{2n}^{1/(2n)} \le Cn$. If any even moment vanishes, positivity forces the measure to be supported at zero. Otherwise the Carleman sum dominates $C^{-1}\sum n^{-1}$ after finitely many terms and diverges. The classical Hamburger Carleman theorem gives determinacy. Positivity, this determinacy, and the separately supplied support condition constitute (Reg). Item 1 of the specified arithmetic comparison then gives VB*. The growth estimate alone does not construct that operator comparison or its support. □

Remark 62.4.8 *(domain of* $\mathrm{R}_{\mathrm{analytic}}$*).* $(\mathrm{R}_{\mathrm{analytic}})$ is a one-sided upper-growth condition, distinct from a two-sided asymptotic. Its relation to RH is not determined here: the condition may be strictly weaker, or RH-equivalent. It supplies the exact positivity and upper-growth information that Carleman's criterion requires. Standard zero-density theorems count zeros in regions; the residual controls a regularised moment functional.

Remark 62.4.9 *(form of the determinacy residual).* $(\mathrm{R}_{\mathrm{analytic}})$ is a sufficient condition for the Vol IV determinacy step. It identifies the exact analytic shape of the positivity theorem required; neither the classical Weil formula nor the Bombieri–Lagarias bounds supply it.

62.5 Consequence for the RH Comparison in Chapter 58

Theorem 62.5.1 *(determinacy consequence for the Chapter 58 single positivity corollary).* Assume P1, P2 and P3 on their stated domains. Assume also the arithmetic moment-functional identification, spectral support, and operator comparison in Theorem 62.4.7. Then the following three additional inputs suffice for the conditional implication to RH:

(i) the Berry–Keating weight is forced by the additive KMS/zeta-partition normalisation (Theorem 62.3.7).

(ii) H-P^{Ar} holds with the Berry–Keating weight, meaning that the Bost–Connes trace is identified with the regularised Weil/Connes trace hierarchy (Theorem 62.3.10).

(iii) $(\mathrm{R}_{\mathrm{analytic}})$: the shifted-zero moments form a positive regularised Hamburger moment sequence with $\mu_{2n}^{1/(2n)} = O(n)$ (Theorem 62.4.7).

Under these three inputs and all the moment, support, operator and P1–P3 hypotheses stated above, the Chapter 58 implication to RH follows.

Proof. (1) provides the uniquely-determined candidate operator $L_{\mathrm{o}}^{\mathrm{Ar}} = L_{\mathrm{o}}^{\mathrm{Ar}}(\lambda_{\mathrm{BK}})$. (2) is precisely the trace-compatibility condition which, via Theorem 57.3.14, asserts H-P^{Ar}. (3) supplies determinacy by Theorem 62.4.7. The assumed moment identification and support then give (Reg), and the operator

comparison gives VB*. Together with the stated P1–P3 and determinant-trace inputs, this is the sufficient arithmetic package of Corollary 58.4.3. □

COROLLARY 62.5.2 *(structure of the determinacy reduction).* The determinacy comparison reduces the Chapter 58 single positivity theorem to three named residuals:

(W) *Weight normalisation*: an additive Bost–Connes weight with zeta partition function and prime-by-prime KMS compatibility. Under (W), $\lambda = \lambda_{\mathrm{BK}}$.

(H) *H-P trace bridge*: the Bost–Connes/Dedekind-eta heat trace is the admissible regularised Weil/Connes zero trace. Under (H), H-P^{Ar} holds for the BK operator.

($\mathrm{R}_{\mathrm{analytic}}$) *Carleman positivity*: the shifted-zero moments form a positive regularised Hamburger moment sequence and satisfy $\mu_{2n}^{1/(2n)} = O(n)$. Under ($\mathrm{R}_{\mathrm{analytic}}$), Hamburger determinacy holds.

All three together give the residual H-P/VB implication only with the moment-functional identification, spectral support, operator comparison and P1–P3 hypotheses of the preceding theorem.

Proof. Direct from Theorem 62.5.1. (W) fixes the candidate operator; (H) supplies determinant-trace matching; and ($\mathrm{R}_{\mathrm{analytic}}$) supplies determinacy. Omitting any one leaves either no fixed operator, no zero trace, or no VB* converse. □

62.6 RESIDUAL CONDITIONS

After the determinacy reductions, the Chapter 58 RH implication requires:

(i) **(W) Weight normalisation**. The BK weight is forced once the additive zeta partition function is fixed prime-by-prime. The remaining assertion is that that the Vol IV Friedrichs construction really lands in this KMS/zeta normalisation.

(ii) **(H) H-P trace bridge**. The analytic theorem is the admissible regularised extension identifying the BC/Dedekind-eta heat trace with the Connes zero trace; the classical Weil explicit formula applies to admissible test functions and is a step toward, not a substitute for, this identification.

(iii) ($\mathrm{R}_{\mathrm{analytic}}$) **Carleman positivity**. The required analytic input is a positive regularised shifted-zero moment functional with $\mu_{2n}^{1/(2n)} = O(n)$; this estimate lies beyond the reach of the Bombieri–Lagarias Li-coefficient bounds by Proposition 62.4.3.

(iv) **Compatibility with the Chapter 58 hypothesis**. The RH completion hypothesis of Definition 58.4.1 requires P1, P2, P3, H-P^{Ar}, and Hamburger determinacy together. P1 is conditional on arithmetic Positselski (requires a non-formal theorem); P2 unconditional; P3 conditional on Koszul–Petersson compatibility (requires a non-formal theorem); H-P^{Ar} (RH-equivalent); determinacy reduces to ($\mathrm{R}_{\mathrm{analytic}}$).

Remark 62.6.1 *(determinacy consequences).* H-P^{Ar} determinant-trace matching and Hamburger determinacy are RH-equivalent or RH-adjacent analytic problems. The determinacy comparison gives:

(i) *Conditional uniqueness of the weight system*: the Berry–Keating $\lambda(m) = \log m$ is forced by additive zeta/KMS normalisation.

(ii) *Explicit identification of the trace-compatibility hierarchy*: the infinite sequence of conditions is the regularised Weil/Connes trace bridge; the classical Weil formula applies to admissible test functions and is a step in the bridge.

(iii) *Independence of Li-coefficient bounds and Carleman moments*: the Bombieri–Lagarias bounds do not imply the Carleman estimate by Proposition 62.4.3.

(iv) *The single analytic residual* (R_{analytic}): Hamburger determinacy reduces to positivity plus linear upper growth for the regularised moments.

(v) *Compatibility with Chapter 58*: the three residuals (W), (H), (R_{analytic}) give the H-P/VB implication after the conditional P1/P3 inputs, arithmetic moment identification, spectral support and operator comparison are supplied.

62.7 Determinacy Boundary

(i) **Weight selection is uniquely determined after normalisation** (Theorem 62.3.7). Among four canonical tests, only the Berry–Keating $\lambda(m) = \log m$ survives as a BC semigroup weight with zeta partition function (Theorem 62.3.5).

(ii) **The trace-compatibility hierarchy is the regularised Weil/Connes bridge** (Theorem 62.3.10, Corollary 62.3.11). The H-P^{Ar} trace identity needs an admissible extension of the explicit formula to the BC heat-trace family.

(iii) **Hamburger determinacy reduces to a single analytic positivity residual** (Theorem 62.4.7). Under (R_{analytic}), the moments are positive and satisfy $\mu_{2n}^{1/(2n)} = O(n)$, so Carleman's criterion holds.

(iv) **Li-coefficient bounds do not give Carleman moments** (Proposition 62.4.3). Li-coefficient bounds are oscillatory zero-sum bounds; a separate positivity and domination theorem is required for Carleman.

(v) **Three precisely-named residuals** (Corollary 62.5.2): weight normalisation (W), H-P trace bridge (H), and Carleman positivity (R_{analytic}).

(vi) **Domain of the reduction**. H-P^{Ar} reduces to the Connes absorption-trace conjecture (RH-equivalent); Hamburger determinacy reduces to (R_{analytic}) (RH-adjacent); no new RH-equivalent positivity language beyond the the residual splitting list of Det, HB+, BD+ is produced.

(vii) **The residual conjunction**. The three residuals (W), (H), (R_{analytic}) are each precisely stated; their conjunction, together with the conditional P1/P3 inputs, the arithmetic moment identification, spectral support and operator comparison, gives the conditional Vol IV implication to RH.

The two analytic problems are the Bost–Connes absorption-trace bridge and positivity with Carleman-scale upper growth for the regularised shifted-zero moments.

Chapter 63

Arithmetic and Geometric Local Equivalences

The critical-level fundamental local equivalence (FLE) and its quantum and small variants are theorems in the geometric Langlands programme over complex curves. The arithmetic branch of this volume studies $\mathcal{V}^{\mathrm{prim}}$, the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2, and its conjectural companions F1, F2, F3. This chapter compares the geometric domains with the mixed-characteristic carriers required by F1/F2/F3. Arithmetic-FLE realization requires the actual functors and compatibility maps in the conditions of Section 63.5.

63.1 Source Theorems

Theorem 63.1.1 *(geometric critical-level FLE).* The 2024 geometric-Langlands proof constructs the critical-level fundamental local equivalence in the geometric setting over a smooth projective curve in characteristic 0:

$$\mathrm{KL}(G)_{\mathrm{crit}} \;\simeq\; \mathrm{IndCoh}^{*}\big(\mathrm{Op}^{\mathrm{mf}}_{\check{G}}\big),$$

with compatibility with Kac–Moody localization. Its source is Arinkin–Beraldo–Campbell–Chen–Faergeman–Gaitsgory–Lin–Raskin– Rozenblyum, *Proof of the geometric Langlands conjecture II: Kac–Moody localization and the FLE*, arXiv:2405.03648.

Theorem 63.1.2 *(quantum and small FLE sources).* The quantum and small FLE layer consists of local geometric and metaplectic/quantum statements over a complex curve. Campbell–Dhillon–Raskin's *Fundamental local equivalences in quantum geometric Langlands* (arXiv:1907.03204) and Gaitsgory–Lysenko's small-FLE work (arXiv:1903.02279) establish equivalences whose source categories are Kazhdan–Lusztig or metaplectic representations and whose target categories are quantum groups or root-of-unity modules over a formal disk. The arithmetic analogue of these equivalences is an open problem at each finite prime.

Remark 63.1.3 *(domain of the geometric FLE sources).* The FLE sources operate within the geometric Langlands, Kac–Moody, Whittaker, and root-of-unity quantum-group framework over complex curves. A local categorical p-adic Langlands equivalence over $\mathbb{Q}_p$, a globalization over $\overline{\mathrm{Spec}\,\mathbb{Z}}$, and an Emerton–Gee full Weil/(φ,Γ) target comparison each require additional technology: Fargues–Scholze's geometrization, prismatic or pro-étale methods, and the Emerton–Gee eigenvariety construction.

63.2 Domain Distinction: Geometric FLE vs F1/F2/F3

Proposition 63.2.1 *(F1/F2/F3 as a distinct mixed-characteristic programme).* . The arithmetic branch's F1 (local categorical Langlands comparison for $GL_2/\mathbb{Q}_p$ against the Emerton–Gee stack), F2 (mixed-characteristic E_2 Hecke enhancement and restricted tensor product), and F3 (Ben-Zvi–Nadler Hochschild-trace comparison against the full Weil/(φ,Γ) target) constitute a mixed-characteristic local-global Langlands and Hochschild-trace programme whose source and target categories are disjoint from those of the geometric FLE.

Proof. The geometric FLE (Theorem 63.1.1) pairs critical-level Kac–Moody or Whittaker/factorizable categories as source with oper or quantum-group categories over a smooth projective complex curve as target. F1 pairs the spherically-finite automorphic category for $GL_2/\mathbb{Q}$ as source with ind-coherent sheaves on the Emerton–Gee stack as target. F2 requires a mixed-characteristic E_2 Hecke enhancement and restricted tensor product. F3 requires a Ben-Zvi–Nadler Hochschild-trace comparison against the full Weil/(φ, Γ) arithmetic target. The targets of F1, F2, F3 are Emerton–Gee and Weil/(φ, Γ) stacks; the inputs at finite primes are adelic Hecke categories, not Beilinson–Drinfeld chiral algebras over a complex curve. □

Remark 63.2.2 *(finite-prime categorical structure).* At a finite prime p, the relevant categorical structure is the category $\mathrm{Coh}(\mathrm{Bun}_G)$ of coherent sheaves on the moduli stack of G-bundles on the Fargues–Fontaine curve, equipped with the Fargues–Scholze spectral action (arXiv:2102.13459), together with Hecke correspondences, diamonds, and (φ, Γ)-modules. The archimedean fibre carries classical Kac–Moody and chiral intuition, providing the motivating analogy; the finite-prime framework is governed by Fargues–Scholze geometrization and Emerton–Gee eigenvarieties.

63.3 Coefficient Categories and Geometric Domains

Remark 63.3.1 *(local/global type distinction).* F1, F2, and F3 are local-global Langlands and Hochschild-trace conjectures. Their source is the automorphic category for $GL_2/\mathbb{Q}$ or its local p-adic analogue; their target is the Emerton–Gee stack or the full Weil/(φ, Γ) coherent sheaf theory. These source and target types differ from those of the geometric FLE.

Remark 63.3.2 *(finite-prime chiral structure).* At a finite prime, the relevant structure is the Beilinson–Drinfeld factorization algebra and the Hecke correspondence on Bun_G, governed by Fargues–Scholze geometrization. The archimedean fibre carries Kac–Moody and chiral intuitions as a motivating analogy.

Remark 63.3.3 *(quantum-group and root-of-unity source domain).* The root-of-unity and small-FLE sources (Campbell–Dhillon–Raskin, Gaitsgory–Lysenko) are geometric and quantum: they operate over a complex curve with a quantum parameter q a root of unity or with a metaplectic covering. The parameter p^{-s} appearing in local Hecke eigenvalues at a prime p is a spectral parameter, distinct from a root-of-unity quantum-group parameter.

Remark 63.3.4 *(function-field transport and number-field domain).* Raskin's globalization operates over a function field. The transport to a number field requires: (a) a local categorical comparison F1 at each prime, and (b) a prismatic or BC-diamond-glue transition across primes. Both remain open.

Remark 63.3.5 *(mixed-characteristic substrate).* The arithmetic compactification $\overline{\mathrm{Spec}\,\mathbb{Z}}$ carries an archimedean place and mixed-characteristic fibres. A curve in characteristic 0 carries neither. The arithmetic programme requires mixed-characteristic methods (prismatic cohomology, perfectoid geometry) at each finite prime and complex-analytic methods at the archimedean place.

Remark 63.3.6 *(independent form for arithmetic FLE).* Arithmetic FLE has no pair of independent constructions in the present arithmetic formalism. An arithmetic FLE theorem requires first the boundary conditions of Section 63.5.

Remark 63.3.7 *(AGKRRV 2024 source and target).* Arinkin–Beraldo–Campbell–Chen–Faergeman–Gaitsgory–Lin–Raskin–Rozenblyum (arXiv:2405.03648) establishes the critical FLE between $\mathrm{KL}(G)_{\mathrm{crit}}$ and $\mathrm{IndCoh}^*(\mathrm{Op}^{\mathrm{mf}}_{\check{G}})$: source is critical-level Kac–Moody, target is monodromic opers

on a complex curve. The Emerton–Gee stack is a mixed-characteristic eigenvariety; its objects are (φ, Γ)-modules, not monodromic opers.

Remark 63.3.8 *(F3/BZN form against full Weil target).* F3 asks for a Ben-Zvi–Nadler Hochschild-trace identification between the automorphic side and coherent sheaves on the Weil/(φ, Γ) stack. The inertia-only loop object $B\widehat{\mathbb{Z}}$ captures only the tame/procyclic part of inertia; the full Weil group retains wild inertia and Frobenius data. F3 with the full Weil target is a conjecture.

Remark 63.3.9 *(spectral parameter vs quantum-group parameter).* The Hecke eigenvalue at a prime p is recorded by the spectral parameter p^{-s} or equivalently by the Satake image in $\mathrm{Rep}(\check{G})$. The quantum-group deformation parameter q appearing in the quantum FLE is a root of unity or a formal parameter; identifying $q = p^{-s}$ requires an explicit independent bridge; this bridge is the sixth condition in Section 63.5.

Remark 63.3.10 *(Fargues–Scholze, Emerton–Gee, and Dotto–Emerton–Gee).* Fargues–Scholze (arXiv:2102.13459) provides the spectral action on $\mathrm{Coh}(\mathrm{Bun}_G)$ via the Fargues–Fontaine curve. Emerton–Gee (arXiv:1908.07185) constructs the stack of (φ, Γ)-modules. Dotto–Emerton–Gee establishes full faithfulness of a functor to mod-p representations; an equivalence of ∞-categories between the automorphic and the Emerton–Gee coherent side is the content of F1.

Remark 63.3.11 *(Hypotheses of the three comparisons).* F1 carries form *Conditional*: the local categorical comparison is supported by Fargues–Scholze (arXiv:2102.13459) and Emerton–Gee (arXiv:1908.07185) and requires the adelic-descent and BC-diamond-glue steps. F2 carries form *Conditional*: the mixed-characteristic E_2 Hecke enhancement and restricted tensor product are formally accessible but unproved. F3 carries form *Conjecture*: the full Weil/(φ, Γ) target comparison is beyond current techniques. These comparison hypotheses remain necessary for the corresponding conditional implications.

Remark 63.3.12 *(local Satake/Yangian normalization).* The local Satake isomorphism identifies the spherical Hecke algebra with the representation ring of $\check{G}$. An arithmetic Yangian structure, if it exists, must be grounded in an independent comparison between the Satake filtration and an explicit Yangian coproduct; this identification remains open.

Remark 63.3.13 *(BC-diamond-glue decomposition).* The BC-diamond-glue problem decomposes into three parts: (a) the local BZCHN/Emerton–Gee comparison at each prime p, (b) cross-prime prismatic transition maps, and (c) global Bernstein-centre compatibility. Each part is open.

Remark 63.3.14 *(wild-prime correction).* At $p = 2$ and $p = 3$, the source for the local comparison carries ramification and wild inertia data not present in the tame case. A conjectural correction accounts for this; the precise form depends on the source used for the local comparison.

63.4 Geometric Equivalences and Arithmetic Comparison Data

Theorem 63.4.1 *(geometric FLE: domain and logical form).* The critical-level FLE $\mathrm{KL}(G)_{\mathrm{crit}} \simeq \mathrm{IndCoh}^*(\mathrm{Op}^{\mathrm{mf}}_{\check{G}})$ and the quantum/small FLE equivalences (Campbell–Dhillon–Raskin, Gaitsgory–Lysenko) are proved in the geometric Langlands setting over a complex curve. Their source is Campbell–Dhillon–Raskin (arXiv:1907.03204), Gaitsgory–Lysenko (arXiv:1903.02279), and Arinkin–Beraldo–Campbell–Chen–Faergeman–Gaitsgory–Lin–Raskin–Rozenblyum (arXiv:2405.03648). These results hold over smooth projective curves in characteristic 0.

Remark 63.4.2 *(archimedean chiral structure and finite-prime domain).* The Kac–Moody and chiral algebra structures provide the motivating analogy at the archimedean place. At finite primes, the geometric structures are Beilinson–Drinfeld factorization algebras, Hecke correspondences, and the Fargues–Scholze spectral action; the finite-prime analogue of the critical-level FLE is the content of F1.

Remark 63.4.3 *(F1, F2, F3, and Bernstein-centre comparison data).* F1 (local categorical Langlands comparison for $GL_2/\mathbb{Q}_p$ via Emerton–Gee, with Fargues–Scholze spectral action as input) carries form *Conditional*: the comparison requires adelic-descent and BC-diamond-glue steps. F2 (mixed-characteristic E_2 Hecke enhancement and restricted tensor product for the adelic assembly) carries form *Conditional*: the ∞-categorical Tate restricted tensor product is accessible in principle but unproved. F3 (Ben-Zvi–Nadler Hochschild-trace identification against the full Weil/(φ, Γ) target, with the full Weil group including wild inertia and Frobenius data) carries form *Conjecture*. BC-diamond-glue decomposes into local BZCHN/Emerton–Gee comparison, cross-prime prismatic transition maps, and global Bernstein-centre compatibility; each component is open. The wild-prime correction at $p = 2, 3$ is a source-sensitive conjecture; the precise form depends on the local comparison chosen.

63.5 Open Conditions

(i) Formulate the mixed-characteristic local categorical equivalence F1: construct a comparison between the spherically-finite automorphic ∞-category for $GL_2/\mathbb{Q}_p$ and ind-coherent sheaves on the Emerton–Gee stack, with the Fargues–Scholze spectral action (arXiv:2102.13459) as input.

(ii) Extend the loop-space comparison from the inertia-only object $B\widehat{\mathbb{Z}}$ to the full Weil group (with wild inertia and Frobenius data) and prove the flat pullback statement in the full Weil/(φ, Γ) setting.

(iii) Prove profinite formal-loop continuity for $\mathrm{Map}(B\widehat{\mathbb{Z}}, -)$ in the formal Noetherian pro-étale setting, supplying the foundational input for the inertia-only portion of F3.

(iv) Prove the mixed-characteristic E_2 Hecke enhancement and the ∞-categorical Tate restricted tensor product required for F2.

(v) Prove BC-diamond-glue in its three components: (a) the local BZCHN/Emerton–Gee comparison, (b) cross-prime prismatic transition maps, and (c) global Bernstein-centre compatibility.

(vi) Construct an independent bridge between the Satake spectral parameter p^{-s} and the quantum-group deformation parameter q of the quantum FLE, grounded in an explicit comparison of the Satake filtration and the Yangian coproduct.

(vii) Establish two independent constructions of arithmetic FLE.

Remark 63.5.1 *(source role of the geometric FLE results).* The geometric FLE (Theorems 63.1.1 and 63.1.2), quantum geometric Langlands, and Raskin's globalization provide motivating analogies and local-model inputs for F1, F2, F3. Each such use requires an explicit independent bridge; the bridges are the conditions listed above.

Chapter 64

Two-Prime Restriction and Bernstein Actions

A global Galois representation restricts to a representation at each finite place. Reconstructing the global object from two restrictions is a different problem. Even with fixed determinant and absolutely irreducible residual representation, two restrictions can agree for distinct global lifts. The resulting deformation ring map nevertheless constructs a pairwise pullback module and its local central actions. Comparing this module with a global prismatic sheaf requires an isomorphism of the actual objects, including their extension data.

64.1 The Deformation Problem

Fix distinct finite primes p, q and a coefficient prime $p_0 \neq p, q$. Let k be a finite field of characteristic p_0, and put $W = W(k)$. Choose a finite set S of places of $\mathbb{Q}$ containing p, q, p_0, ∞. Write $G_{\mathbb{Q},S}$ for the Galois group of the maximal extension unramified outside S. Fix a continuous representation $\bar{\rho} : G_{\mathbb{Q},S} \to GL_2(k)$ which is absolutely irreducible, and let $\bar{D}$ be its determinant polynomial law. Here a determinant of dimension two is a multiplicative homogeneous polynomial law of degree two on the group algebra, as in Definition 73.1.1. Its characteristic coefficients, rather than a trace alone, define the object in all residual characteristics.

Choose decomposition-group maps $G_{\mathbb{Q}_p}, G_{\mathbb{Q}_q} \to G_{\mathbb{Q},S}$. Choose closed local and global deformation conditions preserved by restriction. These may include a fixed determinant character lifting $\det \bar{\rho}$. For a finite local W-algebra A with residue field k, let $\mathcal{D}_{\mathrm{glob}}(A)$ and $\mathcal{D}_v(A)$ denote the corresponding sets of continuous lifts of the residual determinant, for $v = p, q$. The local residual restrictions need not be absolutely irreducible.

Chenevier's representability theorem gives complete Noetherian local rings R^{Ch}, R^{Ch}_p, R^{Ch}_q for these functors. The precise hypotheses and primary locators are in Proposition 73.1.2: Chenevier, arXiv:0809.0415, Proposition 3.3 and Example 3.4, p. 42, and Example 3.6 and Proposition 3.7, p. 43. Each closed condition must be represented by the quotient used here. These are formal deformation rings over one coefficient ring W. An identification with functions on a local or global spectral stack is additional geometric data.

A Pair of Indistinguishable Local Restrictions

Proposition 64.1.1 *(nonuniqueness with absolutely irreducible residual representation).* There are distinct continuous rank-two determinant deformations over $\mathbb{Z}/8\mathbb{Z}$, with the same absolutely irreducible residual representation and fixed determinant character, whose restrictions at 3 and 5 coincide.

Proof. Let K be the splitting field of $X^3 - X - 1$ over $\mathbb{Q}$. The polynomial has no root modulo 2, hence is irreducible over $\mathbb{Q}$. Its discriminant is -23, so its Galois group is S_3. An integral standard representation

of this group is generated by

$$A = \begin{pmatrix} 0 & -1 \\ 1 & -1 \end{pmatrix}, \qquad B = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Direct multiplication gives $A^3 = B^2 = 1$ and $BAB = A^{-1}$. Modulo 2, the two eigenlines of A over $\mathbb{F}_4$ are interchanged by B. Thus this residual representation is absolutely irreducible. Inflate the integral representation to $\rho : G_{\mathbb{Q}} \to GL_2(\mathbb{Z}_2)$.

Let χ be the quadratic character of $L = \mathbb{Q}(\sqrt{241})$. For $v = 3, 5$, the polynomial $X^2 - 241$ has the simple root 1 modulo v. A root u_r modulo v^r lifts uniquely in its residue class modulo v^r: the correction $u_r + cv^r$ is determined by an equation with invertible coefficient $2u_r$ modulo v. Taking the limit gives a root in $\mathbb{Z}_v$. Hence $\chi|_{G_{\mathbb{Q}_v}} = 1$ for both places. Set $\rho' = \chi\rho$. Then

$$\bar{\rho}' = \bar{\rho}, \qquad \det \rho' = \chi^2 \det \rho = \det \rho.$$

The restrictions of ρ and ρ' at 3 and 5 agree. Both are unramified outside $S = \{2, 3, 5, 23, 241, \infty\}$.

The unique quadratic subfield of K is $\mathbb{Q}(\sqrt{-23})$, which differs from L. Consequently $K \cap L = \mathbb{Q}$, and the composite extension has Galois group $S_3 \times C_2$. Choose g whose image is $(1, -1)$. Then

$$\det(T - \rho(g)) = T^2 - 2T + 1, \qquad \det(T - \rho'(g)) = T^2 + 2T + 1.$$

The traces are 2 and 6 modulo 8. Thus the determinant laws of the two reductions modulo 8 are distinct lifts of the same residual law, with the asserted common local restrictions and fixed determinant character. □

The example lies in a single finite-ramification deformation problem. A more restrictive arithmetic condition could exclude one lift. Uniqueness on such a condition would require its own proof.

64.2 Restriction, Closed Image, and Fibres

The local product functor is represented by

$$B_{p,q} = R_p^{\mathrm{Ch}} \widehat{\otimes}_W R_q^{\mathrm{Ch}} = \varprojlim_r (R_p^{\mathrm{Ch}}/\mathfrak{m}_p^r) \otimes_W (R_q^{\mathrm{Ch}}/\mathfrak{m}_q^r).$$

The completion is for the sum of the maximal ideals. Restriction is a natural transformation $\mathcal{D}_{\mathrm{glob}} \to \mathcal{D}_p \times \mathcal{D}_q$, so its map on representing rings has the opposite direction.

PROPOSITION 64.2.1 *(the formal restriction diagram).* Restriction induces a continuous local W-algebra homomorphism

$$r_{p,q}^{\sharp} : B_{p,q} \longrightarrow R^{\mathrm{Ch}}, \qquad x \otimes y \longmapsto r_p^{\sharp}(x) r_q^{\sharp}(y). \tag{64.1}$$

For the map in Equation (64.1), put $J_{p,q} = \ker r_{p,q}^{\sharp}$ and $C_{p,q} = B_{p,q}/J_{p,q}$. Then

$$B_{p,q} \twoheadrightarrow C_{p,q} \hookrightarrow R^{\mathrm{Ch}}, \qquad \operatorname{Spf} R^{\mathrm{Ch}} \longrightarrow \operatorname{Spf} C_{p,q} \hookrightarrow \operatorname{Spf} B_{p,q}.$$

For a continuous local map $b : B_{p,q} \to A$, the fibre over the prescribed local pair is represented over A by $R^{\mathrm{Ch}} \widehat{\otimes}_{B_{p,q},b} A$.

Proof. Restricting the universal determinant gives maps $r_v^\sharp : R_v^{\mathrm{Ch}} \to R^{\mathrm{Ch}}$. Their images commute, and their W-actions agree. The completed tensor-product property gives $r_{p,q}^\sharp$ with the displayed formula. The kernel is closed. The quotient is complete and injects into R^{Ch}. Since the rings are profinite, its image is closed. The formal-spectrum diagram reverses these maps. For a finite local A-algebra A', a map from the completed base change to A' is precisely a map $R^{\mathrm{Ch}} \to A'$ whose restriction to $B_{p,q}$ is the prescribed map through A. This proves the fibre assertion. It is the same construction as Theorem 73.1.4. □

Definition 64.2.2 *(the closed image of two-prime restriction).* The formal scheme Spf $C_{p,q}$ is the closed image of restriction inside the local deformation product. A proposed two-prime Selmer algebra $R_{p,q}^{\mathrm{Ch}}$ requires a specified $B_{p,q}$-algebra structure and comparison $R_{p,q}^{\mathrm{Ch}} \to C_{p,q}$ before the two can be identified. The quotient $C_{p,q}$ itself imposes the kernel relations only.

Example 64.2.3 *(a flat closed-image map with a nonliftable point).* Let $B = k[[x]]$ and $R = k[[t]]$, with $x \mapsto t^2$. Every series in t is uniquely $f(t^2) + t\,g(t^2)$. Thus R is free of rank two over B, and the map is injective. Its kernel quotient is B itself. Nevertheless, the local point $B \to k[\epsilon]/(\epsilon^2)$, $x \mapsto \epsilon$, has no lift to R. A local image of t is $a\epsilon$, whose square is zero. Flatness does not turn the closed image into the image functor on these Artinian points.

Example 64.2.4 *(an ordinary fibre with nontrivial derived structure).* For $B = k[[x]] \to R = k$, $x \mapsto 0$, the fibre over the residue point has ordinary coordinate ring k. The free resolution $[B \xrightarrow{x} B]$, in cohomological degrees -1, 0, gives

$$k \otimes_B^{\mathbb{L}} k \simeq k \oplus k[1], \qquad H^{-1}(k \otimes_B^{\mathbb{L}} k) = k.$$

Thus the derived fibre retains information lost by the ordinary fibre. The same calculation proves that this map is not flat.

Remark 64.2.5 *(the information retained by restriction).* The kernel quotient records equations satisfied by local pairs. The fibres record their global lifts. Proposition 64.1.1 shows that those lifts need not be unique, so $r_{p,q}^\sharp$ need not be surjective. In a derived deformation theory the fibre uses derived completed tensor product. None of these constructions identifies a Nygaard filtration or supplies a comparison with prismatic sheaves.

64.3 The Pairwise Pullback and Its Central Actions

Definition 64.3.1 *(completed external product and pullback).* Let M_p, M_q be finite modules over the local deformation rings. Their completed external product is the finite $B_{p,q}$-module

$$M_{p,q} = \varprojlim_r (M_p/\mathfrak{m}_p^r M_p) \otimes_W (M_q/\mathfrak{m}_q^r M_q).$$

The module obtained by ordinary restriction pullback is

$$M_{p,q}^{\mathrm{res}} = R^{\mathrm{Ch}} \widehat{\otimes}_{B_{p,q}} M_{p,q} = \varprojlim_r \frac{R^{\mathrm{Ch}} \otimes_{B_{p,q}} M_{p,q}}{\mathfrak{m}_{\mathrm{glob}}^r (R^{\mathrm{Ch}} \otimes_{B_{p,q}} M_{p,q})}. \tag{64.2}$$

The algebraic base change is finite over R^{Ch} and therefore already complete. Equation (64.2) also specifies its topology.

PROPOSITION 64.3.2 *(the action on the formal pullback).* Let Z_p, Z_q be unital W-algebras acting R_p^{Ch}-linearly and R_q^{Ch}-linearly on M_p, M_q, respectively. Each acting endomorphism is continuous for the maximal-ideal topology. Then $M_{p,q}^{\mathrm{res}}$ has a canonical action of $Z_p \otimes_W Z_q$, given by

$$(z_p \otimes z_q)(a \otimes (m_p \otimes m_q)) = a \otimes (z_p m_p \otimes z_q m_q).$$

This action commutes with the R^{Ch}-action.

Proof. Finite presentations of M_p, M_q show that $M_{p,q}$ is finite over $B_{p,q}$. Base change gives a finite module over R^{Ch}. Local linearity makes the displayed action compatible with the balancing relations and with every quotient in the inverse limits. It therefore defines an action on the completed tensors. The two local actions affect separate factors, so they commute. Multiplication on the first factor commutes with both. No topology on the abstract algebras Z_p, Z_q is needed. □

The associated coherent sheaf on Spf R^{Ch} is the ordinary pullback of the completed external product. The derived construction replaces the external product and pullback by their derived completed versions. Its boundedness requires additional Tor conditions. The ordinary pullback is exact only on a domain where the required higher Tor groups vanish.

PROPOSITION 64.3.3 *(transport of ordinary central actions).* For a W-linear category C, let $Z(C) = \mathrm{End}(\mathrm{id}_C)$ be its ordinary centre. A W-linear equivalence $F : C \to \mathcal{D}$ induces an isomorphism

$$Z(C) \xrightarrow{\sim} Z(\mathcal{D}). \tag{64.3}$$

For a fully faithful functor, this statement applies to its essential image. It does not identify the centre of a larger target category.

Proof. Choose a quasi-inverse G and the unit and counit isomorphisms. A natural endomorphism z of id_C defines an endomorphism of $\mathrm{id}_{\mathcal{D}}$ by conjugating FzG with the counit. Naturality gives a central action, and composition and addition are preserved. This defines the map in Equation (64.3). The construction with G is its inverse. Restricting a fully faithful functor to its essential image makes it an equivalence. □

Remark 64.3.4 *(local coefficients and Bernstein blocks).* For smooth representations of $GL_2(\mathbb{Q}_v)$ in characteristic zero with coefficient prime different from v, the Bernstein decomposition has the form

$$\mathrm{Rep}(GL_2(\mathbb{Q}_v)) = \prod_{\mathfrak{s}} \mathrm{Rep}_{\mathfrak{s}}(GL_2(\mathbb{Q}_v)). \tag{64.4}$$

For the blocks in Equation (64.4), the ordinary scalar comparison and its precise domain are proved in Proposition 116.2.2. Its image in the spectral categorical centre is the scalar subalgebra of Proposition 116.2.5. Using a Bernstein centre as Z_v in the formal pullback requires an action over the chosen coefficient ring and on the actual module M_v. A categorical comparison additionally needs a functor with specified essential image. A local (φ, Γ)-module at residue prime v is not identified here with a deformation over $W(k)$ of coefficient characteristic $p_0 \neq v$.

64.4 Equivariant Isomorphisms on Formal Charts

The module $M^{\mathrm{res}}_{p,q}$ is constructed from local data. Let N be an independently specified global module. The pairwise comparison asks for an isomorphism from the former to the latter which intertwines their central actions. Equal determinant laws alone do not solve this problem.

Example 64.4.1 *(extension data invisible to determinant laws).* Let $R = k[[t]]$ and $M = N = R^2$. Give them actions of $R[z]$ by

$$z|_M = 0, \qquad z|_N = J = \begin{pmatrix} 0 & t \\ 0 & 0 \end{pmatrix}.$$

For every polynomial f, one has $f(J) = f(0)1 + f'(0)J$, so both actions have characteristic polynomial $(X - f(0))^2$ for $f(z)$. The determinant polynomial laws agree after every coefficient extension. The actions also coincide modulo t. An invertible intertwiner U would satisfy $JU = 0$, contradicting $J \neq 0$. These are reducible algebra representations. They exhibit the loss of extension data for coherent objects; they do not contradict reconstruction of a representation from an absolutely irreducible residual determinant.

Proposition 64.4.2 *(the scheme of equivariant isomorphisms).* Let $(R, \mathfrak{m}, k)$ be a complete Noetherian local ring. Let M, N be free R-modules of rank n with actions of an R-algebra generated by $a_1, \dots, a_s$. Choose bases and let $P_i, Q_i \in \mathrm{Mat}_n(R)$ denote the action matrices on M, N. The functor of equivariant isomorphisms is represented by

$$\mathrm{Isom}(M, N) = \mathrm{Spec}\, \frac{R[u_{ab}, d]}{(d \det(U) - 1,\ (Q_i U - U P_i)_{ab} : i, a, b)}. \tag{64.5}$$

Here $U = (u_{ab})$, with $1 \le a, b \le n$ and $1 \le i \le s$.

Proof. Over any commutative R-algebra A, a matrix U is invertible exactly when its determinant is a unit. The variable d specifies the unique inverse of that determinant. Intertwining the generators is equivalent to intertwining the whole algebra. Thus maps from the coordinate ring in Equation (64.5) to A are exactly the equivariant isomorphisms $M \otimes_R A \to N \otimes_R A$, naturally in A. □

Proposition 64.4.3 *(successive lifting obstructions).* In the preceding situation, put $I_r = \mathfrak{m}^r/\mathfrak{m}^{r+1}$ for $r \ge 1$. Let U_r be an invertible intertwiner modulo $\mathfrak{m}^r$. Choose a lift $\widetilde{U}$ modulo $\mathfrak{m}^{r+1}$ and set

$$E_i = Q_i \widetilde{U} - \widetilde{U} P_i \in \mathrm{Mat}_n(I_r).$$

Write bars for reduction modulo $\mathfrak{m}$, and define

$$L_r : \mathrm{Mat}_n(I_r) \longrightarrow \mathrm{Mat}_n(I_r)^s, \qquad V \longmapsto (\overline{Q}_i V - V \overline{P}_i)_i.$$

The class $[(E_i)_i] \in \operatorname{coker} L_r$ is independent of the lift. It vanishes precisely when this U_r extends to an invertible intertwiner modulo $\mathfrak{m}^{r+1}$. A compatible sequence of such lifts determines an equivariant isomorphism over R.

Proof. Changing $\widetilde{U}$ by $V \in \mathrm{Mat}_n(I_r)$ changes the defects by $L_r(V)$, since $\mathfrak{m} I_r = 0$. Thus the class is independent of the lift and vanishes exactly when a correction solves every intertwining equation. The determinant of a corrected lift remains invertible modulo the maximal ideal, hence is a unit. Completeness

gives the matrix limit of a compatible sequence. The intertwining equations pass to the limit, and its determinant is a unit because its residue is. Conversely an equivariant isomorphism over R gives such a compatible sequence by reduction. □

The obstruction depends on the specified partial lift U_r. Vanishing for a compatible sequence, rather than separate choices at unrelated orders, constructs the limit. For general coherent complexes the comparison uses a derived equivariant Hom complex. The finite free criterion does not assert that the intended arithmetic sheaves satisfy its hypotheses.

64.5 Global Actions and Geometric Comparison

PROPOSITION 64.5.1 *(the action generated by local centres).* Let E be a commutative ring and Z_v commutative unital E-algebras. For finite sets S of places put $A_S = \bigotimes_{v\in S,E} Z_v$, with transition maps inserting units. Set

$$A = \varinjlim_{S \text{ finite}} A_S. \tag{64.6}$$

Pairwise commuting unital actions $\alpha_v : Z_v \to \mathrm{End}_E(M)$ on an E-module induce a unique action

$$\alpha : A \to \mathrm{End}_E(M), \qquad \alpha(\otimes_{v\in S} z_v) = \prod_{v\in S} \alpha_v(z_v).$$

Its image is $A/\ker\alpha$. Natural actions on an E-linear category instead give a map to its ordinary centre.

Proof. The product of the commuting actions is multiplicative and E-multilinear on each finite product. The tensor-product property gives an action of A_S. Inserting a unit changes no endomorphism, so these maps are compatible. The colimit in Equation (64.6) therefore gives α. The quotient assertion is the first isomorphism theorem. Products of natural endomorphisms are natural, which proves the categorical assertion. □

PROPOSITION 64.5.2 *(faithfulness and generation for a global scalar centre).* Suppose the preceding actions define $\alpha : A \to Z(C)$ on an E-linear category. Then

$$A/\ker\alpha \xrightarrow{\sim} \mathrm{im}\,\alpha \subseteq Z(C). \tag{64.7}$$

This image is the entire ordinary centre exactly when every central endomorphism is generated by the finite local actions. The map from A itself is an isomorphism exactly when it is also faithful. No identification with R^{Ch} is implicit in this statement.

Proof. The quotient isomorphism in Equation (64.7) follows from the preceding proposition. Surjectivity means precisely that every central endomorphism belongs to this image. Injectivity means $\ker\alpha = 0$. Together these are exactly the isomorphism conditions. □

Remark 64.5.3 *(first-order fixed-determinant deformations).* Let $V = k^2$ with action $\bar\rho$, and let $\mathrm{ad}\,\bar\rho = \mathrm{End}_k(V)$ with conjugation action. A lift over $k[\epsilon]/(\epsilon^2)$ has the form $(1+\epsilon c(g))\bar\rho(g)$. Multiplicativity is the continuous cocycle equation for c. The fixed-determinant condition is $\mathrm{tr}\,c(g) = 0$. Strict change of basis changes c by the coboundary of an element of $\mathrm{ad}\,\bar\rho$. Thus the tangent space before additional local conditions is

$$\frac{Z^1_{\mathrm{cts}}(G_{\mathbb{Q},S}, \mathrm{ad}^0\,\bar\rho)}{d\ \mathrm{ad}\,\bar\rho}.$$

The denominator consists of traceless cocycles. When 2 is invertible, scalar subtraction identifies it with $d\ \mathrm{ad}^{\circ}\ \bar{\rho}$, giving the usual $H^{1}_{\mathrm{cts}}(G_{\mathbb{Q},S}, \mathrm{ad}^{\circ}\ \bar{\rho})$. At characteristic two this simplification needs justification. Additional deformation conditions restrict this tangent problem. A tangent-space comparison does not identify the complete rings.

The Geometric Pairwise and Global Problems

Choose a coefficient base E for a geometric realization. Suppose local spaces X_p, X_q, a global space X, and a morphism $r : X \to X_p \times_E X_q$ have been constructed in a specified formal, analytic, or derived category. Specify coefficient comparison maps relating this diagram to the deformation rings above. Let $\mathcal{F}_p, \mathcal{F}_q$ be the local coherent objects, and let $\mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}$ be an independently defined global object. The superscript records the intended prismatic realization; its existence is an additional construction. Work in a domain where the external product and Lr^* preserve the chosen category of coherent complexes, for example on perfect complexes. Supply the local centre actions over E and their compatibility with the coefficient maps.

Proposition 64.5.4 *(external-product and pullback Tor-independence).* Suppose the local and global objects are coherent sheaves in cohomological degree zero, in a geometric domain with the stated derived external product and derived pullback. Put $\mathcal{M} = \mathcal{F}_p \boxtimes_E \mathcal{F}_q$ and $\mathcal{M}^{\mathbb{L}} = \mathcal{F}_p \boxtimes^{\mathbb{L}}_E \mathcal{F}_q$. The external-product Tor-independence condition is that the canonical augmentation $\mathcal{M}^{\mathbb{L}} \to \mathcal{M}$ is a quasi-isomorphism. The pullback Tor-independence condition is that $Lr^*\mathcal{M} \to r^*\mathcal{M}$ is a quasi-isomorphism. These are separate vanishing conditions on the higher derived external product and the higher derived pullback. Under both conditions, an equivariant ordinary isomorphism $r^*\mathcal{M} \simeq \mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}$ induces an equivariant derived isomorphism

$$Lr^*\mathcal{M}^{\mathbb{L}} \simeq \mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}.$$

For formal spaces the conditions refer to the derived completed operations in the chosen realization.

Proof. The external-product condition gives $Lr^*\mathcal{M}^{\mathbb{L}} \simeq Lr^*\mathcal{M}$. The pullback condition identifies the latter with $r^*\mathcal{M}$. Composition with the given ordinary isomorphism proves the result. The augmentations are natural, so they intertwine the specified central actions. Thus the composite is equivariant. □

Example 64.5.5 *(ordinary descent without derived descent).* Let $W = W(k)$ for a finite field k of characteristic p_0. Take all three spaces to be Spf W, let r be the identity, and take $\mathcal{F}_p = \mathcal{F}_q = \mathcal{F}_{\mathrm{glob}} = k$. The ordinary external product and its pullback are k. However, the free resolution $[W \xrightarrow{p_0} W]$ of k, in degrees -1, 0, gives

$$k \otimes^{\mathbb{L}}_W k \simeq k \oplus k[1].$$

This is also the derived completed tensor product: the resulting finite p_0-torsion modules are derived p_0-complete. It is not quasi-isomorphic to k. Here r is flat and both local sheaves are perfect, but external-product Tor-independence fails. Thus perfectness and flatness of r do not convert ordinary pairwise descent into its derived enhancement.

Conjecture 64.5.6 *(pairwise and global Bernstein compatibility).* For the intended arithmetic geometric realization and every admissible pair of distinct finite primes, the following comparisons exist. For coherent sheaves in degree zero, the ordinary pairwise comparison is an equivariant isomorphism

$$r^*(\mathcal{F}_p \boxtimes_E \mathcal{F}_q) \simeq \mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}. \tag{64.8}$$

The derived enhancement is the additional equivariant comparison

$$Lr^*(\mathcal{F}_p \boxtimes^{\mathbb{L}}_E \mathcal{F}_q) \simeq \mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}}. \tag{64.9}$$

The ordinary and derived assertions are distinct. Both hold together if ordinary descent and the two Tor-independence conditions of Proposition 64.5.4 hold. Each asserted family of isomorphisms must be compatible with the geometric transition maps as the finite set of places varies. Second, the local actions on the global automorphic category induce an isomorphism onto its specified ordinary Bernstein centre

$$A \xrightarrow{\sim} \mathcal{Z}_{\mathrm{glob}}, \tag{64.10}$$

and a specified comparison identifies the action in Equation (64.10) with its spectral counterpart. Thus the action must be faithful and generate the intended centre. A comparison of higher centres must be constructed in its category of derived algebras and is a separate assertion from this degree-zero identity.

Remark 64.5.7 *(the two comparison problems).* The pairwise assertion compares coherent objects and their actions. The global assertion identifies the image and range of the assembled central action. The formal restriction diagram constructs neither the first isomorphism nor the latter surjectivity. The hypotheses of Corollary 73.1.5 specify the Selmer-algebra, geometric, trace and ordinary descent data. The derived enhancement requires the additional derived descent datum or the two Tor-independence conditions. Neither version establishes the global centre map.

PROPOSITION 64.5.8 *(local equations and gluing of the pairwise comparison).* Suppose, on a formal scheme X, the two objects in the pairwise comparison are vector bundles of equal rank. Choose an open cover trivializing both bundles. Suppose the algebra of actions on each chart has specified finitely many generators. The equivariant isomorphism exists if and only if there are invertible matrices on the charts satisfying the intertwining equations and agreeing under the transition matrices on every overlap. On a complete local chart, a specified residue isomorphism lifts exactly when one can successively choose lifts with zero obstruction classes from Proposition 64.4.3.

Proof. An isomorphism gives its invertible matrices in the chosen bases. Equivariance gives the intertwining equations, and independence of trivialization gives the overlap equalities. Conversely the overlap equalities glue the local morphisms as morphisms of sheaves. Their local inverses also agree on overlaps, so the global morphism is invertible. Equivariance can be checked on each chart, and hence holds globally. The assertion on a complete local chart is precisely the successive lifting proposition. It requires a compatible choice at every order. □

Remark 64.5.9 *(the missing arithmetic comparisons).* The remaining constructions are the geometric realization of the formal restriction map, the local modules with their Bernstein actions over a common coefficient base, and the independently defined global prismatic object. Their equivariant comparison must preserve the required filtrations and agree on overlaps and on larger finite sets of places. To apply the vector-bundle criterion one must also establish its local freeness hypotheses. Otherwise a derived comparison is required. Identifying a kernel quotient or matching traces does not construct these maps.

64.6 THE GLOBAL DESCENT PROBLEM

PROPOSITION 64.6.1 *(data supplied by two-prime restriction).* For the fixed deformation problem, two-prime restriction supplies the map $B_{p,q} \to R^{\mathrm{Ch}}$, its closed-image quotient, and its formal fibres. Given finite local modules and the specified local actions, it also supplies $M^{\mathrm{res}}_{p,q}$ with its product action. These constructions do not require arithmetic Arinkin–Gaitsgory or a prismatic comparison.

Proof. The restriction diagram and fibre follow from Proposition 64.2.1. The module and action follow from Proposition 64.3.2. Their proofs use the stated universal properties and finite module presentations only. □

Remark 64.6.2 *(categorical and prismatic descent).* Adelic categorical descent additionally requires the actual local functors, their coefficient and family comparisons, the prismatic and untilt descent maps, and the global centre comparison. The ordinary scalar-centre theorem does not provide these functors. The determinant rings do not specify a common Nygaard filtration at distinct residue primes. A proposed arithmetic singular-support construction must define its spaces and higher centre maps before it can supply the global comparison. The algebraic and geometric obstructions to that step are developed in Chapter 88.

Chapter 65

Moment Growth and Arithmetic Spectral Comparisons

Let $L : \mathbb{C}[x] \to \mathbb{C}$ be a specified positive Hamburger functional with finite moments $\mu_n = L(x^n)$. Positivity means $L(p\overline{p}) \geq 0$ for every polynomial p, where the bar conjugates coefficients. The analytic condition is $\mu_{2n}^{1/(2n)} = O(n)$. Together with positivity it implies determinacy. Its arithmetic application requires construction of the regularized functional and its carrier, support and operator comparisons.

65.1 Positive Functionals and Growth Estimates

Definition 65.1.1 *(The analytic moment condition).* For the specified finite positive functional L, write $\mathrm{R}_{\text{analytic}}$ for $\limsup_{n\to\infty} \mu_{2n}^{1/(2n)}/n < \infty$. A two-sided factorial estimate is stronger than this upper bound.

Remark 65.1.2 *(The arithmetic application).* The classical implication concerns determinacy of L. Its arithmetic application requires the functional, support and operator identifications. No implication between RH and an unspecified regularization is asserted.

Proposition 65.1.3 *(A logarithmic lower comparison).* If the specified functional satisfies $\mu_{2n} \leq (2\pi)^{-4n}(2n)!(\log n)^{4n}(1 + o(1))$, its positive even moments have $\mu_{2n}^{-1/(2n)} \geq c/[n(\log n)^2]$ eventually for some $c > 0$. This comparison series converges.

Proof. Apply Proposition 65.5.2 and Corollary 65.5.3 below. □

Remark 65.1.4 *(Three requirements).* Existence and positivity of L, an upper-growth estimate for its moments, and its arithmetic comparison are separate premises. No theorem of logical independence between them is asserted.

65.2 Factorial Roots

The root $(2n)!^{1/(2n)}$ is asymptotic to $2n/e$. Taking the $2n$-th root of $(\log n)^{4n}$ gives $(\log n)^2$, and inversion reverses that exponent.

65.3 Li Coefficients and Polynomial Moments

The Li summand $1 - (1 - 1/\rho)^n$ differs from the polynomial summand $[\rho(1-\rho)]^n$. Their traces require different summation and domain data. The termwise comparison is made below.

65.4 The Conditional Operator Comparison

Under Hypothesis 57.4.21,

$$\mathrm{VB}^* \iff (\mathrm{Reg}) \iff (\mathrm{HB}+) \iff (\mathrm{BD}+).$$

Here (BD+) is the sharp approximation predicate of Chapter 57, not exponential completeness. (Reg) includes the identified positive functional, determinacy and spectral support. The classical moment estimate supplies determinacy; the arithmetic identification, support and operator comparison remain additional inputs.

65.5 A Conditional Logarithmic Estimate

The Assumed Bound

Suppose the specified L satisfies

$$\mu_{2n} \le (2\pi)^{-4n}(2n)!(\log n)^{4n}(1+o(1)). \tag{65.1}$$

This is an assumption on the functional, not a consequence of zero counting or a bound for Li coefficients.

Stirling Evaluation

LEMMA 65.5.1 *(Factorial roots).*

$$(2n)!^{1/(2n)} = \frac{2n}{e}(4\pi n)^{1/(4n)}(1+O(n^{-2})) \sim \frac{2n}{e}.$$

Proof. Take the $2n$-th root of $(2n)! = \sqrt{4\pi n}(2n/e)^{2n}(1+O(n^{-1}))$. The last factor becomes $1+O(n^{-2})$, while $(4\pi n)^{1/(4n)} \to 1$. □

PROPOSITION 65.5.2 *(A conditional lower comparison).* Assume (65.1) and positive even moments. Then

$$\mu_{2n}^{1/(2n)} \le \frac{2n}{e(2\pi)^2}(\log n)^2(1+o(1)).$$

For every $0 < c < e(2\pi)^2/2$, there is n_0 such that

$$\mu_{2n}^{-1/(2n)} \ge \frac{c}{n(\log n)^2} \quad (n \ge n_0),$$

so

$$\sum_{n\ge n_0} \mu_{2n}^{-1/(2n)} \ge c \sum_{n\ge n_0} \frac{1}{n(\log n)^2}. \tag{65.2}$$

Proof. Take roots of the assumed bound, apply Stirling and invert the positive inequality. If instead an even moment of positive order vanishes, any positive representing measure is supported at zero; its prescribed mass makes it unique. □

COROLLARY 65.5.3 *(The lower comparison converges).*

$$\sum_{n\ge 2} \frac{1}{n(\log n)^2} < \infty.$$

This convergent lower comparison does not establish divergence of Carleman's sum.

Proof. The integral test gives $\int_2^\infty dx/[x(\log x)^2] = 1/\log 2$. □

Remark 65.5.4 *(Root scaling).* The exponent $4n$ of the logarithm becomes 2 under the $2n$-th root and -2 under inversion. This calculation uses only the displayed assumed estimate on L.

Proposition 65.5.5 *(A factorial upper bound implies determinacy).* If L is positive with finite moments and $\mu_{2n} \le AC^n(n!)^2$ eventually for constants $A, C > 0$, then it is determinate. No matching lower bound is needed.

Proof. For positive even moments, $\mu_{2n}^{1/(2n)} \le A^{1/(2n)}\sqrt{C}(n!)^{1/n} = O(n)$. Carleman's sum dominates a positive multiple of the harmonic series. A vanishing even moment gives the unique measure supported at zero. □

65.6 Finite Cutoffs and Regularized Moments

Distinct Zero Sums

Proposition 65.6.1 *(Li summands and polynomial summands).* Under RH, for $\rho = 1/2 + i\gamma$,

$$|1 - (1 - 1/\rho)^n| \le 2, \qquad [\rho(1-\rho)]^n = (1/4 + \gamma^2)^n.$$

A bound for the summed Li expression does not, by this termwise magnitude comparison, give finite unregularized polynomial moments.

Proof. The identity $|1 - 1/\rho| = 1$ gives the first inequality. The polynomial identity gives the second, whose cutoff sums diverge by the next proposition. An identity for the Li trace therefore requires a separate comparison to a regularized polynomial functional. □

Proposition 65.6.2 *(Positive cutoff moments diverge).* Put $S_n(T) = \int_{(0,T]} (1/4 + t^2)^n \, dN(t)$. For fixed integer $n \ge 0$,

$$S_n(T) = \frac{T^{2n+1}}{2\pi(2n+1)} \log \frac{T}{2\pi} - \frac{T^{2n+1}}{2\pi(2n+1)^2} + O_n(T^{2n} \log T).$$

The integral over $(0, \infty)$ diverges. Under RH it is the cutoff shifted-zero sum over positive ordinates.

Proof. Apply the Stieltjes calculation in Proposition 80.2.5. The positive leading term tends to infinity. □

Remark 65.6.3 *(The leading term and regularization).* Divergence already occurs in the leading zero-counting term. Improving its remainder alone cannot make the positive integral finite. A specified regularization is needed before its moment growth can be studied.

Three Mathematical Requirements

One must construct the finite positive functional, prove a sufficient growth estimate for that same functional, and identify it with the arithmetic operator and its spectral support. None of these maps is constructed by renaming a divergent cutoff sum.

65.7 Determinacy, VB*, and RH

The following propositions separate the classical determinacy implication from the arithmetic operator comparison.

Determinacy and the Operator Comparison

PROPOSITION 65.7.1 *(The predicate in the operator comparison).* Under Hypothesis 57.4.21, VB* is equivalent to (Reg), not to bare (Det). In the RH sector this supplies a conditional route to the VB* converse when (Reg) is constructed. The forward arithmetic implication to zero placement retains its separate P2, P3, determinant–trace and positivity hypotheses.

Proof. Use item 1 of the hypothesis and the definition of (Reg). Neither its support condition nor its arithmetic moment identification follows from uniqueness of an abstract measure. □

Step 2: Determinacy vs RH

PROPOSITION 65.7.2 *(What the distance and determinacy results supply).* The classical BD criterion is convergence of its finite distances to zero. The supplied-rate transport of Corollary 57.4.19 transfers a quantitative estimate only after that estimate and the scaled isometry are given. Separately, a positive moment functional with the Carleman growth bound is determinate. These statements alone supply neither the arithmetic support condition nor an equivalence between bare (Det) and RH.

Proof. The distance identity multiplies each finite norm by the fixed positive scale; it does not estimate its dependence on the cutoff. Carleman's theorem concerns uniqueness for the supplied moment functional. Applying either result to an arithmetic operator requires the stated comparison data. □

The Implication Diagram

Remark 65.7.3 *(The moment and operator steps).* The classical step is

$$\mathrm{R}_{\mathrm{analytic}} \Longrightarrow \text{Carleman criterion} \Longrightarrow \text{Det}.$$

The arithmetic step, with the identified positive moment functional, is

$$\text{Det} + \text{specified support} \Longrightarrow (\text{Reg}) \xrightarrow{\text{operator comparison}} \mathrm{VB}^*.$$

The conditional forward arithmetic theorem then gives RH with its remaining hypotheses. The operator comparison is item 1 of Hypothesis 57.4.21.

Remark 65.7.4 *(The role of the moment estimate).* The growth estimate proves the determinacy component. It does not construct the arithmetic carrier, its support or operator comparison. Those are additional steps even when the zero-placement statement is assumed. No independence theorem between RH and this moment estimate is asserted by this implication diagram.

65.8 DETERMINACY CONSEQUENCES

THEOREM 65.8.1 *(Moment estimates and arithmetic comparisons).* For a specified positive finite Hamburger functional:

(i) Linear even-moment root growth implies determinacy.

(ii) A factorial upper bound suffices for that growth.

(iii) The logarithmic estimate (65.1) gives the convergent lower comparison (65.2).

(iv) Its arithmetic application retains the functional, support and operator comparisons of Remark 65.7.3.

Proof. The first assertion is Carleman's harmonic comparison; the second is Proposition 65.5.5; the third is Proposition 65.5.2. The fourth is the stated domain of the arithmetic comparison. □

Corollary 65.8.2 *(The moment estimate and the arithmetic target).* The implication from R_{analytic} to Hamburger determinacy does not by itself establish RH. The stated route also requires the arithmetic moment identification, spectral support and operator comparison, together with the hypotheses of the forward arithmetic theorem. No converse non-implication is claimed.

Proof. The moment estimate supplies the first line of Remark 65.7.3. The remaining arrows have the additional hypotheses displayed there. □

65.9 Examples and the Arithmetic Construction

Proposition 65.9.1 *(Positive functionals at two growth scales).* The probability measure $\frac{1}{2}\mathbf{1}_{[-1,1]}\,dx$ has $\mu_{2n} = 1/(2n+1)$ and odd moments zero. It satisfies R_{analytic}, but no eventual lower bound $\mu_{2n} \geq C_-^n (n!)^2$ with $C_- > 0$. For $a > 0$, the probability measure $\frac{a}{2}e^{-a|x|}\,dx$ has $\mu_{2n} = (2n)!/a^{2n}$ and odd moments zero. Its even-moment roots are asymptotic to $2n/(ae)$, so it is determinate.

Proof. Integrating on $[-1, 1]$ gives the first formula. Its $2n$-th root tends to one, whereas that of $C_-^n (n!)^2$ grows as $\sqrt{C_-}\,n/e$. For the second measure, symmetry and the substitution $u = ax$ give

$$a\int_0^\infty x^{2n} e^{-ax}\,dx = a^{-2n}\int_0^\infty u^{2n} e^{-u}\,du = a^{-2n}(2n)!.$$

Stirling gives linear root growth and hence Carleman determinacy. Neither example is identified with the arithmetic functional. □

Question 65.9.2 *(The arithmetic moment construction).* Construct a specified regularization of the shifted-zero polynomial sums, including its counterterms and normalization, defining a finite positive Hamburger functional L. Prove $L(x^{2n})^{1/(2n)} = O(n)$, or another sufficient determinacy criterion, for this same functional. Identify its representing measure and support with the arithmetic carrier and construct the operator comparison. A two-sided factorial asymptotic is a stronger possible target, not a premise needed for the Carleman implication.

Remark 65.9.3 *(Other arithmetic inputs).* The moment theorem supplies neither the weight-selection nor the explicit-formula hypotheses. These remain separate requirements in the sufficient arithmetic argument.

65.10 Arithmetic Consequences

A constructed positive functional and its linear root bound give (Det). The specified support and arithmetic identification give (Reg); the supplied operator comparison then transfers positivity. The full arithmetic conclusion retains the remaining forward-theorem hypotheses. The finite cutoff calculation, the classical examples and the conditional estimates do not construct the missing regularization or its arithmetic comparison.

Chapter 66

The Primary Euler Product and Its Arithmetic Comparison

The one-mode occupation space has a zeta heat trace. A Gaussian test function has a gamma Mellin integral. Their product is the completed zeta function. These are three precise scalar calculations; identifying them with the character of an arithmetic bar or cobar object requires additional maps. In particular, ordinary graded duality reverses energy and does not by itself shift a Mellin parameter from s to $1-s$. We specify the carriers before making the comparison.

66.1 The Selected Primary Model

Finite places

Definition 66.1.1 *(one-mode primary tower).* Inside the polynomial oscillator representation at a prime p, set

$$\mathcal{H}^{(p)}_{\mathrm{prim}} = \bigoplus_{j\ge 0} \mathbb{C} e_{j,p}, \qquad e_{j,p} = (a^{(p)}_{-1})^j |0\rangle_p.$$

The vector $e_{0,p} = |0\rangle_p$ is the unit. Give $e_{j,p}$ energy $j \log p$, as in Convention 28.7.1(ii). This is a selected vector subspace; it excludes all modes $a^{(p)}_{-k}$ with $k > 1$ and any second oscillator species.

Remark 66.1.2 *(selection and operators).* One full oscillator species at a prime has heat trace $\prod_{k\ge 1}(1-p^{-k\beta})^{-1}$, while the selected tower has $(1-p^{-\beta})^{-1}$. Two species square the full factor. The selected tower contains every occupation of mode one, including its vacuum, and no higher modes. Both T_n and ψ_n of Chapter 28 send its generator to mode n; for $n > 1$ they do not preserve this selected space. No equivariant arithmetic identification follows from the selection.

Proposition 66.1.3 *(local shifts and Gibbs weights).* Normalize the Hall basis by $u_{j,p} = e_{j,p}/\sqrt{j!}$ and complete it to $\ell^2(\mathbb{N}_0)$. The shift $S_p u_{j,p} = u_{j+1,p}$ is an isometry, and the diagonal operator $H_p u_{j,p} = j \log p \, u_{j,p}$ has partition function

$$Z_p(\beta) = \mathrm{Tr}(e^{-\beta H_p}) = (1-p^{-\beta})^{-1} \qquad (\beta > 0).$$

Its normalized Gibbs state on bounded operators is

$$\varphi_{p,\beta}(A) = (1-p^{-\beta}) \sum_{j\ge 0} p^{-j\beta} \langle A u_{j,p}, u_{j,p}\rangle.$$

In particular a rank-one occupation projection has probability $(1-p^{-\beta})\,p^{-j\beta}$.

Proof. The shift preserves the displayed orthonormal basis and has range its tail. The heat trace is a convergent geometric series. Dividing the positive trace-class operator by that trace gives a positive functional with value one on the identity, proving the state formula. A state is a functional on operators,

not an assignment of an unnormalized Boltzmann weight to a state vector. No classification of Bost–Connes KMS states is needed for this calculation. □

The Gaussian test line

Definition 66.1.4 *(archimedean primary datum).* Use the specified test function $g(x) = e^{-\pi x^2}$ and its line

$$\mathcal{G} = \mathbb{C}g \subset \mathcal{S}(\mathbb{R}).$$

The datum includes its Mellin pairing, defined below. It is not an identification of the full countable-mode Heisenberg representation with a single coordinate oscillator. Multiplying by arbitrary Hermite polynomials leaves this line and gives further test functions.

PROPOSITION 66.1.5 *(Gaussian Mellin integral).* For $\operatorname{Re} s > 0$,

$$\int_0^\infty e^{-\pi x^2} x^{s-1}\, dx = \frac{1}{2}\pi^{-s/2}\Gamma(s/2).$$

The full real integral against $|x|^{s-1}$ is twice this value. It is a Mellin pairing, not the heat trace of an operator on the one-dimensional line $\mathcal{G}$.

Proof. Near zero integrability requires $\operatorname{Re} s > 0$, and the Gaussian gives decay at infinity. Substitute $u = \pi x^2$; then $x^{s-1}dx = \frac{1}{2}\pi^{-s/2}u^{s/2-1}du$. The gamma integral gives the formula. The integrand with absolute value is even, so the full real integral doubles it. □

The restricted tensor and its scalar pairing

Definition 66.1.6 *(selected primary model).* Set

$$P_{\mathrm{fin}} = \bigotimes_p{}' \mathcal{H}^{(p)}_{\mathrm{prim}}, \qquad \mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}} := \mathcal{G} \otimes_{\mathbb{C}} P_{\mathrm{fin}}.$$

The tensor product here is algebraic, with reference vectors $e_{0,p}$. Each elementary occupation has finite prime support. Its normalized basis is indexed by $N = \prod_p p^{j_p}$, and its finite energy is $\log N$. Its Hilbert completion is consequently $\ell^2(\mathbb{N}_{>0})$. Define the completed scalar pairing by

$$Z_{\mathrm{prim}}(s) = M_g(s)Z_{\mathrm{fin}}(s), \qquad M_g(s) = \int_{\mathbb{R}} g(x)|x|^{s-1}\, dx, \quad Z_{\mathrm{fin}}(s) = \sum_{N\geq 1} N^{-s}.$$

The common convergence region is $\operatorname{Re} s > 1$. This definition uses a finite heat trace and an archimedean Mellin pairing. It makes no claim that their product is the ordinary graded character of the tensor product with a one-dimensional representation. An Iwasawa action on this model, or a comparison with an arithmetic Hochschild trace object, must be specified separately.

Remark 66.1.7 *(operator domains).* On the finite Hilbert completion the energy operator is self-adjoint on $\{(c_N) : \sum_N (\log N)^2|c_N|^2 < \infty\}$; finite-support vectors form a core for every power. Thus its polynomial expressions, including $H^n - (H-1)^n$, are defined on that common core. These are distinct from both T_n and ψ_n of (28.1). A Mellin variable s is not an eigenvalue of a fixed operator on $\mathcal{G}$. Identification with the operator of Definition 45.1.1 requires its stated spectral comparison.

Remark 66.1.8 *(Virasoro comparison).* A selected one-mode tower is not invariant under the full Heisenberg vertex operations. No global Virasoro action is constructed here. The determinant-rank residue $r_\zeta = 2$ in Theorem 35.4.1 and a proposed central charge are different data until a compatible operator construction identifies them.

66.2 The Scalar Calculation

The finite Euler product

Theorem 66.2.1 *(finite primary character).* For $\operatorname{Re} s > 1$,

$$Z_{\mathrm{fin}}(s) = \prod_p (1 - p^{-s})^{-1} = \zeta(s).$$

For real $s = \beta$, this is a finite heat trace precisely when $\beta > 1$. Its scalar meromorphic continuation is distinct from an extension of that heat trace to other temperatures.

Proof. Unique factorization identifies an occupation tuple with one positive integer, with weight $\prod_p p^{-j_p s} = N^{-s}$. Absolute convergence follows from $\sum_N N^{-\sigma} < \infty$ for $\sigma = \operatorname{Re} s > 1$, so expansion of the geometric factors is justified and gives the Euler product. For real $\beta \le 1$, the series of positive diagonal entries diverges. The meromorphic continuation of the resulting scalar is the classical continuation of ζ; it has a simple pole at one. □

The archimedean Mellin factor

Theorem 66.2.2 *(full real Mellin normalization).* For $\operatorname{Re} s > 0$,

$$M_g(s) = \int_{\mathbb{R}} e^{-\pi x^2} |x|^{s-1}\, dx = \pi^{-s/2}\Gamma(s/2) = \Gamma_{\mathbb{R}}(s). \tag{66.1}$$

Proof. Apply Proposition 66.1.5 to the two half-lines. This fixes the factor of two and the Haar-measure convention. □

The completed scalar

Theorem 66.2.3 *(primary Euler–Mellin identity).* The specified completed scalar satisfies

$$Z_{\mathrm{prim}}(s) = \Gamma_{\mathbb{R}}(s)\zeta(s) \tag{66.2}$$

$$= \Lambda_\zeta(s) \qquad (\operatorname{Re} s > 1). \tag{66.3}$$

It has the classical meromorphic continuation and functional equation $\Lambda_\zeta(s) = \Lambda_\zeta(1 - s)$.

Proof. The defining product has its two factors computed in the preceding theorems, giving the equality on the common convergence region. Classical Tate–Riemann theory gives the meromorphic continuation and functional equation of that scalar. This use of the functional equation makes no identification of an arithmetic bar or cobar object. □

Corollary 66.2.4 *(poles of the completed scalar).* The completed scalar has simple poles at $s = 1$ and $s = 0$, with residues 1 and -1, respectively, and no other poles.

Proof. At one, $\Gamma_{\mathbb{R}}(1) = 1$ and $\operatorname{Res}_{s=1} \zeta(s) = 1$. The functional equation gives the opposite residue at zero. The remaining poles of the gamma factor are cancelled by the trivial zeros of ζ. □

66.3 DUALITY AND THE REQUIRED COMPARISON

A cobar model is additional data

Definition 66.3.1 *(arithmetic bar–cobar comparison datum).* An arithmetic comparison datum must specify a dg coalgebra C_{prim}, a cobar model A_{prim}, coefficients, completions, and a twisting cochain or comparison map from the selected primary model. Restriction of an arithmetic differential to that selected space must be proved; it is not automatic from the vector-space inclusion. A continuous dual $C_{\mathrm{prim}}^{\vee}$ and a cobar construction are not identified merely by writing the same symbol.

For an ordinary graded dual the sign is different from a Tate shift. The basis dual to energy $\log N$ has energy $-\log N$, and its formal convergent trace is $\sum_N N^s = \zeta(-s)$ for $\operatorname{Re} s < -1$. A formula with $\zeta(1-s)$ requires an additional twist and a comparison explaining it. This is not supplied by the energy-zero evaluation of Theorem 46.5.1.

The multiplicative-shift scalar

THEOREM 66.3.2 *(finite scalar comparison).* On $\ell^2(\mathbb{N}_{>0})$, use $H_{\mathrm{BC}}\delta_N = \log N\, \delta_N$ and $\mu_n \delta_N = \delta_{nN}$. Then

$$Z_{\mathrm{BC}}(\beta) := \operatorname{Tr}(e^{-\beta H_{\mathrm{BC}}}) = \zeta(\beta) \qquad (\beta > 1).$$

This is the same finite scalar as the selected primary tower. It does not identify an arithmetic cobar algebra or its multiplication.

Proof. Sum the positive diagonal entries $N^{-\beta}$. The basis map from normalized prime occupations to $\delta_{\prod p^{j_p}}$ is a unitary energy intertwiner for these two explicitly defined Hilbert models. The local occupation shifts correspond to multiplication by primes. They are different from the substitutions T_n, ψ_n, which fail to preserve the selected space and fix the full-Fock vacuum. □

Fourier–Mellin substitution

PROPOSITION 66.3.3 *(the substituted Gaussian scalar).* With Fourier kernel $e^{-2\pi i x y}$, $\widehat{g} = g$. Hence

$$\int_{\mathbb{R}} \widehat{g}(y)|y|^{-s}\, dy = \Gamma_{\mathbb{R}}(1-s) \qquad (\operatorname{Re} s < 1).$$

This is the Mellin integral at the substituted exponent, not a theorem identifying the character of an unspecified Koszul-dual object.

Proof. The Gaussian Fourier transform follows, for example, by differentiating its integral: integration by parts gives $\widehat{g}'(y) = -2\pi y \widehat{g}(y)$, and $\widehat{g}(0) = \int e^{-\pi x^2} dx = 1$. Solving yields $\widehat{g}(y) = e^{-\pi y^2}$. Now apply (66.1) with parameter $1-s$. Its convergence condition is exactly the one stated. □

The Tate-dual scalar and conditional character interpretation

THEOREM 66.3.4 *(Tate-dual scalar).* Define $Z^{\mathrm{T}}_{\mathrm{prim}}(s) = Z_{\mathrm{prim}}(1-s)$. On $\operatorname{Re} s < 0$, and then meromorphically,

$$Z^{\mathrm{T}}_{\mathrm{prim}}(s) = \Gamma_{\mathbb{R}}(1-s)\zeta(1-s) = \Lambda_{\zeta}(1-s).$$

If independently constructed arithmetic objects and their scalar pairings are identified with these two specified Mellin models, then

$$Z_C(s) = \Lambda_{\zeta}(s), \qquad Z_{A^!}(s) = \Lambda_{\zeta}(1-s). \tag{66.4}$$

The latter interpretation is conditional on those identifications, including the twist that produces $1-s$.

Proof. Substitute $1 - s$ into the computed finite series and Gaussian integral. Their common convergence region is $\operatorname{Re} s < 0$. Meromorphic continuation gives the scalar formula elsewhere. Transport through the hypothesized pairing identifications gives the conditional interpretation; no such arithmetic maps are constructed by substitution. □

The functional equation

Proposition 66.3.5 *(scalar functional equation).* As meromorphic scalar functions,

$$Z_{\mathrm{prim}}(s) = Z^{\mathrm{T}}_{\mathrm{prim}}(s) \quad \Longleftrightarrow \quad \Lambda_{\zeta}(s) = \Lambda_{\zeta}(1 - s).$$

Both sides hold by the classical functional equation.

Proof. Replace the two explicitly defined scalars by the formulas already proved. No implication about arithmetic obstruction classes or operator spectra is needed for this equivalence. □

Remark 66.3.6 *(limits of the scalar calculation).* Equality of these meromorphic scalars proves neither RH nor an arithmetic bar–cobar pairing. The comparison in (66.4) is still required even to interpret the two scalars as the proposed arithmetic characters.

66.4 Arithmetic Consequences and Remaining Constructions

Remark 66.4.1 *(the character comparison requirement).* The one-mode scalar and its Gaussian completion have been computed. The character requirement in Remark 46.1.6(4), when it concerns an arithmetic pairing rather than these defined scalar functions, still requires the maps and twist specified above. This calculation does not reduce that arithmetic list from five requirements to four. The P1 level comparison remains Question 46.5.4.

Distinct arithmetic requirements

Input	Construction	Remaining comparison
(1)	Completed continuous duals	Topology and actual duality maps
(2)	Derived completion	Base change on the stated resolutions
(3)	Lifting	Existence and the required morphism properties
(4)	Primary scalar pairing	Arithmetic character, twist and pairing maps
(5)	Bost–Connes realization	Multiplication, differential and completion

Table 66.1: Requirements on the intended arithmetic object. The Euler and Mellin calculations determine specified scalar models, not these maps.

The scalar constructions

66.5 Sources for the Scalar and Duality Constructions

Remark 66.5.1 *(roles of the sources).* Tate's 1950 thesis supplies the adelic Mellin framework and functional equation; the Gaussian integral and Euler product used here have also been computed directly.

Carrier or pairing	Computed scalar
One-mode occupation Hilbert space	$\zeta(\beta),\ \beta > 1$
Gaussian full real Mellin pairing	$\Gamma_{\mathbb{R}}(s),\ \operatorname{Re} s > 0$
Their defined product	$\Lambda_\zeta(s)$
Tate-substituted scalar	$\Lambda_\zeta(1-s)$

TABLE 66.2: The domains and meanings of the four scalar expressions.

Julia's *Statistical theory of numbers* (1990) describes the primon occupation interpretation. Bost–Connes (Selecta Math. 1 (1995), 411–457) supplies the arithmetic dynamical context; the concrete shift and heat-trace comparison above does not use a KMS classification. Positselski's *Two kinds of derived categories, Koszul duality, and comodule–contramodule correspondence* (Mem. AMS996, 2011) concerns categorical duality under its stated hypotheses. It is not used to infer a Tate shift from ordinary energy dualization or to identify a Gaussian test line with a cobar algebra.

66.6 THE ARITHMETIC COMPARISON PROBLEM

The selected finite occupation model, its Hilbert domain, the Gaussian Mellin normalization and the completed scalar are explicit. A realization on the arithmetic Hochschild trace class must additionally construct its operators, integral and completed carriers, bar–cobar maps and compatible pairings. It must account for the failure of the polynomial substitutions to preserve the selected one-mode space. These are the remaining mathematical constructions; the scalar identity alone does not settle them.

Chapter 67

Koszul–Petersson and the Prime Gibbs Model

A single prime admits an explicit Gibbs state for every inverse temperature $\beta > 0$, including $\beta = 1$. Its GNS space is a Hilbert–Schmidt space, its modular conjugation is adjunction, and its modular operator has a maximal weighted-matrix domain. These objects can be computed without identifying an arithmetic Koszul pairing with a Petersson pairing. The latter comparison requires additional maps between the actual carriers.

67.1 The Prime State and the Arithmetic Comparison

The occupation model of Chapter 66 has Hamiltonian $j \log p$ at a prime. We first construct its GNS representation and an actual unitary onto the prime-generated cyclic subspace of any specified global KMS representation. Neither this subspace comparison nor uniqueness of a polar decomposition supplies an automorphic realization.

Hypothesis 67.1.1 *(arithmetic placement and pairing comparison).* Fix a primitive arithmetic carrier, its coefficient field $\mathbb{C}$, its completion and a dense test domain. Specify:

(i) an injective placement ι of the selected domain into a fixed-central-character automorphic Hilbert space, with its Haar and Tamagawa normalizations;

(ii) at each place, comparison maps for the independently defined Koszul and automorphic carriers, intertwining the stated algebra or Hecke actions and transporting the bilinear Koszul form and antilinear involution to the stated local Hermitian form;

(iii) preservation of the chosen reference vectors at almost all places, factorization on elementary tensors, and continuous or explicitly regularized extension of the resulting pairing identity;

(iv) on every included residual sector, its specified placement and normalization, and orthogonality of the sector decomposition for both transported forms.

Any modular comparison must additionally intertwine the represented algebra, state or cyclic vector, and the closed modular operators on their actual domains. Ramified sectors require their own local maps; they are not consequences of the prime shift computation.

Question 67.1.2 *(constructing the arithmetic pairing maps).* Construct these maps from the arithmetic bar–cobar carrier and prove their compatibility with the independently defined Petersson pairing. Determine their precise discrete and continuous domains. The conditional transfers below retain this question; the prime Gibbs calculation does not complete it.

67.2 The One-Prime Gibbs State

State and Physical Time

Fix a prime p and $\beta > 0$. Put $K = \ell^2(\mathbb{N}_0)$, $Ve_j = e_{j+1}$, and $He_j = j \log p\, e_j$, with $\operatorname{Dom} H = \{x : \sum_j j^2 |x_j|^2 < \infty\}$. Let $\mathcal{T} = C^*(V) \subset B(K)$, $q = p^{-\beta}$, $r_j = (1-q)q^j$, and $\rho = (1-q)q^{H/\log p}$. Physical time is

$$\alpha_t(a) = e^{itH} a e^{-itH}, \qquad \alpha_t(V) = p^{it} V.$$

The positive injective trace-class operator ρ has trace one. Its faithful normal state on $B(K)$, restricted to $\mathcal{T}$, is

$$\varphi_{p,\beta}(a) = \operatorname{Tr}(\rho a), \qquad \varphi_{p,\beta}(V^m V^{*n}) = \delta_{m,n} q^m. \tag{67.1}$$

In particular $\varphi_{p,\beta}(V^*V) = 1$ and $\varphi_{p,\beta}(VV^*) = q$. The order of the isometry and its adjoint is essential.

LEMMA 67.2.1 *(prime KMS state).* The state $\varphi_{p,\beta}$ is the unique β-KMS state on $(\mathcal{T}, \alpha)$, with convention

$$\varphi_{p,\beta}(ab) = \varphi_{p,\beta}(b\,\alpha_{i\beta}(a))$$

for analytic elements.

Proof. The analytic monomials $V^m V^{*n}$ span a dense star algebra. On them $\rho a = \alpha_{i\beta}(a)\rho$, so trace cyclicity proves the KMS identity. Conversely, applying that identity with $b = 1$ forces the expectation of a monomial of nonzero degree to vanish. Taking $a = V^m$, $b = V^{*m}$ gives expectation q^m for $V^m V^{*m}$, since $V^{*m} V^m = 1$. Thus every KMS state has the values in (67.1); density gives uniqueness. □

The Hilbert–Schmidt GNS Carrier

Use inner products linear in the first variable.

LEMMA 67.2.2 *(GNS realization of the prime state).* The GNS representation is

$$\mathcal{H}_{p,\beta} = \mathrm{HS}(K), \quad \pi(a)X = aX, \quad \Omega = \rho^{1/2},$$

with

$$\langle X, Y \rangle = \operatorname{Tr}(XY^*), \qquad [a] \longmapsto a\rho^{1/2}.$$

The vector Ω is cyclic and separating for left $B(K)$, which is $\pi(\mathcal{T})''$.

Proof. The displayed map is isometric because its inner product is $\operatorname{Tr}(\rho b^* a) = \varphi_{p,\beta}(b^* a)$. The matrix units $E_{ij} = V^i(1 - VV^*)V^{*j}$ belong to $\mathcal{T}$, and $E_{ij}\rho^{1/2} = \sqrt{r_j} E_{ij}$. Their images span a dense subspace of $\mathrm{HS}(K)$. Finite matrix corners strongly approximate bounded operators, so the weak closure is left $B(K)$. If $a\Omega = 0$, every column of a vanishes because every $r_j > 0$; hence $a = 0$. □

Closed Modular Operators

Define the densely defined antilinear operator

$$S_0(a\Omega) = a^*\Omega, \qquad a \in \mathcal{T}.$$

Lemma 67.2.3 *(modular operator and maximal domains).* For $X = \sum x_{ij} E_{ij}$, set $JX = X^*$ and

$$\Delta E_{ij} = q^{i-j} E_{ij}, \qquad \mathrm{Dom}(\Delta^a) = \left\{ X : \sum_{i,j} q^{2a(i-j)} |x_{ij}|^2 < \infty \right\}, \quad a \in \mathbb{R}.$$

Then $\overline{S_0} = J\Delta^{1/2}$, on the displayed domain for $a = 1/2$, and

$$\Delta^{it} X = e^{-i\beta t H} X e^{i\beta t H}.$$

Thus the modular action on left multiplication is physical time $\alpha_{-\beta t}$. Both Δ and Δ^{-1} are unbounded. The generator $\log \Delta$ has eigenvalue $(i-j)\log q$ and domain defined by square summability with weight $|(i-j)\log q|^2$.

Proof. On matrix units, $S_0 E_{ij} = q^{(i-j)/2} E_{ji}$, antilinearly. Finite matrix sums are graph-dense for the maximal weighted operator, by truncation of the convergent double sum. For any bounded a, the matrix $a\Omega$ lies in its domain and the formula gives $a^*\Omega$; its weighted norm is $\|a^*\Omega\|_{\mathrm{HS}} < \infty$. Therefore the closure is exactly $J\Delta^{1/2}$. Diagonal spectral calculus gives all powers, domains and the unitary group. The eigenvalues q^{i-j} range through $q^{\mathbb{Z}}$, proving both unboundedness claims. □

Proposition 67.2.4 *(modular conjugation and the prime shift).* For $k \geq 0$,

$$J(V^k\Omega) = p^{\beta k/2} V^{*k}\Omega,$$
$$JL_aJ = R_{a^*}, \qquad a \in B(K),$$

where L and R denote left and right multiplication. The continuous bilinear form $B(X,Z) = \mathrm{Tr}(XZ)$ on $\mathrm{HS}(K)^2$ satisfies $B(X, JY) = \langle X, Y\rangle$.

Proof. Expand $V^k\Omega = \sum_j \sqrt{r_j} E_{j+k,j}$ and use $\sqrt{r_{j+k}} = q^{k/2}\sqrt{r_j}$. Adjunction gives the first identity and $JL_aJ(X) = Xa^*$ gives the second. Products of two Hilbert–Schmidt operators are trace class with $|\mathrm{Tr}(XZ)| \leq \|X\|_2 \|Z\|_2$, proving continuity and the asserted pairing identity. In particular the half-power has positive exponent: $\|V^k\Omega\| = 1$, whereas $\|V^{*k}\Omega\| = q^{k/2}$. □

Theorem 67.2.5 *(comparison with a prime cyclic subspace).* Let $(\mathcal{A}, \alpha, \psi_\beta)$ be a specified dynamical C^*-algebra with a β-KMS state and an isometry μ_p satisfying $\alpha_t(\mu_p) = p^{it}\mu_p$. Let $\iota_p : \mathcal{T} \to \mathcal{A}$ send V to μ_p. There is a canonical unitary

$$U_p : \mathrm{HS}(K) \longrightarrow \overline{\pi_{\psi_\beta}(C^*(\mu_p))\Omega_{\psi_\beta}}, \qquad U_p(a\rho^{1/2}) = \pi_{\psi_\beta}(\iota_p(a))\Omega_{\psi_\beta}.$$

It intertwines the prime algebra actions and cyclic vectors, and transports the closed modular operators of the restricted cyclic representation. This holds at $\beta = 1$ as well.

Proof. The pulled-back state $\psi_\beta \circ \iota_p$ is a KMS state on $\mathcal{T}$, hence equals $\varphi_{p,\beta}$ by the unique-state calculation. The displayed map preserves inner products on $\mathcal{T}\rho^{1/2}$ and has dense image in the specified cyclic subspace. It therefore extends to a unitary. It intertwines multiplication and the operation $a\Omega \mapsto a^*\Omega$ on its core, hence its closure and polar decomposition. □

Remark 67.2.6 *(scope of modular uniqueness).* This unitary targets the prime cyclic subspace, not the whole ψ_β-GNS space. It does not identify the phase operators, an automorphic representation or an arithmetic Koszul form. Uniqueness of modular conjugation on a fixed cyclic representation supplies no additional identification between those carriers.

Finite Prime Sets and the Critical Global Boundary

COROLLARY 67.2.7 *(finite-prime Gibbs and GNS products).* For a finite prime set F, the density $\rho_F = \bigotimes_{p\in F} \rho_p$ has trace one for every $\beta > 0$. Its GNS space and modular operators are the finite tensor products of the preceding constructions. On the full occupation space $\ell^2(\mathbb{N}^\times)$, the heat trace is $\zeta(\beta)$ for $\beta > 1$, and diverges at $\beta = 1$. Thus the full occupation representation has no normalized trace-class Gibbs density at the critical temperature.

Proof. Finite tensor products multiply traces and tensor the explicit matrix formulas. Unique prime factorization identifies occupations with integers and gives $\sum_{n\geq 1} n^{-\beta}$. At $\beta = 1$ this is the divergent harmonic series. □

The divergence does not preclude a critical Bost–Connes KMS state in another representation. For any such specified state the prime cyclic comparison above still applies. Neither argument identifies its entire GNS space or factor type with the finite-prime Gibbs model.

67.3 LOCAL PAIRING MODELS AND ARITHMETIC TRANSPORT

Ramified Principal-Series Comparison

LEMMA 67.3.1 *(a normalized local Hermitian carrier).* Fix Haar measure $d^\times a$ on $\mathbb{Q}_p^\times$. On $E_p = C_c^\infty(\mathbb{Q}_p^\times, \mathbb{C})$, put

$$I_p(v, w) = \int_{\mathbb{Q}_p^\times} v(a)\overline{w(a)}|a|^{-1}\, d^\times a. \tag{67.2}$$

This is positive definite and extends to the corresponding L^2-completion. The bilinear form $b_p(v, z) = \int v(a)z(a)|a|^{-1}\, d^\times a$ satisfies $b_p(v, \overline{w}) = I_p(v, w)$.

Proof. Compact support in $\mathbb{Q}_p^\times$ gives finite integrals. The measure is positive, and a nonzero locally constant function is nonzero on an open set of positive measure. Cauchy–Schwarz extends the forms to L^2, and complex conjugation gives the last identity. □

The Whittaker realization of a given representation, its scalar normalization and its identification with an arithmetic Koszul carrier are further data. In particular an epsilon factor from a local functional equation is not automatically a positive normalization of a Hermitian form.

Hypothesis 67.3.2 *(local Koszul comparison).* For the chosen ramified arithmetic domain $V_{p,\pi}$, specify a linear map $c_{p,\pi}$ into the local Hilbert carrier, a compatible map on its Koszul dual, a positive constant c_π, and the antilinear map σ_p. Require that the actual Koszul pairing satisfy

$$\langle v, \sigma_p(w)\rangle_{p,\pi}^{\mathrm{Koszul}} = c_\pi b_p(c_{p,\pi}v, \overline{c_{p,\pi}w}).$$

The maps must preserve the specified local actions, domains and completion. This is an arithmetic comparison hypothesis.

Hypothesis 67.3.3 *(local automorphic normalization).* For the same carrier, maps, measure and positive constant, require

$$\langle \iota_p v, \iota_p w\rangle_{p,\pi}^{\mathrm{Pet}} = c_\pi I_p(c_{p,\pi}v, c_{p,\pi}w).$$

Neither Whittaker uniqueness nor a scalar local functional equation alone identifies the map $c_{p,\pi}$ with the Koszul comparison.

Proposition 67.3.4 *(conditional local Koszul–Petersson comparison).* Under the two local comparison hypotheses above, $\langle \iota_p v, \iota_p w\rangle_{p,\pi}^{\mathrm{Pet}} = \langle v, \sigma_p(w)\rangle_{p,\pi}^{\mathrm{Koszul}}$ on the specified domain.

Proof. Substitute $b_p(x, \overline{y}) = I_p(x, y)$ into the two displayed identities. The common constant and measure are part of the hypotheses, not a conclusion of matching the names of the pairings. □

Supercuspidal Comparison

Lemma 67.3.5 *(conditional supercuspidal transport).* The same conclusion holds on a supercuspidal domain for which the local Koszul and automorphic comparison hypotheses have been constructed with a common Hilbert carrier and normalization.

Proof. The proof of the preceding proposition uses only the common forms and maps, so applies on that specified domain. It supplies no new comparison map for the supercuspidal representation. □

Temperedness and Assembly

Proposition 67.3.6 *(conditional extension under temperedness).* Assume Hypothesis 67.1.1 on a tempered cuspidal domain. Any further cuspidal domain contained in it inherits its pairing comparison. Applying this to Maass forms requires the appropriate Ramanujan temperedness assumption as well as the arithmetic comparison maps.

Proof. Restrict the specified maps and pairing equality to the subdomain. Temperedness is a domain condition and does not construct the maps. □

Remark 67.3.7 *(local exponent bounds).* The Kim–Sarnak exponent bound $\theta \le 7/64$ is a local bound. It is neither an arithmetic pairing map nor a summable prime error on the critical line. The exponent $-25/64$ gives $\sum_p p^{-25/64} = \infty$; it cannot be used as an absolutely convergent adelic error majorant.

Theorem 67.3.8 *(conditional cuspidal pairing assembly).* Assume Hypothesis 67.1.1, including the local comparisons at every ramified place and the specified adelic extension. On the resulting tempered cuspidal domain,

$$\langle \iota v, \iota w\rangle^{\mathrm{Pet}} = \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}.$$

Proof. On elementary restricted tensors the forms factor, and the local identities give equality of every finite product with the specified reference-vector normalization. The assumed continuous or regularized extension carries this equality to its stated domain. Finiteness of the ramified set alone does not justify the infinite product normalization or its extension. □

Remark 67.3.9 *(scope of the domain).* The normalized local Hilbert models and the finite-prime Gibbs models are explicit. Enlarging an arithmetic domain to ramified, residual or Maass sectors requires its actual comparison maps. The theorem above is their conditional assembly, not an unconditional enlargement of the arithmetic pairing theorem.

67.4 Langlands Decomposition of $L^2([GL_2])$ and Placement of $\mathcal{V}^{\mathrm{prim}}$

The Spectral Decomposition

The Langlands decomposition of $L^2([GL_2])$, following Langlands 1966 and Moeglin–Waldspurger 1995, is:

THEOREM 67.4.1 *(spectral decomposition of $L^2([GL_2])$).* There is an orthogonal decomposition of $G(\mathbb{A})$-modules:

$$L^2([GL_2]) \;=\; L^2_{\mathrm{cusp}}([GL_2]) \;\oplus\; L^2_{\mathrm{res}}([GL_2]) \;\oplus\; L^2_{\mathrm{cont}}([GL_2]),$$

where:

- $L^2_{\mathrm{cusp}}([GL_2])$ is the cuspidal spectrum, a direct sum of irreducible unitary representations $\pi = \bigotimes'_v \pi_v$ with π_p generic tempered at almost all primes;
- $L^2_{\mathrm{res}}([GL_2])$ is the residual spectrum (in the GL_2 case generated by one-dimensional characters pulled up from the determinant), consisting of $GL_2(\mathbb{A})$-reducible automorphic representations from residues of Eisenstein series at specific points;
- $L^2_{\mathrm{cont}}([GL_2])$ is the continuous spectrum, realised as the direct integral $\int^{\oplus}_{\mathrm{Re}(s)=1/2} \mathrm{Ind}_B^G(\chi_s)\,|\xi(2s)|^{-2}\,ds$ for $\chi_s = |\cdot|^s \otimes |\cdot|^{-s}$.

Proof. Langlands 1966 *On the Functional Equations Satisfied by Eisenstein Series* §6–7 for the construction; Moeglin–Waldspurger 1995 *Spectral Decomposition and Eisenstein Series for GL_n* for the published GL_n exposition; for GL_2 specifically see Gelbart 1975 *Automorphic Forms on Adele Groups* Ch. II. □

Placement of $\mathcal{V}^{\mathrm{prim}}$

Hypothesis 67.4.2 *(discrete arithmetic placement).* Choose the primitive arithmetic vector carrier, its dense domain and its completion. The discrete placement required in Hypothesis 67.1.1 is an injective map

$$\iota : \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \longrightarrow L^2_{\mathrm{cusp}} \oplus L^2_{\mathrm{res}},$$

with fixed central character and specified Haar normalization. Its chosen residual component and vacuum normalization are part of the datum. The Langlands decomposition of the target does not construct this map. A continuous-spectrum comparison requires its own direct-integral or distributional carrier and is not a map of a distribution into L^2 without further hypotheses.

67.5 Scalar Continuum Models and the Pairing Problem

The Scalar Coefficient Domain

Use the Riemann completed function ξ with $\xi(1-z) = \xi(z)$ and $\xi(\overline{z}) = \overline{\xi(z)}$. Let U be the points s on $\mathrm{Re}\, s = 1/2$ where $\xi(2s)$ and $\xi(2s-1)$ are finite and nonzero.

Definition 67.5.1 *(scalar scattering coefficient model).* For $s \in U$, set $d(s) = |\xi(2s)|^{-2} > 0$ and $M(s) = \xi(2s-1)/\xi(2s)$. Define

$$P(s) = (1 + |M(s)|^2)d(s).$$

This is a scalar model. Identifying it with a coefficient of an actual truncated Petersson pairing requires that pairing, its truncation parameter and its measure normalization.

The Proposed Koszul Coefficient

Definition 67.5.2 *(scalar Koszul coefficient model).* On the same domain define

$$K(s) = M(s)^{-1}d(s) = \frac{\xi(2s)}{\xi(2s-1)}|\xi(2s)|^{-2}.$$

This scalar is not asserted to be the spectral measure of an arithmetic Koszul pairing. Such a comparison requires the continuous carrier, coefficient map and regularization.

Theorem 67.5.3 *(strict discrepancy of the two scalar models).* For every $s \in U$, one has $|M(s)| = 1$, $P(s) = 2d(s)$, and

$$P(s) - K(s) = d(s)(2 - M(s)^{-1}).$$

In particular

$$d(s) \le |P(s) - K(s)| \le 3d(s),$$

so the models are unequal everywhere on U.

Proof. Write $s = 1/2 + it$. Functional equation and conjugation give $\xi(2s) = \xi(1 + 2it) = \xi(-2it) = \overline{\xi(2it)}$. The numerator and denominator of M therefore have equal nonzero modulus. Substitution gives the difference, and the triangle and reverse triangle inequalities give the two bounds. □

Remark 67.5.4 *(phase and scale).* Multiplication by the phase M gives $MK = d = P/2$, not P. Multiplication by $2M$ matches these scalar models. Neither scalar identity constructs a positive spectral measure, an isometry, or an arithmetic bar–cobar comparison.

Corollary 67.5.5 *(scope of the scalar obstruction).* A proposed continuous pairing comparison whose coefficients are exactly P and K on U, with the same measure and no additional transport, cannot identify them. A comparison using another normalization must construct that normalization and its maps; the scalar discrepancy does not exclude such a construction.

Proof. Their difference has modulus at least $d > 0$. The last assertion only separates this fixed-normalization obstruction from a comparison with different data. □

Remark 67.5.6 *(continuous pairings require more than one coefficient).* The scalar functions above specify no bivariate pairing kernel. In particular they do not determine an off-diagonal truncated Eisenstein pairing or its diagonal limit. On the critical line, $s_1 + \overline{s_2} - 1 = i(t_1 - t_2)$, which vanishes exactly when $s_1 = s_2$. Any formula dividing by this quantity must treat that diagonal with its actual truncation and limit. The classical Maass–Selberg and Arthur identities concern the automorphic side; they supply no integrated equality with an arithmetic Koszul pairing without the missing comparison maps.

67.6 Conditional Arithmetic Pairing Consequences

Theorem 67.6.1 *(conditional P3 on the specified cuspidal domain).* Assume Hypothesis 67.1.1 and the discrete placement of Hypothesis 67.4.2 on the chosen tempered cuspidal carrier. Then the pullback of the Petersson form is positive definite and agrees there with the transported Koszul form composed with the specified antilinear involution.

Proof. Injectivity of ι makes the pullback of a positive-definite form positive definite. The local pairing comparisons and their specified adelic extension give equality of forms by Theorem 67.3.8. The prime GNS theorem alone does not supply either hypothesis. □

Remark 67.6.2 *(domain of arithmetic transport).* The prime Gibbs and Hilbert–Schmidt calculations are unconditional on their stated carriers. Extension of the arithmetic pairing to ramified, holomorphic, Maass or residual sectors requires its placement and pairing maps on each sector. Ramanujan controls a temperedness condition; it is not the missing isometry. Continuous spectrum additionally requires its measure comparison.

The Sufficient RH Implication

COROLLARY 67.6.3 *(conditional use in a sufficient RH implication).* A sufficient RH implication that assumes P3 may use the preceding conditional theorem only on its specified domain and with all of its arithmetic comparison hypotheses. Identifying the relevant Li or Weil trace with that domain is a further spectral comparison. The other hypotheses of the sufficient implication remain in force.

Proof. Substitute the conditional pairing conclusion for the P3 premise only after its hypotheses and the shared trace domain are supplied. This logical substitution constructs neither set of hypotheses. □

67.7 PRIME MODELS AND REMAINING MAPS

The positive constructions are the normalized prime Gibbs state, its Hilbert–Schmidt GNS realization, the closed modular operators, the finite-prime product, and the unitary onto a specified global state's prime cyclic subspace. Their domains and state normalizations are explicit. The local integral form (67.2) is another independently defined positive Hermitian model.

The arithmetic construction still requires the maps in Hypothesis 67.1.1. The residual-spectrum vacuum, ramified Whittaker models and continuous spectral measures must be identified on their actual carriers. A scalar partition function, the uniqueness of modular conjugation, and a spectral decomposition of the target do not provide those maps.

67.8 THE ARITHMETIC COMPARISON PROBLEM

Question 67.1.2 retains the intended Koszul–Petersson comparison. The finite and prime models specify normalization tests and actual Hilbert-space maps; the arithmetic placement and pairing compatibility remain to be constructed. At the critical global temperature, the prime cyclic comparison continues to hold for a specified KMS state even though the full occupation Gibbs trace diverges.

Chapter 68

Fi.a.3: Bushnell–Henniart Block Exhaustion at Wild Primes

Block exhaustion asks whether the wild block functor reaches every object of the proposed spectral category. The conditional argument uses three inputs: a BH type-block comparison, an actual extension-class comparison, and compact generation by the specified spectral objects. Finite lists and equal local dimensions alone do not imply essential surjectivity.

The local arithmetic identifications used below are hypotheses, including the coefficient-compatible block models and maps in Questions 54.4.8 and 54.4.9. The finite-algebra resolutions in that chapter do not classify the arithmetic blocks. In particular, the degree-one dimensions do not construct a map to an Emerton–Gee fibre. Whenever a comparison uses the three-vertex radical-square-zero model, its nonzero Yoneda product in degree two must also be preserved.

68.1 Statement

Setup

Fix $p \in \{2, 3\}$, a specified common coefficient ring R, a smooth full central character $\chi : \mathbb{Q}_p^\times \to R^\times$, and a conductor bound N. Any use of a field k in a finite-algebra model includes a specified coefficient map and base-change comparison to this arithmetic setting. No identification of prime-to-p coefficients with the integral Emerton–Gee coefficients is presumed. Let $\mathbf{T}^{\mathrm{BH}}_{p,\chi}$ be the chosen type-index set in that setting. Assume the wild enhancement (H2) and wild block-functor datum (H3) of Theorem 61.7.1, including presentable stable categories C^{BH}_τ, $\mathcal{D}_\tau$, exact colimit-preserving fully faithful functors Φ_τ, and specified categorical decompositions

$$C \simeq \prod_\tau C^{\mathrm{BH}}_\tau, \qquad \mathcal{D} \simeq \prod_\tau \mathcal{D}_\tau.$$

The notation for the arithmetic source and spectral support category below includes their supplied identifications with C and $\mathcal{D}$. The componentwise functor $\Phi^{\mathrm{wild}}_{p,\chi} = \prod_\tau \Phi_\tau$ exists under these data. A type list alone supplies neither these categorical products nor a geometric coproduct decomposition of an Emerton–Gee stack. The proposed formal components and their singular support remain part of the enhancement and comparison data.

The BH Block-Exhaustion Statement

Definition 68.1.1 *(BH-exhausted block).* Fix $p \in \{2, 3\}$, χ and τ. Let C^{BH}_τ be the specified presentable stable realization of the representation block, and put $\mathcal{D}_\tau = \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG,wild},p,\chi,\tau}_{GL_2})$. For the chosen functor $\Phi^{\mathrm{wild}}_{p,\chi,\tau} : C^{\mathrm{BH}}_\tau \to \mathcal{D}_\tau$, the block is BH-exhausted if that functor is essentially surjective. Generation by spectral objects alone is not this condition; their images through the functor must be identified.

THEOREM 68.1.2 *(BH block exhaustion under the complete comparison data).* Fix $p \in \{2, 3\}$ and χ. Assume the wild-enhancement and block-functor data of Conjectures 61.5.7 and 61.5.5, including exact colimit-preserving full faithfulness and compatible categorical decompositions. Assume further:

(A) For each block, a compact object $P_\tau \in \mathcal{C}_\tau^{\mathrm{BH}}$, an actual spectral object $Q_\tau \in \mathcal{D}_\tau$, and an equivalence $\Phi^{\mathrm{wild}}_{p,\chi,\tau}(P_\tau) \simeq Q_\tau$, as required by Conjecture 68.7.1. The proposed Q_τ is the derived structure sheaf of the BH closed point, with the stated singular support.

(B) The actual arithmetic extension-class comparison of Conjecture 68.7.3 is supplied for these objects and functors.

(C) The category $\mathcal{D}_\tau$ is compactly generated, Q_τ is compact, and $\mathcal{D}_\tau^c = \mathrm{thick}(Q_\tau)$, as in Conjecture 68.7.5.

Then every specified block is BH-exhausted, and the componentwise functor on the supplied categorical decompositions is an equivalence.

Proof. Condition (C) makes Q_τ a localizing generator: its localizing closure contains the thick closure and every colimit of compact objects. Condition (A) places it in the chosen functor's image. Proposition 61.4.7 therefore makes the block functor an equivalence, and the supplied categorical decompositions assemble these componentwise. Condition (B) retains the arithmetic extension compatibility. Full faithfulness in all degrees comes from the block-functor datum, not from a degree-one comparison. □

Remark 68.1.3 *(why F1.a.3 is the smallest residual).* Chapter 61 records the following local residuals for F1.a: F1.a.1 (block exhaustion at $p \geq 5$), F1.a.2 (wild-EG enhancement at $p \in \{2, 3\}$), the wild block functor datum, and F1.a.3. The explicit finite-algebra calculations in Chapter 54 remain available. Their transport to arithmetic blocks requires the local-model identifications, class maps and generator comparisons stated below; a type list or an equality of dimensions supplies none of these maps.

68.2 PROOF REDUCTION AND SOURCE COMPARISON

The following reductions distinguish type enumeration, extension classes, geometric components and compact generation.

BH tame-wild enumeration at $p = 2$. *Obstruction.* Enumerate Bushnell–Kutzko types in $\mathbf{T}^{\mathrm{BH}}_{2,\chi}$. Show that wild types at $p = 2$ are classified in conductor $\leq N$ by the unramified principal series, the tame supercuspidal, the wild supercuspidal types of bounded conductor, and the spherical (Iwahori-fixed) type absorbing the Ext^1-extension of Question 54.4.8. *Calculation.* The BH classification (Bushnell–Henniart 2006 §11–13) gives the exact list; the wild conductor-exponent bound is $a(\chi) + 2$, cf. BH §12.1. *Obstruction: (A), the BH type-block comparison conjecture.*

BH tame-wild enumeration at $p = 3$. *Obstruction.* Enumerate Bushnell–Kutzko types in $\mathbf{T}^{\mathrm{BH}}_{3,\chi}$. Show that the wild primary block at $p = 3$ has three restricted-weight simples L_0, L_1, L_2 with the A_2-linear-quiver Ext^1-structure of Question 54.4.9. *Required comparison.* Identify the proposed three BH types with the three restricted-weight simples; the two quiver edges $\alpha_{01} \in \mathrm{Ext}^1(L_0, L_1)$, $\alpha_{12} \in \mathrm{Ext}^1(L_1, L_2)$ lift to two non-split extensions in the category, each corresponding to a derived-structure fibre in the wild-enhanced EG component. *Residual: (B), the Paskunas wild* Ext^1*-compatibility.*

Essential surjectivity via type-by-type exhaustion. *Obstruction.* Fix a hypothetical $\mathcal{F} \in \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2})$ not in the essential image of $\Phi^{\mathrm{wild}}_{p,\chi}$. Decompose $\mathcal{F}$ along the BH-component decomposition of the wild-EG stack. Each summand $\mathcal{F}_\tau$ lives on a single component $\mathcal{X}^{\mathrm{EG,wild},p,\chi,\tau}_{GL_2}$. *Calculation.* By (C), $\mathcal{F}_\tau$ is a colimit of shifts of the derived structure sheaf of x_τ; by (A),

each such shift is in the image of $\Phi^{\mathrm{wild}}_{p,\chi,\tau}$; hence $\mathcal{F}_\tau$ itself is, and the full $\mathcal{F}$ is. Contradiction. *Residual: (C), wild-EG compact-generator identification.*

Comparison with the wild-EG decomposition of Chapter 61. *Obstruction.* Does the BH-component decomposition coincide with the Bushnell–Henniart fibre-correspondence decomposition of Conjecture 61.5.7(3)? *Calculation.* A comparison must identify both indexing sets with $\mathbf{T}^{\mathrm{BH}}_{p,\chi}$ and construct the proposed derived-fibre identifications (1 at $p = 2$ matching Question 54.4.8, 2 at $p = 3$ matching Question 54.4.9). The local model and its comparison remain additional inputs.

Unconditional closure test. *Obstruction.* Can (A), (B), (C) collectively close on existing primary literature? *Calculation.* (A) is known for $p \geq 5$ by Paskunas 2013 in the Breuil–Mezard framework; its transport to $p \in \{2, 3\}$ via Bushnell–Henniart types requires a direct match of types to structure sheaves not yet stated. (B) is known numerically (both sides have the same dimension) but the identification of the Ext^1-classes themselves with the degree-1 derived fibre is not recorded in Colmez 2010 or Paskunas 2013; it is a conjectural enhancement. (C) is standard for compactly-supported perfect complexes on classical formal schemes but requires proof in the derived-enhanced case. None of the three is closable from currently-stated primary literature; all three are individually tractable. *Final obstruction: (A), (B), (C), three named conjectures.*

The source comparison for each reduction step is recorded in §68.9. The first four analyses close conditionally on (A), (B), (C); the fifth identifies the three as the minimal conjectural set.

68.3 Bushnell–Henniart Tame-Wild Types at $p = 2$

The Classification

Proposition 68.3.1 *(Bushnell–Henniart 2006 classification at $p = 2$).* Fix a central character $\chi : \mathbb{Z}_2^\times \to k^\times$ and a conductor bound N. The bounded set $\mathbf{T}^{\mathrm{BH}}_{2,\chi}$ of Bushnell–Kutzko types with central character χ and conductor exponent at most N consists of three sorts of types:

(i) **Unramified principal-series types.** One type per unramified character $\psi : \mathbb{Q}_2^\times \to k^\times$ with $\psi|_{\mathbb{Z}_2^\times}$ square-rooting χ. The associated representation is the parabolic induction from the Borel of $\psi \otimes \psi^{-1}\chi$.

(ii) **Tame supercuspidal types.** One type per tame character ψ of a quadratic unramified extension $\mathbb{Q}_2(\sqrt{u})$ with $u \in \mathbb{Z}_2^\times \setminus (\mathbb{Z}_2^\times)^2$, inducing to a supercuspidal representation of $GL_2(\mathbb{Q}_2)$.

(iii) **Wild supercuspidal types.** One type per admissible wild character of a ramified quadratic extension $E/\mathbb{Q}_2$, with conductor exponent in the range imposed by χ and by $n \leq N$.

The bounded set is finite: $|\mathbf{T}^{\mathrm{BH}}_{2,\chi}| < \infty$, bounded in terms of N and $a(\chi)$.

Source. Bushnell–Henniart 2006 *The Local Langlands Conjecture for $GL(2)$*, Grundlehren 335, Springer. Chapter 11 for the principal series and tame supercuspidal classification; Chapter 12 for the wild supercuspidal classification and conductor exponents at $p = 2$; Chapter 13 for the counting formula. □

Remark 68.3.2 *(the Ext^1-carrying type at $p = 2$).* The proposed degree-one contribution at two requires an actual arithmetic block and extension class, as in Question 54.4.8. In characteristic two, trivial and sign characters coincide. Their names therefore do not identify two distinct constituents of a parabolic induction. Locating the desired class in a principal series block, and any vanishing assertion for supercuspidal blocks, requires a calculation in those specific coefficient categories.

Matching to Spectral Components

PROPOSITION 68.3.3 *(type-to-component match at $p = 2$).* Assume the BH type-block comparison Conjecture 68.7.1 and the wild-EG enhancement Conjecture 61.5.7. Then each $\tau \in \mathbf{T}^{\mathrm{BH}}_{2,\chi}$ corresponds to a unique component $\mathcal{X}^{\mathrm{EG,wild},2,\chi,\tau}_{GL_2}$ of the wild-enhanced EG stack, with:

- Unramified principal-series type τ: classical component indexed by a reducible residual Galois representation ρ with $\det \rho = \chi \cdot \chi_{\mathrm{cyc}}$; for the trivial $\psi = \mathbf{1}$, the component carries the degree-1 derived fibre of dimension 1 (the wild-EG enhancement).
- Tame supercuspidal type τ: classical component, no derived enhancement; corresponds to an irreducible residual ρ induced from a tame character of a quadratic unramified extension.
- Wild supercuspidal type τ: classical component, no derived enhancement; corresponds to an irreducible residual ρ induced from a wild character of a quadratic ramified extension.

The type-to-component map is a bijection.

Proof. **Step 1: residual-Galois match.** Each BH type τ has an associated L-parameter $\phi_\tau : W_{\mathbb{Q}_2} \to GL_2(k)$ by the local Langlands correspondence of Bushnell–Henniart 2006 §18, with determinant $\det \phi_\tau = \chi \cdot \chi_{\mathrm{cyc}}$. The residual representation ρ_τ is the reduction mod-p of ϕ_τ. The EG component $\mathcal{X}^{\mathrm{EG},2,\chi,\rho_\tau}_{GL_2}$ is the formal neighbourhood of ρ_τ. **Step 2: enhanced fibre at reducible ρ.** The local-model hypothesis must supply the proposed extension class, its arithmetic coefficient carrier, and its comparison to the one-dimensional derived direction. This is the input asked for in Question 54.4.8; it is not a consequence of a dimension count or of distinct trivial and sign characters in characteristic two. **Step 3: semisimplicity at irreducible ρ.** For τ a tame or wild supercuspidal, ρ_τ is irreducible; the deformation functor is smooth (Emerton–Gee arXiv:1908.07185 §6.2); no derived enhancement is needed. **Step 4: bijectivity.** Finiteness on both sides follows from Bushnell–Henniart §13 (left-hand) and the connected-component decomposition of $\mathcal{X}^{\mathrm{EG},2,\chi}_{GL_2}$ (right-hand). The bijection is the local Langlands correspondence for $GL_2(\mathbb{Q}_2)$ at the residual level. □

68.4 BUSHNELL–HENNIART TAME-WILD TYPES AT $p = 3$

The Classification and the A_2-Quiver Structure

PROPOSITION 68.4.1 *(Bushnell–Henniart 2006 classification at $p = 3$).* Fix $\chi : \mathbb{Z}_3^\times \to k^\times$ and a conductor bound N. The bounded set $\mathbf{T}^{\mathrm{BH}}_{3,\chi}$ consists of:

(i) **Unramified principal series.** Parabolically induced from the Borel of $GL_2(\mathbb{Q}_3)$.

(ii) **Tame supercuspidals.** One per tame character of the unramified quadratic extension $\mathbb{Q}_3(\sqrt{u})$ with $u \in \mathbb{Z}_3^\times \setminus (\mathbb{Z}_3^\times)^2$.

(iii) **Wild supercuspidals.** One per admissible wild character of a ramified quadratic extension $E/\mathbb{Q}_3$, with conductor exponent $a(\chi) + 1 \le n \le N$.

(iv) **Additional principal-block local-model hypothesis.** Specify three arithmetic simples and an exact equivalence taking them to the three simple right modules of $B = k(0 \xrightarrow{a} 1 \xrightarrow{b} 2)/(ab)$, in the coefficient category of Question 54.4.9. This identification is additional data, not a consequence of a classification of tame or wild types.

Source. Bushnell–Henniart 2006 §11 (principal series), §12 (tame supercuspidal), §13 (wild supercuspidal), §15 (wild types at small primes). The conductor bound cuts the infinite admissible character families

to a finite Bushnell–Kutzko set. The fourth item is a separate local-model hypothesis. The cited type classification does not supply that equivalence or its extension maps. □

Proposition 68.4.2 *(the three-vertex extension pattern).* For right modules over $B = k(0 \xrightarrow{a} 1 \xrightarrow{b} 2)/(ab)$, the adjacent extension groups $\mathrm{Ext}^1_B(S_0, S_1)$ and $\mathrm{Ext}^1_B(S_1, S_2)$ are one-dimensional. Their Yoneda product is nonzero in $\mathrm{Ext}^2_B(S_0, S_2) = k$, whereas $\mathrm{Ext}^1_B(S_0, S_2) = 0$. An exact arithmetic block equivalence taking its three simples to these right modules would transport these statements and products. Such an equivalence is an additional hypothesis.

Proof. The projective resolution in Example 54.4.4 computes the adjacent and degree-two groups and their product. The length-one path count in Proposition 54.4.3 gives the vanishing between non-adjacent simples. An exact equivalence transports extensions and their Yoneda compositions. □

Matching to Spectral Components

Proposition 68.4.3 *(type-to-component match at $p = 3$).* Assume (A) and (B). Each $\tau \in \mathbf{T}^{\mathrm{BH}}_{3,\chi}$ corresponds to a unique component $\mathcal{X}^{\mathrm{EG,wild},3,\chi,\tau}_{GL_2}$ of the wild-enhanced EG stack, with the principal-block types carrying a degree-1 derived fibre of dimension 2 (per Remark 61.5.4), and all other types carrying no derived enhancement.

Proof. **Step 1: classical-component match.** Same as Proposition 68.3.3 Step 1, replacing $p = 2$ by $p = 3$. Each type has an L-parameter ϕ_τ by BH 2006 §18; the residual ρ_τ determines the component. **Step 2: principal-block derived-fibre match.** For τ a principal-block type, ρ_τ is reducible with constituents matching the Steinberg-decomposed restricted-weight simples L_0, L_1, L_2. The two proposed arithmetic Ext^1-classes in Question 54.4.9 must be identified by the local-model map with a two-dimensional Ext^1-space in the deformation functor of ρ_τ. By Conjecture 61.5.7(2), this is realised as the degree-1 derived fibre of dimension 2 in $\mathcal{X}^{\mathrm{EG,wild},3,\chi,\tau}_{GL_2}$. **Step 3: semisimplicity at irreducible ρ.** Same as the $p = 2$ case. All supercuspidal types give smooth classical components. **Step 4: bijectivity.** Same as the $p = 2$ case. □

68.5 Essential Surjectivity via Type-by-Type Exhaustion

The Exhaustion Argument

Theorem 68.5.1 *(Exhaustion of a specified BH block).* Under all the hypotheses of Theorem 68.1.2, the chosen functor $\Phi^{\mathrm{wild}}_{p,\chi,\tau} : \mathcal{C}^{\mathrm{BH}}_\tau \to \mathcal{D}_\tau$ is an equivalence.

Proof. Its image contains the generator Q_τ by (A) and (C). The exact colimit-preserving full faithfulness supplied by (H3) allows Proposition 61.4.7 to apply. The specified degree-one comparison (B) is preserved; it is not used as a substitute for higher mapping-spectrum data. □

Corollary 68.5.2 *(Assembly on the specified categorical blocks).* Under all the hypotheses of Theorem 68.1.2, the componentwise functor on the supplied block decompositions is an equivalence of presentable stable categories.

Proof. The inverse is the componentwise inverse of the block equivalences, transported through the specified categorical decompositions. □

68.6 Wild Emerton–Gee Fibres and Block Extension Spaces

Dimensional Comparison

PROPOSITION 68.6.1 *(conditional dimensional comparison at $p = 2$).* Suppose the arithmetic extension carrier and the derived fibre in Question 54.4.8 are both constructed and identified with k^1. Then their dimensions agree and equal 1. This numerical equality does not select a comparison map or a distinguished class.

Proof. An identification with k^1 gives dimension 1 on each side. Choosing an isomorphism between two vector spaces of this dimension requires further data; dimensions alone do not specify it. □

PROPOSITION 68.6.2 *(conditional dimensional comparison at $p = 3$).* Suppose the arithmetic extension carrier and the derived fibre in Question 54.4.9 are both constructed and identified with k^2. Then their dimensions agree and equal 2. This numerical equality does not select a comparison map or a distinguished class.

Proof. An identification with k^2 gives dimension 2 on each side. Choosing an isomorphism between two vector spaces of this dimension requires further data; dimensions alone do not specify it. □

Structural Consistency

PROPOSITION 68.6.3 *(conditional compatibility of component decompositions).* Suppose a BH-to-spectral comparison identifies the components indexed by $\mathbf{T}^{\mathrm{BH}}_{p,\chi}$, their supports and their actual derived fibres with those of the wild-EG datum. Then it identifies the corresponding component decompositions. Equality of indexing sets or dimensions alone is insufficient for this conclusion.

Proof. The specified component maps assemble over their common indexing set. Their fibre identifications are part of the hypothesis, rather than a consequence of equal dimensions. □

Remark 68.6.4 *(data for block exhaustion).* The hypotheses (A), (B), and (C) must supply the block comparison, extension-class compatibility and compact generators. A list of local dimensions supplies none of these three maps or constructions.

68.7 The Three Conditional Inputs

(A) BH Type-Block Comparison

Conjecture 68.7.1 *(BH type-block comparison).* . Fix $p \in \{2, 3\}$, χ, and $\tau \in \mathbf{T}^{\mathrm{BH}}_{p,\chi}$. The projective indecomposable generator $P_\tau \in \mathrm{Block}^{\mathrm{BH}}_\tau$ is a compact object of $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_\chi$, and its image under $\Phi^{\mathrm{wild}}_{p,\chi}$ is the derived structure sheaf of the BH closed point $x_\tau \in \mathcal{X}^{\mathrm{EG,wild},p,\chi,\tau}_{GL_2}$.

Remark 68.7.2 *(evidence for the BH type-block comparison).* Three lines of evidence:

- Paskunas 2013 establishes the analogous statement for $p \geq 5$ (Publ. IHES 118 §6): each projective indecomposable of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$ maps under Colmez–Montreal to the structure sheaf of a residual-Galois closed point. At $p \in \{2, 3\}$, the Paskunas argument requires modification because the block structure is more complex; the comparison at $p \in \{2, 3\}$ is the extension of Paskunas' result to the BH type list, with the same projective-to-structure-sheaf identification.

- Bushnell–Henniart 2006 §18 establishes the type-to-parameter match: each BH type τ has an associated L-parameter ϕ_τ. The projective generator P_τ is the type's indicator-character-module; the BH comparison conjecture asserts that this module maps to the derived structure sheaf of the closed point x_τ determined by $\phi_\tau \pmod p$.
- Compactness of P_τ: the block is a finitely-generated module over its local endomorphism algebra (BH 2006 §12.3), hence P_τ is compact in the derived category of the block.

The conjectural content is the precise image identification (second bullet), not compactness or finiteness.

(B) Paskunas Wild Ext^1*-Compatibility*

Conjecture 68.7.3 *(Paskunas wild-block* Ext^1*-compatibility).* . Fix $p \in \{2,3\}$ and a principal-block type $\tau \in \mathbf{T}^{\mathrm{BH}}_{p,\chi}$ with reducible residual ρ_τ. The Ext^1-class(es) of Question 54.4.8 (at $p=2$) or Question 54.4.9 (at $p=3$) on the automorphic side matches, as k-vector space with specific class(es), the degree-1 cotangent fibre of the wild-enhanced EG stack Definition 61.5.2 at the residual ρ_τ. The match respects the class labels: the class α_{01} matches one Ext^1-direction of the cotangent fibre; α_{12} matches the other specified direction at $p=3$.

Remark 68.7.4 *(dimensions and class comparisons).* The dimensions in Propositions 68.6.1 and 68.6.2 are conditional on the specified arithmetic local models. Even when these models are supplied, equality of dimensions does not construct a map carrying the extension classes to prescribed cotangent directions. That requires a comparison of the actual deformation complexes.

(C) Wild-EG Compact-Generator Identification

Conjecture 68.7.5 *(Wild spectral compact generation).* For the specified wild block, $\mathcal{D}_\tau$ is compactly generated. Its proposed derived closed-point structure sheaf Q_τ is an actual compact object of the nilpotent-support category and $\mathcal{D}^c_\tau = \mathrm{thick}(Q_\tau)$. The thick closure includes shifts, finite cones and retracts. Its localizing closure is consequently the whole category.

Remark 68.7.6 *(Support and the generator).* A closed-point structure sheaf does not generate an arbitrary ambient derived category. For example, in $D(k[t])$, localization at t kills $k = k[t]/(t)$ and its entire localizing closure, but does not kill $k[t]$. Thus k cannot generate $D(k[t])$. The chosen support category, compactness of the proposed image, and its thick generation in (C) are essential data. Formal neighbourhoods or a derived enhancement alone do not verify these assertions for the arithmetic target.

68.8 Consequence for F1.a and F1

F1.a Closure at Wild Primes

Theorem 68.8.1 *(F1.a at wild primes, conditional).* Assume every hypothesis of Theorem 68.1.2, including the wild enhancement, the fully faithful exact colimit-preserving block functors and specified decompositions, as well as (A), (B), and (C). Then F1.a holds at $p \in \{2,3\}$: there is an equivalence

$$\Phi^{\mathrm{wild}}_{p,\chi} \colon \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big)_\chi \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}\big),$$

compatible with the specified block decomposition. Variation in χ additionally requires Conjecture 61.6.3.

Proof. Fully-faithfulness is Theorem 61.5.6. Essential surjectivity is Corollary 68.5.2. Both hold under the stated hypotheses. □

F1.a Closure at All Primes

COROLLARY 68.8.2 *(F1.a at all primes, conditional, sharpened).* Assume (H1)–(H5) of Theorem 61.7.1, with wild block exhaustion supplied by all the hypotheses of Theorem 68.1.2. Then F1.a holds at every prime and every central character χ: there is a single family equivalence

$$\Phi^{\mathrm{LocCat}}_{p,\chi}\colon \mathrm{D}^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big)_\chi \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG,wild\text{-}enhanced},p,\chi}_{GL_2}\big).$$

The central-character variation Theorem 61.6.4 also requires the family datum Conjecture 61.6.3.

Proof. Apply the specified categorical decompositions and effective family descent to Theorem 61.4.8 (at $p \geq 5$), Theorem 68.8.1 (at $p \in \{2,3\}$), and Theorem 61.6.4 (central-character variation, conditional on the family datum). □

The Updated F1 Obstruction Decomposition

PROPOSITION 68.8.3 *(F1 obstruction decomposition after BH block exhaustion).* The total F1 obstruction decomposition (combining F1.a.1–F1.a.3 with $\mathrm{L}_{\mathrm{ACD}}$) factors into the following named conjectural inputs:

(i) F1.a.1: block exhaustion at $p \geq 5$ (Conjecture 61.4.5), substantial non-formal theorem.
(ii) F1.a.2: wild-EG enhancement at $p \in \{2,3\}$ (Conjecture 61.5.7), substantial non-formal theorem.
(iii) Wild block functor datum at $p \in \{2,3\}$ (Conjecture 61.5.5).
(iv) F1.a.3.A: BH type-block comparison (Conjecture 68.7.1), substantial non-formal theorem.
(v) F1.a.3.B: Paskunas wild Ext^1-compatibility (Conjecture 68.7.3), substantial non-formal theorem.
(vi) F1.a.3.C: wild-EG compact-generator identification (Conjecture 68.7.5), substantial non-formal theorem.
(vii) Central-character family datum (Conjecture 61.6.3).
(viii) $\mathrm{L}_{\mathrm{ACD}}$: adelic categorical descent (Ch. 43), substantial non-formal theorem.

The block-exhaustion implication uses (A)–(C) together with the actual functors and decompositions in Theorem 68.1.2.

Proof. The enumeration is direct. F1.a.1, F1.a.2, the wild block functor datum, and the central-character family datum are inherited from Chapter 61. F1.a.3 factors as (A)+(B)+(C) by Theorem 68.1.2. $\mathrm{L}_{\mathrm{ACD}}$ is the adelic residual of Chapter 43. □

68.9 RESIDUAL CONDITIONS AND SOURCE COMPARISONS

Named Residuals Introduced

F1.a.3 factors into three sub-conjectures:

(i) Conjecture 68.7.1 (F1.a.3.A): projective indecomposables of BH blocks map to derived structure sheaves of BH closed points under the twisted DEG functor.
(ii) Conjecture 68.7.3 (F1.a.3.B): the non-semisimple Ext^1-classes on the automorphic side match the degree-1 cotangent fibres on the wild-enhanced EG stack, as classes (dimensional agreement under the explicit local-model hypotheses of Proposition 68.6.1 and Proposition 68.6.2).
(iii) Conjecture 68.7.5 (F1.a.3.C): compact generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on each wild-EG component by the derived structure sheaf of the BH closed point.

Conditional BH Comparisons

The following comparisons retain the local-model and decomposition hypotheses of their cited propositions:

(i) Dimensional comparison at $p = 2$ (Proposition 68.6.1): $1 = 1$.
(ii) Dimensional comparison at $p = 3$ (Proposition 68.6.2): $2 = 2$.
(iii) Structural consistency with Chapter 61 (Proposition 68.6.3): the BH-component decomposition matches the wild-EG decomposition of Chapter 61 structurally.

These statements give dimension and decomposition comparisons only under those hypotheses. The remaining arithmetic constructions include class-level match, compact generation, and projective-to-structure-sheaf comparison.

Wild Blocks at $p = 2$ and $p = 3$

The representation-theoretic inputs are Bushnell–Henniart (2006), §§11–13, Carter (1989), §7.3, Lusztig (1980), Jantzen (2003), Chapter II, §8, and Paskunas (2013), §6. The Dotto–Emerton–Gee comparison is confined to $p \geq 5$; extending it to $p = 2, 3$ requires the wild functor datum as well as (A). Bushnell–Henniart uses Langlands-normalised parameters. Comparing these with the Emerton–Gee moduli problem (arXiv:1908.07185) requires the specified parameter and conductor conventions.

At $p = 2$, the source is the block $\mathrm{Block}_{\tau}^{\mathrm{BH}}$ of smooth $GL_2(\mathbb{Q}_2)$-representations with central character χ. The geometric target is the component $\mathcal{X}_{GL_2}^{\mathrm{EG,wild},2,\chi,\tau}$; the comparison is between the associated stable presentable categories. Block restriction, the type-to-component correspondence of Bushnell–Henniart, §18, and formation of the derived structure sheaf must be compatible with the proposed functor. The required inputs are the enhancement and wild functor datum, together with (A), (B), and (C).

At $p = 3$, the analogous comparison uses the A_2-linear-quiver conventions, with radical-square-zero relations, of Auslander–Reiten–Smalø (1995), Chapter VII, §2. The proposed degree-one dimension is two rather than one, as in Question 54.4.9. This numerical datum does not establish the arithmetic local model. The three hypotheses (A), (B), and (C), including their compatibility with block restriction, are still required at $p = 3$.

Block Exhaustion and Compact Generators

The essential-surjectivity argument uses compact generation and formal deformation theory as formulated in Gaitsgory–Rozenblyum, Vol. II, Lurie's *Higher Algebra*, §4.8.2, and Pridham–Toen–Vezzosi, DAG VIII. Thick generation of compact objects uses shifts, finite cones and retracts; localizing generation also allows arbitrary colimits; the comparison is formulated in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$. Orthogonality of the blocks makes the block-by-block assembly diagonal only under the specified categorical decompositions. The fully faithful colimit-preserving functor and its lifted compact generators give essential surjectivity by Theorem 68.1.2.

Wild Components and Extension Classes

The comparison uses three inputs: the wild Emerton–Gee stack of Chapter 61, the block Ext^1-calculations of Chapter 54, and the type classification of Bushnell–Henniart (2006). These are separate geometric, homological and representation-theoretic inputs.

The geometric comparison is formulated in derived formal algebraic stacks over $\mathrm{Spf}\,\mathbb{Z}_p$. The degree-one fibre dimensions in Chapter 61 agree with the block extension dimensions by Proposition 68.6.1 and Proposition 68.6.2. The identification of individual classes requires hypothesis (B); it is stronger than

equality of dimensions. The comparison uses the functorial Bushnell–Henniart fibre correspondence of Bushnell–Henniart (2006), §18. The class-level identification remains the content of (B).

The Remaining Wild-Prime Comparisons

The comparison uses Langlands-normalised parameters and the specified conductor conventions in stable presentable ∞-categories. Its three unresolved inputs have distinct mathematical content:

- (A) requires the projective-to-structure-sheaf comparison of Paskunas at $p \geq 5$ to extend to the specified blocks at $p = 2, 3$.
- (B) requires the individual Ext^1-classes to match the cotangent-fibre directions under the deformation-theoretic map.
- (C) requires the relevant compact-generation theorem for the derived-enhanced wild Emerton–Gee stack.

The needed representation-theoretic and geometric inputs are those of Paskunas, Bushnell–Henniart, Emerton–Gee, Gaitsgory–Rozenblyum, and Pridham–Toen–Vezzosi. Their functorial compatibility with the specified arithmetic carriers is part of (A), (B), and (C). The conditional F1.a.3 implication uses all three in addition to the enhancement, functors and decompositions of Theorem 68.1.2.

68.10 Block Exhaustion Boundary

(i) F1.a.3 concerns exhaustion by the finite Bushnell–Henniart type list together with the specified extension-class comparisons in Chapter 54 (Remark 68.1.3).

(ii) The condition is: essential surjectivity of the twisted DEG-type functor $\Phi^{\mathrm{wild}}_{p,\chi}$ of Theorem 61.5.6 at $p \in \{2, 3\}$, reducing to type-by-type exhaustion via the BH block decomposition.

(iii) BH tame-wild classification at $p = 2$ (Proposition 68.3.1): finite list of unramified principal-series, tame supercuspidal, and wild supercuspidal types. The proposed Ext^1-carrying block requires the identification (Remark 68.3.2).

(iv) At $p = 3$, the additional local-model hypothesis in Proposition 68.4.1 permits arithmetic transport of the proved finite three-vertex calculation in Proposition 68.4.2. The arithmetic identification remains the comparison requested in Question 54.4.9.

(v) Dimensional comparison under the specified local models: both $p = 2$ (dimension 1) and $p = 3$ (dimension 2) match between the Ext^1-side and the derived-fibre side (Proposition 68.6.1, Proposition 68.6.2).

(vi) Structural compatibility under the component comparison: the BH-component decomposition coincides with the wild-EG decomposition of Chapter 61 (Proposition 68.6.3).

(vii) Essential surjectivity on a single BH block (Theorem 68.5.1): proved under every hypothesis of Theorem 68.1.2. Assembly across types (Corollary 68.5.2): equivalence of the twisted DEG-type functor.

(viii) The three comparison hypotheses are (A) the BH type-block comparison (Conjecture 68.7.1), (B) the Paskunas wild Ext^1 comparison (Conjecture 68.7.3), and (C) wild-EG compact generation (Conjecture 68.7.5).

(ix) The F1.a.3 conclusion also requires the enhancement and the fully faithful colimit-preserving block functors and decompositions.

(x) The consequence for the F1 table (Proposition 68.8.3) is that F1.a factors into named conjectural inputs: F1.a.1, F1.a.2, the wild block functor datum, F1.a.3.A–C, and the central-character family datum; F1 adds L_{ACD}. This is the finest factorisation of the F1 residual recorded here.

There is no unconditional closure of F1.a.3. The dimensional and structural comparisons require their specified arithmetic local models, while block exhaustion remains conditional on all the hypotheses of Theorem 68.1.2.

Chapter 69

Arithmetic Fundamental Local Equivalence: Selmer-Derived Target and Open Categorical Equivalences

69.1 Selmer-Derived Global Spectral Stack

A global spectral target must impose the global Galois relation and its local conditions simultaneously. The formal deformation functors of Chapter 10 provide a precise pullback on a common coefficient category. A geometric stack representing that functor, and a comparison with local parameter stacks, require further hypotheses.

Definition 69.1.1 *(Selmer deformation functor).* Fix a finite field k of characteristic ℓ. Choose a finite ramification set S containing the archimedean place and ℓ. Fix a continuous representation $\bar{\rho} : G_{\mathbb{Q},S} \to \mathrm{GL}_2(k)$, and a determinant lift $\delta : G_{\mathbb{Q},S} \to W(k)^\times$. Use the category $\mathrm{Art}_{W(k)}$ of augmented simplicial Artinian local coefficient algebras from §10.6.

Let $\mathcal{D}^{\mathrm{or}}_{G,\delta}$ denote the derived continuous deformation functor with an identification of its determinant with δ. Arrows preserve that identification. For each finite $v \in S_f$, supply a pointed local functor $\mathcal{D}^{\mathcal{L}}_v$ and a morphism $\mathcal{D}^{\mathcal{L}}_v \to \mathcal{D}^{\mathrm{or}}_{G_{\mathbb{Q}_v},\delta|_v}$ on this same coefficient category.

Define

$$\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\delta,\mathcal{L}} := \mathcal{D}^{\mathrm{or}}_{G_{\mathbb{Q},S},\delta} \times^h_{\prod_{v\in S_f} \mathcal{D}^{\mathrm{or}}_{G_{\mathbb{Q}_v},\delta|_v}} \prod_{v\in S_f} \mathcal{D}^{\mathcal{L}}_v. \tag{69.1}$$

This notation initially denotes a functor to spaces. It denotes a geometric stack only when such a representative has been constructed. A local Emerton–Gee or Weil-parameter description can be used after its comparison with the indicated local functor, on the specified coefficient category, is supplied.

Proposition 69.1.2 *(Selmer tangent complex).* At the residual point, suppose the tangent of each $\mathcal{D}^{\mathcal{L}}_v$ is $L_v[1]$, with its induced map $g_v : L_v \to C^\bullet(G_{\mathbb{Q}_v}, \mathrm{ad}^\circ \bar{\rho})$. Then

$$T\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\delta,\mathcal{L}} \simeq C^\bullet_{\mathcal{L}}(G_{\mathbb{Q},S}, \mathrm{ad}^\circ \bar{\rho})[1], \tag{69.2}$$

where $C^\bullet_{\mathcal{L}}$ is the mapping fiber of

$$C^\bullet(G_{\mathbb{Q},S}, \mathrm{ad}^\circ \bar{\rho}) \oplus \prod_{v\in S_f} L_v \xrightarrow{\mathrm{res}-g} \prod_{v\in S_f} C^\bullet(G_{\mathbb{Q}_v}, \mathrm{ad}^\circ \bar{\rho}).$$

Proof. The tangent functor preserves the homotopy pullback (69.1). Propositions 10.6.1 and 10.6.2 compute its global and full local tangent complexes. Their fiber is the displayed Selmer complex, as in Theorem 10.7.1. □

Its cohomology groups $H^0_{\mathcal{L}}$, $H^1_{\mathcal{L}}$, and $H^2_{\mathcal{L}}$ occur in tangent degrees -1, 0, 1. They record infinitesimal automorphisms, deformations, and obstructions. If each g_v is an inclusion of complexes, a quotient by L_v gives an equivalent description. A general morphism of local conditions requires the fiber above. The trace-zero coefficients rely on preserving a determinant identification, rather than merely its value.

Neither geometric representability nor Noetherianity follows from this tangent formula. Quasi-smoothness is also a separate condition on a geometric representative. For derived schemes it allows a nonzero tangent group in degree one: the dual-number scheme of Example 10.7.2 is an explicit case. Real-place complexes have not been included in (69.1). A compact-support interpretation must specify them, especially for $\ell = 2$.

69.2 Local Geometrisation and Its Domain

The following collects what Fargues–Scholze, Emerton–Gee, and Dotto–Emerton–Gee establish in the local setting. These are the inputs to the conditional programme of §69.3.

Theorem 69.2.1 *(local inputs, Fargues–Scholze / Emerton–Gee / Dotto–Emerton–Gee).* (assembling external results).

(i) *Local geometrisation and spectral action* (Fargues–Scholze arXiv:2102.13459). For each prime p, the Fargues–Scholze spectral action equips $D^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])$ with an action of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathrm{LocSys}_{GL_2})$ and supplies local Langlands geometrisation and Hecke functoriality.

(ii) *Local (φ, Γ) parameter stacks* (Emerton–Gee arXiv:1908.07185). For each prime p, the Emerton–Gee stack $\mathcal{X}^{\mathrm{EG},p}_{GL_2}$ parametrises two-dimensional (φ, Γ)-modules over $\mathbb{Q}_p$ with a well-behaved moduli structure; local conditions $\mathcal{X}_v^{\mathcal{L}_v} \hookrightarrow \mathcal{X}^{W,\varphi\Gamma}_{GL_2,v}$ are open or closed substacks.

(iii) *Fully faithful functor at fixed central character* (Dotto–Emerton–Gee arXiv:2603.26887). For primes $p \geq 5$, there exists a fully faithful functor

$$D^{\text{sph-fin}}_{GL_2(\mathbb{Q}_p),\chi} \hookrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG},p}_{GL_2,\chi}\big)$$

for each fixed central character χ. Essential surjectivity, the cases $p = 2, 3$, and the central-character-family statement remain open.

(iv) *Archimedean OPE confined to archimedean factor*. The Hochschild-trace candidate $\mathcal{V}^{\mathrm{prim}}$ carries chiral OPE structure at the archimedean factor $v = \infty$ via the $(\mathfrak{gl}_2, O(2))$-module structure; finite places carry locally constant sheaf data and Hecke-algebra actions via the Satake isomorphism. Chiral OPE structure is an archimedean-fibre phenomenon.

(v) *Commutative Bethe–Hecke algebra*. At each finite prime p, the centre of the spherical Hecke algebra $\mathcal{H}(GL_2(\mathbb{Q}_p), GL_2(\mathbb{Z}_p))$ is commutative and acts on $\mathcal{V}^{\mathrm{prim}}$ via the Satake isomorphism. This commutative Bethe–Hecke structure is the correct Hecke-algebraic shadow; higher Hopf or Yangian structures require separate verification at each prime.

(vi) *Classical Kim arithmetic Chern–Simons*. Kim's arithmetic Chern–Simons theory arXiv:1510.05818 supplies classical arithmetic CS torsors on the arithmetic curve and action lines in K_2. The quantum boundary category $\partial_q\mathrm{ACS}$ of Conjecture 69.3.6 is a distinct object from $\mathcal{V}^{\mathrm{prim}}$; its construction is open.

69.3 Conditional Categorical Equivalences

The local inputs of §69.2 establish the spectral action, the (φ, Γ) parameter stacks, and full faithfulness at fixed central character. A complete arithmetic FLE requires four further categorical equivalences, each an open problem conditional on a named hypothesis.

Conjecture 69.3.1 *(local categorical comparison).* . For every prime p there is an equivalence

$$D^{\text{sph-fin}}\big([GL_2(\mathbb{Q}_p)]\big) \simeq \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{EG},p}_{GL_2}\big), \tag{69.3}$$

compatible with Hecke functors, central-character families, and the Fargues–Scholze spectral action. The Dotto–Emerton–Gee functor establishes full faithfulness for $p \geq 5$ at fixed central character; the conjecture adds essential surjectivity, the cases $p = 2, 3$, and the family statement.

Conjecture 69.3.2 *(adelic categorical descent).* . Under the local categorical comparison (69.3) at all primes, the local categories glue to the global automorphic category $D([GL_2])^{\text{sph-fin}}$ via an equivalence compatible with Whittaker models, Bernstein centres, the archimedean $(\mathfrak{g}, K)$ factor, and Eisenstein and continuous spectrum. Representation-level restricted tensor products are classical (Flath); the categorical descent is the open statement.

Conjecture 69.3.3 *(mixed-characteristic Iwahori E_2).* . The mixed-characteristic local Iwahori Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ carries an E_2-monoidal structure compatible with diamond Beilinson–Drinfeld fusion and with the Iwahori stratification:

$$\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p} \in \mathrm{Alg}_{E_2}\big(\mathrm{Cat}_\infty\big). \tag{69.4}$$

Current sources supply spherical fusion and E_1 convolution; the E_2 enhancement is the local input required for the restricted-tensor E_2 transport argument. The restricted-tensor E_2 transport lemma (proved elsewhere in this volume) is a separate, purely categorical statement; its hypotheses require (69.4) as input.

Conjecture 69.3.4 *(full-target arithmetic Ben-Zvi–Nadler).* . For the Selmer-derived full Weil/(φ, Γ) target, the arithmetic Ben-Zvi–Nadler comparison is

$$\mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \simeq \mathcal{O}\big(\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}\big)^{\mathrm{flat}}, \tag{69.5}$$

where $\mathrm{LocSys}^{W,\varphi\Gamma}_{GL_2}$ is the full Weil/(φ, Γ) local system stack and $\cdot^{\mathrm{flat}}$ denotes the flat-locus subfunctor. The conjecture requires formal-Noetherian Hochschild continuity for $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ and comparison of the Arinkin–Gaitsgory nilpotent flat locus with the Fargues–Scholze/Emerton–Gee flat locus.

Conjecture 69.3.5 *(categorical arithmetic Whittaker theory).* . The arithmetic Whittaker factorisation lifts from representation-level Whittaker models to a categorical equivalence compatible with the local comparisons of (69.3), adelic descent, and the Selmer-derived spectral stack (69.1). Representation-level Tate–Jacquet–Langlands factorisation is proved; the categorical lift is the open statement.

Conjecture 69.3.6 *(quantum ACS boundary category).* . There exists a quantum boundary category $\partial_q\mathrm{ACS}$ and an equivalence

$$\partial_q\mathrm{ACS} \simeq \mathcal{V}^{\mathrm{prim}}$$

compatible with an appropriate quantisation of Kim's arithmetic Chern–Simons theory arXiv:1510.05818. Kim's theory provides the classical arithmetic CS torsors and action lines in K_2; the quantisation is the open content of this conjecture.

69.4 Proved and Conditional Components of the Arithmetic FLE

Theorem 69.4.1 *(arithmetic FLE: proved and conditional components).* (by enumeration). The arithmetic programme based on $\mathcal{V}^{\mathrm{prim}}$ and the Selmer-derived stack $\mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\partial,\mathcal{L}}$ (69.1) decomposes as follows.

(i) *Constructed as a formal functor.* The Selmer homotopy pullback exists for the supplied local functors and maps on $\mathrm{Art}_{W(k)}$ (Definition 69.1.1). Its tangent is the stated Selmer complex under the local tangent hypotheses (Proposition 69.1.2). Geometric representability and comparisons with the local parameter stacks remain additional requirements.

(ii) *Conditional on Conjecture 69.3.1.* Local categorical comparison at all primes, including essential surjectivity at $p \geq 5$ and the full statement at $p = 2, 3$.

(iii) *Conditional on Conjecture 69.3.1 and Conjecture 69.3.2.* Adelic categorical descent to the global automorphic category.

(iv) *Conditional on Conjecture 69.3.3.* Iwahori E_2-monoidal structure at mixed characteristic; the restricted-tensor E_2 transport lemma applies once this local input is supplied.

(v) *Conditional on Conjecture 69.3.4.* Full-target arithmetic Ben-Zvi–Nadler comparison (69.5).

(vi) *Conditional on Conjecture 69.3.5.* Categorical arithmetic Whittaker factorisation.

(vii) *Conditional on Conjecture 69.3.6.* Quantum ACS boundary category equivalent to $\mathcal{V}^{\mathrm{prim}}$.

$\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class throughout; its chiral OPE structure is confined to the archimedean factor as established in Theorem 69.2.1(4). A vertex algebra requires an OPE on a formal disk defined at every place; $\mathcal{V}^{\mathrm{prim}}$ carries this structure only at $v = \infty$.

Chapter 70

F1.A.1 Unramified Ideal, F1.A.2 Small-Prime Block Extension, and L_{ACD} Cuspidal Descent

The local ordinary, small-prime block, and global cuspidal comparisons have different carriers. Fixed-determinant Frobenius parameters and spherical or Iwahori invariant vectors provide explicit local data. An enhanced compact-generator criterion explains what additional maps would make a categorical comparison an equivalence. The ordinary essential image, the small-prime block functors and global cuspidal descent remain separate arithmetic construction problems. Their Eisenstein extension also requires normalized intertwiners and global spectral synthesis.

70.1 Objects and Comparison Data

Inherited Objects

The intended arithmetic comparisons use the following notation and prior comparison statements, with their carrier and realization hypotheses retained:

- $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_\chi$ and its Dotto–Emerton–Gee functor $\Phi^{\mathrm{DEG}}_{p,\chi}$ (Chapter 61, Theorem 61.3.1);
- the Bushnell–Henniart block decomposition and its type list (Chapter 68; Proposition 68.3.1, Proposition 68.4.1);
- the Selmer-derived global spectral stack $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\delta,\mathcal{L}}$ (Chapter 69, Definition 69.1.1);
- the four subconditions $\mathrm{L}_{\mathrm{ACD}}.0$–$.3$ of Chapter 52, together with Theorem 50.1.3 (F2.c tightened).

The arithmetic comparisons require these objects with specified enhancements and support conditions. The local models below define their own moduli problems; they are not identified with a Selmer stack.

Primary Sources

The deformation, representation and automorphic comparison problems use the following references:

Breuil–Mézard 2002 "Multiplicités modulaires et représentations de $GL_2(\mathbb{Z}_p)$ et de $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$ en $\ell = p$", Duke Math. J. 115. The numerical Breuil–Mézard conjecture.

Kisin 2009 "The Fontaine–Mazur conjecture for GL_2", J. AMS 22. Modularity lifting plus Breuil–Mézard in Hodge–Tate regular weight.

Gee–Kisin 2014 "The Breuil–Mézard conjecture for potentially Barsotti–Tate representations", Forum Math. Pi 2. Breuil–Mézard geometric formulation.

Emerton–Gee arXiv:1908.07185 The Emerton–Gee stack of (φ, Γ)-modules. The arithmetic comparison requires the actual support and cycle constructions on this stack; the elementary unramified framed calculation below has a different carrier.

Dotto–Emerton–Gee arXiv:2603.26887 Fully faithful functor at fixed central character for $p \geq 5$.

Clozel–Harris–Taylor 2008 *Automorphy for some l-adic lifts of automorphic mod l Galois representations*, Publ. Math. IHES 108, 1–181. Automorphy lifting under its conjugate self-duality, regularity and ramification hypotheses.

Harris–Taylor 2001 *The Geometry and Cohomology of Some Simple Shimura Varieties*, Ann. Math. Stud. 151. Shimura-variety cohomology and local Langlands compatibility; this is a different source from the automorphy-lifting paper.

Paškūnas 2014 *Blocks for mod p representations of $GL_2(\mathbb{Q}_p)$*, in *Automorphic Forms and Galois Representations*, Vol. 2, LMS Lecture Note Series 415, 231–247, arXiv:1104.5602. Block structure in the specified representation category.

Colmez–Dospinescu–Paškūnas "The p-adic local Langlands correspondence for $GL_2(\mathbb{Q}_p)$", Cambridge J. Math. 2 (2014). $p = 3$ and reducible principal-block compatibility.

Saito 1997 "Modular forms and p-adic Hodge theory", Invent. Math. 129. Local-global compatibility for the Galois representation attached to a classical newform: the Frobenius trace at an unramified prime $\ell \neq p$ is the sum of the two roots of the Galois Frobenius polynomial and equals the Hecke coefficient a_ℓ in the matching arithmetic normalization. The normalized-induction Hecke operator below uses its explicit $q^{1/2}$ factor.

Taylor–Wiles 1995 "Ring-theoretic properties of certain Hecke algebras", Ann. Math. 141. Big-image Taylor–Wiles hypotheses.

Roles of the comparison data

Breuil–Mézard, Kisin and Gee–Kisin concern deformation rings and cycles. Emerton–Gee concerns the spectral moduli stack, while Dotto–Emerton–Gee constructs a fully faithful functor on its specified coefficient category. Clozel–Harris–Taylor concerns automorphy lifting; Harris–Taylor concerns Shimura-variety cohomology and local Langlands compatibility. Carayol and Saito concern local-global compatibility. Paškūnas and Colmez–Dospinescu–Paškūnas supply block-theoretic questions and constructions in their stated representation categories. Flath gives a factorization of actual representations; Bernstein and Mœglin–Waldspurger concern spectral decomposition. None of these different roles supplies the missing functors, support comparisons or generation statements by itself.

70.2 Fi.a.i: The Unramified Ordinary Ideal

Hypotheses and Target

Setup 70.2.1 *(Taylor–Wiles unramified setup).* Fix a prime $p \geq 5$, a level $N \in \mathbb{Z}_{\geq 1}$ with $\gcd(N, p) = 1$, and a residual Galois representation

$$\bar{\rho}\colon G_{\mathbb{Q}} \to GL_2(\overline{\mathbb{F}}_p)$$

unramified at p and at almost all $\ell \nmid Np$. Descend its coefficients to a finite field k. Fix a full local central character $\chi : \mathbb{Q}_p^\times \to k^\times$ using local reciprocity that sends a uniformizer to geometric Frobenius. In the determinant-identified DEG convention, its corresponding Galois character satisfies $\det \bar{\rho}|_{G_{\mathbb{Q}_p}} = \chi\bar{\varepsilon}^{-1}$, where $\bar{\varepsilon}$ is the residual cyclotomic character. Thus both its inertia values and its value on a uniformizer are fixed. A characteristic-zero comparison also chooses compatible lifts of the central character and determinant, as in the construction of Chapter 86. Assume:

(TW1) $p \geq 5$.

(TW2) $\bar{\rho}|_{G_{\mathbb{Q}(\zeta_p)}}$ is absolutely irreducible.

(TW3) The local residual representation at p has distinct characters in its semisimplification after the chosen coefficient extension. This is local distinguishedness, not a claim that the global representation has diagonal characters.

(TW4) Restrict to the intended ordinary component $\mathrm{Block}^{\mathrm{ord}}_{\bar{\rho}|_{G_{\mathbb{Q}_p}}}$, where the local representation has an unramified invariant line. This line convention must be compared explicitly with the unramified quotient convention of Chapter 86.

The central character in Setup 70.2.1 is ramified on units. Indeed, the residual representation is unramified at p, so its determinant is trivial on inertia, whereas the geometric reciprocity convention gives $\bar{\varepsilon}(u) = \bar{u}$ for $u \in \mathbb{Z}_p^\times$ and $\bar{\varepsilon}(p) = 1$. Thus $\chi(u) = \bar{u}$. This is the convention of Dotto–Emerton–Gee, Section 2.1.1, p. 9. A principal series induced from two unramified characters has trivial central character on units and cannot supply an object of this fixed-χ category.

Proposition 70.2.2 *(central-character-compatible smooth source objects).* Fix a finite extension of $\mathbb{Q}_p$ with integer ring $\mathcal{O}$ and residue field k, a continuous lift $\zeta : \mathbb{Q}_p^\times \to \mathcal{O}^\times$ of χ, and the compatible determinant $\delta = \zeta\varepsilon^{-1}$ under geometric reciprocity, where ε is the p-adic cyclotomic character. Let A be a finite local Artinian $\mathcal{O}$-algebra with residue field k. Write ζ_A for the induced character, and choose an unramified character $\eta_A : \mathbb{Q}_p^\times \to A^\times$. Put $G = GL_2(\mathbb{Q}_p)$ and let B be its upper triangular subgroup. The unnormalized smooth induction

$$I_A = \mathrm{Ind}_B^G(\zeta_A\eta_A^{-1} \otimes \eta_A)$$

consists of locally constant $f : G \to A$ satisfying

$$f\left(\begin{pmatrix} a & b \\ 0 & d \end{pmatrix} g\right) = \zeta_A(a)\eta_A(a)^{-1}\eta_A(d) f(g), \qquad (g_0 f)(g) = f(g g_0).$$

It is a nonzero smooth p-power-torsion $\mathcal{O}$-representation with central character ζ. It has no $GL_2(\mathbb{Z}_p)$-fixed vectors. In particular, no square-root modulus factor is used over A.

Proof. The finite coefficient characters have open kernels. Choose a principal congruence subgroup $K_m \subset GL_2(\mathbb{Z}_p)$ so that the inducing character θ_A of B is trivial on $B \cap K_m$. Define $f(bk) = \theta_A(b)$ on BK_m and zero outside. Two factorizations differ by $B \cap K_m$, so this is well-defined. The image of K_m in the Hausdorff space $B\backslash G$ is compact and open, hence closed as well. The resulting zero extension is locally constant and $f(1) = 1$. More generally, restriction to the compact group $GL_2(\mathbb{Z}_p)$ shows that every locally constant induced function is fixed on the right by some sufficiently small open subgroup: a finite clopen partition refines its local constancy neighbourhoods. This proves smoothness. The ring A is killed by a power of p, so the same is true of I_A. A central scalar x acts by $\zeta_A(x)\eta_A(x)^{-1}\eta_A(x) = \zeta_A(x)$. Choose a unit u whose reduction is not 1. The element $\zeta_A(u) - 1$ is a unit of A. If a vector were fixed by $GL_2(\mathbb{Z}_p)$, it would be annihilated by this unit, hence vanish. □

A determinant twist cannot turn an unramified principal series into this residual central-character family when p is odd. On the cyclic group $\mathbb{F}_p^\times$, such a twist changes the central exponent by $2a$; the required exponent is 1. The congruence $2a = 1 \pmod{p-1}$ has no solution. This remains an obstruction after coefficient extension and, by reduction, for the finite rings A. The characteristic-zero unramified invariant-vector calculation below therefore has a different central-character carrier.

Definition 70.2.3 *(data for the ordinary comparison subcategory).* The representations I_A are actual objects of the smooth p-power-torsion category $\mathcal{A}_\zeta$ of Chapter 86. Their stable colimit closure inside $D(\mathcal{A}_\zeta)$ is a defined source subcategory, but is not asserted to be the ordinary essential-image category. The intended notation $\mathrm{D}^{\text{sph-fin,unr-ord}}([GL_2(\mathbb{Q}_p)])_\chi$ requires the coefficient comparison with $D(\mathcal{A}_\zeta)$, a choice of ordinary source objects, and a proof of the required Hecke-finiteness or admissibility condition. On the spectral side, construct the intended formal neighbourhood $\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi,\text{unr-ord}}$ with its determinant, ordinary flag and support condition. Identify which compatible induced objects, ordinary subquotients or Hida-family objects map to that support, and prove their generator property. The local Frobenius and invariant-vector calculations do not by themselves make these arithmetic identifications.

Statement

The ordinary comparison requires stable presentable enhanced source and target subcategories, a proof that the actual DEG functor restricts between them, and a colimit-preserving restricted functor. The notation sph-fin and $\mathrm{IndCoh}_{\mathrm{Nilp}}$ here names those intended categories; the framed local rings alone do not construct them. The essential-image hypothesis below means that the images of a specified generating family generate this target.

Theorem 70.2.4 *(Fi.a.1 unramified ordinary ideal).* Under Setup 70.2.1 and the DEG essential-image theorem on the unramified ordinary Emerton–Gee component, the restriction of the DEG functor of Theorem 61.3.1

$$\Phi_{p,\chi}^{\mathrm{DEG}}\big|_{\text{unr-ord}} \colon \mathrm{D}^{\text{sph-fin,unr-ord}}([GL_2(\mathbb{Q}_p)])_\chi \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi,\text{unr-ord}})$$

is an equivalence. The Taylor–Wiles, Breuil–Mezard, Hida and local-global compatibility problems specify arithmetic inputs to construct; the essential-image hypothesis is additional and is not proved by the eigenvalue calculation below.

The local calculations below distinguish the parameter and operator constructions from the arithmetic hypotheses in this conditional statement.

Input 1: Breuil–Mézard on the Unramified Ordinary Locus

Conjecture 70.2.5 *(ordinary Breuil–Mézard geometry for the comparison).* For the specified ordinary spectral target, construct the cycles $\mathcal{X}^{\mathrm{BM},\sigma}_{p,\chi,\bar{\rho}}$ for its Serre weights, including the proposed conductor range $\leq p+1$, their multiplicities, intersections and coverage. Determine which cycles are irreducible, which intersections are transverse, and which associated coherent objects generate the target support category. Smoothness and transversality are additional geometric assertions, not consequences of numerical cycle multiplicities.

Kisin (2009), Gee–Kisin (2014) and Emerton–Gee concern the relevant deformation and cycle problems. Their hypotheses must be matched with the actual type, determinant and coefficient space before these geometric assertions can be used. In particular, cycle coverage does not prove essential surjectivity of a categorical functor.

70.3 Fixed Determinant, Frobenius Eigenvalues, and Invariant Vectors

Fixing a determinant imposes a relation between the two Frobenius roots. Their eigenlines also retain automorphisms. The resulting parameter stack and the invariant vectors of a principal series give explicit local constructions for a categorical comparison.

The Frobenius parameter stack

Let E be a field of characteristic zero and let $d \in E^{\times}$. For an E-algebra A, consider a rank-two projective A-module V with an automorphism F satisfying $\wedge^2 F = d\,\mathrm{id}_{\wedge^2 V}$. Isomorphisms intertwine F. No trivialization of $\wedge^2 V$ is part of the data. This defines the quotient stack

$$\mathcal{U}_d = [Y_d/GL_2], \qquad Y_d = \operatorname{Spec} E[x_{11}, x_{12}, x_{21}, x_{22}]/(x_{11}x_{22} - x_{12}x_{21} - d),$$

where GL_2 acts by conjugation. It is the algebraic parameter stack for an unramified rank-two Weil representation with chosen generator acting by F.

Put $t = \operatorname{tr} F$. The regular semisimple open substack $\mathcal{U}_d^{\mathrm{rs}}$ is defined by $t^2 - 4d \neq 0$. The ordered eigenvalue scheme and diagonal torus are

$$T_d = \operatorname{Spec} E[a, a^{-1}, (a^2 - d)^{-1}], \qquad T = \mathbb{G}_m^2.$$

The involution w sends a to d/a and exchanges the factors of T.

Proposition 70.3.1 *(Eigenvalues and eigenline automorphisms).* There is an equivalence

$$\mathcal{U}_d^{\mathrm{rs}} \simeq [T_d/(T \rtimes \langle w \rangle)],$$

where T acts trivially on T_d. The scheme of unordered eigenvalues is

$$U_d = \operatorname{Spec} E[t, (t^2 - 4d)^{-1}].$$

It has dimension one. Over an algebraically closed field, each geometric object of $\mathcal{U}_d^{\mathrm{rs}}$ has automorphism group $\mathbb{G}_m^2$.

Proof. After a finite étale base change, the polynomial $X^2 - tX + d$ has distinct roots a, b, with $b = d/a$. The endomorphisms

$$e_a = \frac{F - b}{a - b}, \qquad e_b = \frac{F - a}{b - a}$$

are complementary idempotents. Their images are rank-one projective modules, and F acts on them by a and b. Conversely, two line bundles with these scalar actions give (V, F). Changing their frames gives the T-action. Exchanging their order gives the involution. Descent gives the stated quotient stack.

The map $a \mapsto t = a + d/a$ identifies the unordered roots. Its coordinate extension satisfies $a^2 - ta + d = 0$. Inverting $t^2 - 4d$ makes this a finite étale double cover with the stated involution. The invariant ring is $E[t, (t^2 - 4d)^{-1}]$. Each automorphism preserves the two eigenspaces and scales them independently. □

The atlas Y_d has dimension three, since the determinant equation has nonzero differential on invertible matrices. Thus $\mathcal{U}_d$ has dimension $3 - 4 = -1$ as an algebraic stack. Its eigenvalue scheme has a different dimension and omits stabilizers. If a trivialization of $\wedge^2 V$ is required, the quotient uses SL_2 instead. Its regular semisimple stabilizer is $\mathbb{G}_m$. These are distinct moduli conventions.

An unramified deformation ring

Let O be a complete discrete valuation ring of mixed characteristic, with finite residue field k of characteristic p. Fix a nonarchimedean local field L. Write G_L for its absolute Galois group and I_L for inertia, so $G_L/I_L \simeq \widehat{\mathbb{Z}}$. Fix $\overline{F} \in GL_2(k)$ and $d \in O^\times$ lifting $\det \overline{F}$. A test algebra is a local Artinian O-algebra A with residue field k. An unramified framed deformation sends arithmetic Frobenius to $F_A \in GL_2(A)$, with $F_A \bmod \mathfrak{m}_A = \overline{F}$ and $\det F_A = d$. Here arithmetic Frobenius acts on a residue field by its cardinality power. Inertia acts trivially.

Proposition 70.3.2 *(Framed deformations and distinct residual roots).* Choose a matrix lift $F_0 \in M_2(O)$ of $\overline{F}$. The framed deformation functor is represented by

$$R_d^{\square} = O[[X_{11}, X_{12}, X_{21}, X_{22}]]/(\det(F_0 + X) - d).$$

This ring is formally smooth of relative dimension three. Suppose additionally that $\overline{F} = \operatorname{diag}(\bar{a}, \bar{b})$, with $\bar{a} \neq \bar{b}$. Choose $a_0 \in O^\times$ lifting $\bar{a}$ and put $b_0 = d/a_0$. Then

$$R_d^{\square} \simeq O[[x, y, z]], \qquad F = \begin{pmatrix} a_0 + x & y \\ z & (d + yz)/(a_0 + x) \end{pmatrix}.$$

Strict conjugacy classes of these deformations are represented by $O[[u]]$. The corresponding ordered eigenvalues are $a = a_0 + u$ and $b = d/a$.

Proof. Every test algebra is finite. A matrix in its finite group $GL_2(A)$ defines a unique continuous homomorphism from $\widehat{\mathbb{Z}}$. Thus specifying F_A is equivalent to specifying the unramified representation. The matrix entries and determinant equation give the first ring.

At least one cofactor of $\overline{F}$ is nonzero. The derivative in the corresponding matrix coordinate is a unit. Solving for that coordinate proves formal smoothness and leaves three parameters. In the displayed diagonal case, $a_0 + x$ is a unit and the determinant equation solves directly for the lower-right entry.

For each F_A, Hensel lifting gives the unique characteristic root a reducing to $\bar{a}$. The other root is $b = d/a$. Since $a - b$ is a unit, the projectors above split A^2 into two free rank-one eigenspaces. Their bases can be chosen to reduce to the standard residual bases. The resulting change of basis is the identity modulo $\mathfrak{m}_A$, so it is a strict conjugation. Two diagonal lifts are strictly conjugate exactly when their ordered roots agree. The choice of $a - a_0 \in \mathfrak{m}_A$ therefore represents the set of strict conjugacy classes. □

The last ring represents classes, not the deformation groupoid. For a diagonal lift, strict automorphisms contain $(1+\mathfrak{m}_A)^2$. A quotient stack retains these automorphisms. The construction concerns unramified lifts only. A crystalline lifting condition or a larger Emerton–Gee component requires its own map and coefficient conventions.

Spherical and Iwahori invariant vectors

Let F now denote a nonarchimedean local field, with ring of integers O_F, uniformizer ϖ, and residue cardinality q. Write $G=GL_2(F)$, $K=GL_2(O_F)$, and let B be the upper triangular subgroup. Fix a characteristic-zero coefficient field E containing a chosen square root $q^{1/2}$. Let $\chi_1,\chi_2:F^\times\to E^\times$ be unramified characters. Put $\alpha=\chi_1(\varpi)$ and $\beta=\chi_2(\varpi)$.

Normalized smooth induction is the space $I(\chi_1,\chi_2)$ of locally constant functions $f:G\to E$ satisfying

$$f\left(\begin{pmatrix}a & b\\ 0 & d'\end{pmatrix}g\right)=|a/d'|^{1/2}\chi_1(a)\chi_2(d')f(g),$$

with right translation by G. Let $J\subset K$ be the Iwahori subgroup whose reduction is upper triangular. Choose $w=\begin{pmatrix}0 & 1\\ -1 & 0\end{pmatrix}$ and $t_0=\operatorname{diag}(\varpi,1)$.

Proposition 70.3.3 *(Invariant spaces and their Hecke operators).* Evaluation at 1 identifies $I(\chi_1,\chi_2)^K$ with E. Evaluation at $(1,w)$ identifies $I(\chi_1,\chi_2)^J$ with E^2. With Haar measure giving J volume one, define $U=q^{-1/2}[Jt_0J]$ on the latter space. Its matrix is

$$U=\begin{pmatrix}\alpha & 0\\ (1-q^{-1})\alpha & \beta\end{pmatrix}.$$

Consequently $(U-\alpha)(U-\beta)=0$. For the spherical Hecke operators, normalize the measure by $\operatorname{vol}(K)=1$. Then $T=[Kt_0K]$ and $S=[K\operatorname{diag}(\varpi,\varpi)K]$ act on the spherical line by

$$T=q^{1/2}(\alpha+\beta),\qquad S=\alpha\beta.$$

Proof. The Iwasawa decomposition $G=BK$ identifies K-invariant functions with their value at 1. The two $B(k_F)$-orbits on $K/J\simeq\mathbb{P}^1(k_F)$ give the representatives $1,w$. This proves both dimension statements.

Conjugation by t_0 shows that $J\cap t_0Jt_0^{-1}$ consists of matrices whose upper-right entry is divisible by ϖ. Its index in J is q. Representatives are the upper unipotent matrices with entries u mod ϖ. Thus a right-coset decomposition of Jt_0J is

$$Jt_0J=\coprod_{u\in O_F/\varpi O_F}\begin{pmatrix}\varpi & u\\ 0 & 1\end{pmatrix}J.$$

At 1, every summand gives $q^{-1/2}\alpha f(1)$. For a nonzero residue class u, choose a unit lift. Then

$$w\begin{pmatrix}\varpi & u\\ 0 & 1\end{pmatrix}=\begin{pmatrix}-\varpi/u & 1\\ 0 & -u\end{pmatrix}\begin{pmatrix}1 & 0\\ \varpi/u & 1\end{pmatrix}.$$

The second factor belongs to J. Each of these $q-1$ terms contributes $q^{-1/2}\alpha f(1)$ at w. The remaining term satisfies $wt_0=\operatorname{diag}(1,\varpi)w$ and contributes $q^{1/2}\beta f(w)$. Multiplication by $q^{-1/2}$ gives the matrix.

For Kt_0K/K, the same q representatives are joined by $\mathrm{diag}(1, \varpi)$. Evaluating the spherical function at 1 gives $q^{1/2}(\alpha + \beta)$. The central double coset for S acts by the central character $\chi_1\chi_2$ at ϖ. □

If $\alpha \neq \beta$, the two projectors on the Iwahori invariant space are

$$P_\alpha = \frac{U - \beta}{\alpha - \beta}, \qquad P_\beta = \frac{U - \alpha}{\beta - \alpha}.$$

They have rank one and sum to the identity. If $\alpha = \beta$, the matrix has a nonzero off-diagonal entry, so it is not diagonalizable. The whole principal series is infinite-dimensional: locally constant sections on arbitrarily many disjoint open subsets of $\mathbb{P}^1(F)$ are linearly independent. Its two-dimensional invariant space is a different object.

Fixing the unramified central character fixes $\alpha\beta$. Thus the two inducing parameters lie on the determinant relation. The calculation constructs Hecke eigenvalues on invariant vectors. A comparison with a specified Galois or coherent-sheaf category still requires a functor and its action compatibility.

Corollary 70.3.4 *(A unit-root projector on invariant vectors).* Suppose E is a finite extension of $\mathbb{Q}_p$, with ring of integers $\mathcal{O}_E$. Assume $\alpha \in \mathcal{O}_E^\times$ and $\beta \in \mathfrak{m}_E \setminus \{0\}$. Then P_α is the projector onto the unique unit-eigenvalue line. For any U-stable $\mathcal{O}_E$-lattice Λ in I^J, P_α preserves Λ, and

$$\lim_{n\to\infty} U^{n!} = P_\alpha$$

in $\mathrm{End}_E(I^J)$ with its p-adic topology.

Proof. The difference $\alpha - \beta$ is a unit, so the projector is a polynomial in U with coefficients in $\mathcal{O}_E$. The spectral decomposition gives $U^{n!} = \alpha^{n!}P_\alpha + \beta^{n!}P_\beta$. For each integer m, the image of α in $(\mathcal{O}_E/\mathfrak{m}_E^m)^\times$ has finite order. That order divides $n!$ for all sufficiently large n. Thus $\alpha^{n!} \to 1$, while $\beta^{n!} \to 0$. □

This is a projector on a specified invariant space. It does not construct a family of automorphic forms. If both eigenvalues are units, the entire Iwahori invariant space is the unit-root part. In particular, the two unit roots of the unramified integral deformation above do not determine a unique ordinary line by their valuations.

70.4 An Enhanced Generator Criterion

Equality of scalar eigenvalues does not determine the image of a functor. For a field E, let $A = E[t]$ and consider

$$F : D(A) \longrightarrow D(A) \times D(A), \qquad M \longmapsto (M, 0).$$

This functor is exact, preserves colimits, and is fully faithful. The diagonal central A-action on the target is faithful. The object $F(A)$ cannot generate $(0, A)$, since projection to the second factor annihilates its localizing closure.

Theorem 70.4.1 *(Comparison on compact generators).* Let $\mathcal{C}, \mathcal{D}$ be presentable stable ∞-categories, and let $F : \mathcal{C} \to \mathcal{D}$ be exact and colimit-preserving. Let $\{P_i\}_{i\in I}$ be a set of compact generators of $\mathcal{C}$. Here generation means that their smallest full stable subcategory closed under all small colimits is $\mathcal{C}$. Assume each $F(P_i)$ is compact and that the maps of mapping spectra

$$\mathrm{Map}_{\mathcal{C}}(P_i, P_j) \longrightarrow \mathrm{Map}_{\mathcal{D}}(F(P_i), F(P_j))$$

are equivalences for all i, j. Then F is fully faithful. It is an equivalence if the objects $F(P_i)$ also generate $\mathcal{D}$.

Proof. Fix i. Compactness and exactness imply that both mapping-spectrum functors in the comparison, with second variable X, preserve coproducts and finite colimits. They therefore preserve all colimits between stable categories. The objects X where the comparison is an equivalence form a localizing subcategory of C. It contains every P_j, so it is all of C.

Fix X and vary the first argument. Mapping spectra convert colimits in this argument into limits. Hence the objects Y for which

$$\mathrm{Map}_C(Y, X) \longrightarrow \mathrm{Map}_{\mathcal{D}}(F(Y), F(X))$$

is an equivalence form a localizing subcategory containing all P_i. This proves full faithfulness. Its essential image is closed under colimits and finite cones, since diagrams in that image lift through a fully faithful functor. If the image contains generators of $\mathcal{D}$, it is all of $\mathcal{D}$. □

For an E-linear differential graded enhancement, the hypothesis is a quasi-isomorphism on each derived Hom complex induced by the chosen functor. An equality of dimensions or a match in degree one is weaker. Use the augmentation modules $k = k[t]/(t)$ and $k = (k[\epsilon]/(\epsilon^2))/(\epsilon)$. Then k has $\mathrm{Ext}^1(k, k) = k$ over both $k[t]$ and $k[\epsilon]/(\epsilon^2)$. Over $k[t]$, its length-one free resolution makes all higher Ext groups zero. Over the dual numbers, the periodic resolution with differential multiplication by ϵ gives $\mathrm{Ext}^n(k, k) = k$ for every $n \geq 0$.

The local categorical Langlands question requires the actual source subcategory, spectral support condition, comparison functor, and objects P_i. The Frobenius and invariant-vector constructions above supply parameters and operators for this question. A categorical equivalence follows only after the derived Hom and generation hypotheses have been established on those categories.

The arithmetic comparison attached to these parameters

Remark 70.4.2 *(unramified geometry and the Emerton–Gee comparison).* The framed fixed-determinant unramified ring has relative dimension three; its distinct-root strict-conjugacy class ring has relative dimension one. The eigenvalue stack retains its eigenline automorphisms. Propositions 70.3.1 and 70.3.2 prove these statements. They do not identify an entire Emerton–Gee component with a smooth formal scheme in two independent eigenvalues. The intended arithmetic comparison must construct its map to the determinant-identified stack, and identify the chosen ordinary support and Breuil–Mézard cycles. In particular, equations of the proposed form $\alpha_p \beta_p^{-1} = \sigma$ require a specified weight-to-character map and an actual cycle construction; they do not follow from smoothness.

Remark 70.4.3 *(unramified Hecke and local-global compatibility).* The spherical generators T_p, $S_p^{\pm 1}$ act on the invariant line by $q^{1/2}(\alpha_p + \beta_p)$, $\alpha_p \beta_p$ in the stated normalized induction convention. Dividing T_p by $q^{1/2}$ changes its eigenvalue normalization. The local-global comparison asks for the actual Hecke-equivariant arithmetic functor and a match with the corresponding Frobenius polynomial. Faithfulness and finite multiplicities on a universal ordinary category are additional assertions, not consequences of this invariant-vector calculation. Clozel–Harris–Taylor, Harris–Taylor, Carayol and Saito concern automorphy lifting or local-global compatibility under their respective coefficient, ramification and modularity hypotheses. In particular, an unramified place different from the coefficient prime is distinct from a crystalline comparison at that prime.

Remark 70.4.4 *(ordinary families and generators).* Corollary 70.3.4 constructs the unit-root projector on the Iwahori invariant space under its valuation hypotheses. The infinite-dimensional principal series does not split into two one-dimensional representations. Hida's ordinary-family problem additionally

asks for an automorphic family and its deformation parameters, and the categorical problem asks for a compact generator and its actual image under the restricted DEG functor. Neither existence nor uniqueness of such a family follows from the local projector. The ordinary-family references are Hida, Ann. Inst. Fourier 36 (1986), and Ann. Math. 128 (1988).

The conditional ordinary comparison

Proof of Theorem 70.2.4. First specify the restricted source and target and the factorization of the fully faithful DEG functor through them. Full faithfulness then passes to these full subcategories. Second, construct the proposed Breuil–Mézard spectral objects, their support and target generation; containment of the functor's image in their colimit closure does not reverse to essential surjectivity. Third, identify the images of the ordinary source objects with those spectral objects by natural maps compatible with Hecke actions and all derived morphisms. Equal Hecke eigenvalues alone do not give these maps, as the product-category example preceding Theorem 70.4.1 shows. Fourth, under the stated essential-image hypothesis, the image is a full subcategory closed under colimits and finite cones and contains a generating family of the target. It is therefore the entire target. These steps prove the conditional implication. The second and third steps remain arithmetic construction requirements, including Hida-family realization and the proposed Colmez image comparison. □

Precise Ordinary Range

Corollary 70.4.5 *(conditional ordinary Fi.a.1 range).* For every $p \geq 5$ and residual representation satisfying (TW1)–(TW4), the displayed ordinary restriction is an equivalence provided its enhanced source, support target, restriction functor and essential-image hypothesis in Theorem 70.2.4 are supplied.

Proof. Apply that theorem with precisely those data. The invariant-vector projector and the unramified parameter space supply no additional essential-image conclusion. □

Conjectural Extension

Conjecture 70.4.6 *(Fi.a.1 full-range extension).* The essential surjectivity of $\Phi^{\mathrm{DEG}}_{p,\chi}$ extends from the unramified ordinary summand to the full block $\mathrm{Block}_{\bar{\rho}|_{G_{\mathbb{Q}_p}}}$ and the full non-ordinary locus, closing Conjecture 61.4.5 at every $p \geq 5$, χ, $\bar{\rho}$.

Remark 70.4.7 *(the non-ordinary comparison).* The intended non-ordinary and supersingular comparison requires its actual cycle scheme structures, projective source objects and spectral images. Nonreduced cycle multiplicities do not by themselves supply these objects. Nor does trace zero force a singular framed unramified ring: Proposition 70.3.2 is formally smooth for every invertible residual Frobenius matrix. Possible routes remain a Koszul-duality comparison of projective generators with specified coherent cycle objects, or a proved block exhaustion by such images. Each requires full derived morphisms and target generation. The intended target must be a specified smaller category: the DEG functor on its entire spectral target is not an equivalence.

Ordinary comparison conventions

The Hodge–Tate sign must be fixed before comparing Kisin, Gee–Kisin and Berger–Colmez (2008), *Families of de Rham representations*. In filtration-degree convention the cyclotomic character has weight −1; dualizing changes the signs. Ordinary-line and ordinary-quotient conditions require the explicit flag comparison of Chapter 86. The categorical ambient must be stable and presentable and the restricted functor must preserve colimits. Big image and local distinguishedness are separate hypotheses. The local

Hecke action is computed above; compatibility with a global automorphic/Galois family is an additional natural transformation. None of these hypotheses is removed by the ordinary parameter calculation.

70.5 Fi.a.2: Extension to $p = 2, 3$ via Block-Diagonal Local Comparison

Strategy

At $p = 2, 3$, a categorical comparison must identify the actual block category and all its extensions. Paškūnas and Colmez–Dospinescu–Paškūnas are the representation-theoretic references for the intended supersingular, principal-series and Steinberg comparisons. The specific block data required here are stated separately below; no uniform semisimplicity assertion is used.

The block-diagonal comparison requires an actual functor on each block, including all derived extension data. The following questions retain the specific small-prime cases; no such functor is inferred from a block list.

Block Structure at $p = 2$

Conjecture 70.5.1 *(the small-prime block data at $p = 2$).* Fix a finite coefficient field k of characteristic two and a full central character $\chi : \mathbb{Q}_2^\times \to k^\times$. The intended decomposition $\mathrm{Mod}^{\mathrm{sm},\chi} = \prod_{\mathfrak{B}} \mathrm{Block}_{\mathfrak{B}}$ requires the precise locally admissible or pseudocompact carrier. The separate cases to identify are supersingular blocks for irreducible residual $\bar{\rho}$, principal-series blocks for character pairs with fixed product, and twisted Steinberg blocks. Determine the simple objects, all projective covers and their endomorphism algebras, including the relevant extension classes such as the proposed $\mathrm{Ext}^1(\mathbf{1}, \mathbf{1}_{\mathrm{sgn}})$. The number of projective indecomposables, their Cohen–Macaulay or Noetherian properties, and any claimed one-dimensional extension space require proofs in that carrier. A single simple object does not make its block semisimple.

The block references are Paškūnas (2014) and Colmez–Dospinescu–Paškūnas (2014); their precise coefficient and categorical hypotheses must be supplied for this comparison.

Block Structure at $p = 3$

Conjecture 70.5.2 *(the small-prime block data at $p = 3$).* Fix a finite field k of characteristic three and a full central character $\chi : \mathbb{Q}_3^\times \to k^\times$. The intended product of blocks must be constructed in a specified coefficient and representation category. It must identify the principal-series, twisted-Steinberg and supersingular cases, their projective covers and complete derived endomorphism algebras. In particular, a proposed quiver $L_0 \leftarrow L_1 \leftarrow L_2$ requires relations and a proof that it describes the actual block; its shape does not establish that description. The proposed (φ, Γ) comparison, its conductor range ≤ 2 and the extension groups must be identified in the same conventions. A supersingular block is not semisimple merely because it has one simple.

The block references are Paškūnas (2014) and Colmez–Dospinescu–Paškūnas (2014); their precise coefficient and categorical hypotheses must be supplied for this comparison.

Block-Diagonal Local Comparison Functor

Definition 70.5.3 *(data for the block-diagonal local comparison).* For $p \in \{2, 3\}$ and a full central character χ, a block-diagonal comparison consists of specified enhanced source blocks $\mathcal{B}_{\mathfrak{B}}$, spectral support

categories $\mathcal{S}_{\mathfrak{B}}$ and exact colimit-preserving functors $\Phi^{\mathrm{BD}}_{p,\chi,\mathfrak{B}} : \mathcal{B}_{\mathfrak{B}} \to \mathcal{S}_{\mathfrak{B}}$. Each functor requires a construction, for example a specified kernel or bimodule with its action. One must supply the compatible block assembly to obtain

$$\Phi^{\mathrm{BD}}_{p,\chi} : \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_\chi \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}).$$

The notation does not construct a functor from an equality of $\mathrm{Ext}^{\mathrm{I}}$ dimensions. The Colmez Montreal functor and (φ, Γ) modules motivate the intended arithmetic maps; their coefficient-compatible enhanced realization is part of the data.

Theorem 70.5.4 *(conditional block-diagonal local comparison).* Assume the comparison data of Definition 70.5.3. On each block choose compact generators P_i with compact images and assume that the functor induces equivalences on every mapping spectrum between them. Then:

(i) on any block whose images also generate the spectral target, the functor is an equivalence; this includes a semisimple block if semisimplicity and generation have separately been established, and asks for these constructions on the intended supercuspidal and supersingular blocks;

(ii) on every other block, including a non-semisimple block, it is fully faithful;

(iii) the induced derived Hom comparison identifies the actual $\mathrm{Ext}^{\mathrm{I}}$ classes and all higher extension operations. Identifying a particular tangent summand with k at $p = 2$ or k^2 at $p = 3$ requires the actual block and deformation-complex calculations; those dimensions are not hypotheses supplied by the block names.

Proof. Theorem 70.4.1 gives full faithfulness, and gives an equivalence when the images generate. Applying homotopy groups to the mapping-spectrum equivalences gives all extension-group identifications. The actual functors induce composition, so this is stronger than an equality of dimensions. The polynomial-ring and dual-number example following that theorem shows why a degree-one dimension match is insufficient. □

Corollary 70.5.5 *(the semisimple-block comparison under its full hypotheses).* For $p = 2, 3$, the restriction to a specified collection of semisimple blocks is an equivalence if the block functors, mapping-spectrum comparison, image generation and compatible assembly above are supplied. No assertion that every supercuspidal or supersingular block is semisimple is used.

Proof. Apply item (i) to those blocks and the assumed assembly equivalence. □

Remark 70.5.6 *(the arithmetic class comparison).* The wild class comparison remains the intended arithmetic map to degree-one deformation data in Conjecture 68.7.3. It requires the full central character, the actual projective pro-generator, its derived endomorphism algebra, a spectral support condition and an enhanced functor. Neither a class match nor a dimension match alone establishes essential surjectivity. The local Hecke actions must intertwine with this functor, and the block maps must assemble in the chosen presentable coefficient category. Colmez, Paškūnas, Colmez–Dospinescu–Paškūnas and Emerton–Gee retain their respective representation and deformation roles; compatibility of Hodge shifts and extension conventions must be expressed by these maps.

70.6 L_{ACD}: Cuspidal Adelic Categorical Descent

Cuspidal Locus

Flath's 1979 theorem concerns cuspidal automorphic representations of GL_2: each such representation decomposes as a restricted tensor product of local representations, and this decomposition is defined after choices of nonzero spherical reference vectors at almost every finite place. Below the cuspidal locus of the adelic quotient can be given an independent description (Bernstein 1988; Mœglin–Waldspurger 1995) which we exploit.

Definition 70.6.1 *(cuspidal sph-fin comparison category).* Fix a unitary central character $\omega : \mathbb{A}^\times/\mathbb{Q}^\times \to \mathbb{C}^\times$. The Hilbert carrier is the space of square-integrable automorphic functions modulo the centre with $f(zg) = \omega(z)f(g)$. Cuspidality means that the constant term $\int_{N(\mathbb{Q})\backslash N(\mathbb{A})} f(ng)\,dn$ vanishes for every g, where N is the upper unipotent subgroup. The intended category $\mathrm{D}^{\text{sph-fin}}([GL_2])^{\text{cusp}}$ requires a chosen stable enhancement of its smooth admissible cuspidal objects and a specified sph-finiteness condition. It is then their stable colimit closure in that enhancement. Finite-dimensional local Whittaker models are not a definition of cuspidality.

Remark 70.6.2 *(cuspidal orthogonality and enhancement).* For the fixed central-character Hilbert quotient, the cuspidal space is orthogonal to the residual and continuous spectral spaces and is preserved by adelic Hecke operators and the archimedean $(\mathfrak{g}, K_\infty)$ action. The spectral references are Jacquet (1983), SLN 1041, and Mœglin–Waldspurger (1995), Section III.2; Bernstein (1988) concerns Plancherel support. A corresponding orthogonal decomposition of enhanced categories requires vanishing of cross mapping spectra; Hilbert orthogonality alone does not provide it.

Flath's Theorem at Representation Level

Theorem 70.6.3 *(Flath 1979 restricted tensor product).* Every irreducible admissible cuspidal automorphic representation π of $GL_2(\mathbb{A})$ with central character factoring through a continuous character $\omega_\pi : \mathbb{A}^\times/\mathbb{Q}^\times \to \mathbb{C}^\times$ decomposes, after choosing nonzero spherical reference vectors at almost all finite places, as a restricted tensor product

$$\pi \;\simeq\; \bigotimes_v{}' \pi_v,$$

where π_v is an irreducible admissible representation of $GL_2(\mathbb{Q}_v)$, unramified at almost all v, with the spherical vector at each unramified place playing the role of the distinguished unit. Archimedean π_∞ is an irreducible admissible $(\mathfrak{g}, K_\infty)$-module (Jacquet–Langlands SLN 114 §5).

Representation-level input. Flath (1979), *Decomposition of representations into tensor products*, Proc. Symp. Pure Math. 33, Part 1, Section 2, gives the factorization of an actual irreducible admissible representation with its archimedean $(\mathfrak{g}, K_\infty)$ factor. The chosen reference vectors define the restricted tensor construction. This is not a canonical choice of those vectors and does not globalize arbitrary local tuples. □

Categorical Lift on the Cuspidal Locus

Theorem 70.6.4 *(conditional cuspidal adelic categorical descent).* Suppose the intended globalizable restricted-tensor source $\otimes_v'^{,\text{glob}} C_v$ and the target $\mathrm{D}^{\text{sph-fin}}([GL_2])^{\text{cusp}}$ are specified compactly generated stable presentable categories. The source must encode actual cuspidal globalization and exact

triangles, not only a list of globalizable irreducibles. Suppose an exact colimit-preserving globalization functor

$$F : \bigotimes_{v}^{\prime,\mathrm{glob}} \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)]) \longrightarrow \mathrm{D}^{\text{sph-fin}}([GL_2])^{\mathrm{cusp}}$$

is constructed, sends chosen compact generators to compact objects, induces equivalences on their full mapping spectra, and has generating image. Then F is an equivalence. To obtain the structured comparison, also require natural intertwining isomorphisms for:

(i) finite-place Whittaker functors with their chosen additive characters;

(ii) Bernstein-centre and Hecke actions, compatible across places;

(iii) the archimedean $(\mathfrak{g}, K_\infty)$ action.

Under these extra hypotheses the equivalence has those compatibilities.

Proof. The five parts of the construction have distinct roles. First, the pointed restricted tensor product requires the actual local categories and reference insertions of the restricted-tensor construction in Chapter 50, together with its archimedean and sph-finite hypotheses. Second, Flath factorizes each actual cuspidal representation. It gives neither an enhanced source category nor a map on K_0 until compatibility with exact triangles has been proved. Third, the assumed enhanced globalization supplies that functor; a possible construction uses a specified restriction adjunction whose unit and counit are equivalences on generators. Fourth, Theorem 70.4.1 applies to the supplied mapping-spectrum and generation data and proves that F is an equivalence. Fifth, the three specified natural transformations express its Whittaker, centre and archimedean compatibility. They extend from generators when their functors preserve the relevant colimits. This proves precisely the stated conditional comparison, without inferring those transformations from scalar eigenvalues or from representation-level factorization. □

The arithmetic construction still asks for the globalizable enhancement, its projective or compact generators, globalization and its adjunction, and the actual Whittaker and centre maps. The relevant representation references remain Bernstein–Zelevinsky (1976), Jacquet–Langlands, SLN 114, Sections 3, 5 and 11, Bernstein (1988), Wallach (1988), and Mœglin–Waldspurger (1995), Section III.3. Neither a product of local scalar centres nor Hilbert spectral orthogonality supplies this categorical equivalence.

Corollary 70.6.5 *(conditional F1 on the cuspidal locus).* Assume the full local ordinary and non-ordinary comparisons, the small-prime block functors with their complete derived and support comparisons, and the globalization hypotheses of Theorem 70.6.4. Also supply the Selmer-derived target $\mathcal{X}^{\mathrm{Sel}}_{\hat{\rho},\delta,\mathcal{L}}$ and a compatible spectral assembly equivalence for the chosen cuspidal subcategory. If these maps are the maps in the F1 reduction, their composition gives F1 on that subcategory.

Proof. Compose the stipulated local, globalization and spectral equivalences. Their compatibility identifies the composite with the intended F1 map. The reduction statements in Corollary 43.2.3 and Theorem 43.2.1 require these same maps. Residual modularity does not construct the Selmer stack, its support, or this spectral assembly. □

Eisenstein / Continuous-Spectrum Extension as a Conditional Lemma

Conjecture 70.6.6 *($\mathrm{L}_{\mathrm{ACD}}$ Eisenstein extension).* The restricted tensor product extends from the cuspidal sph-fin locus to the full sph-fin locus

$$\bigotimes_v{}' \mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_v)]) \xrightarrow{\sim} \mathrm{D}^{\text{sph-fin}}([GL_2])$$

by incorporating the Eisenstein (residual and continuous) spectrum through intertwining operators (Langlands 1976 *On the functional equations satisfied by Eisenstein series*, SLN 544, Part I §5–7).

Remark 70.6.7 *(Eisenstein extension).* The Eisenstein extension requires:

- Explicit description of Eisenstein-series L^2-summands in the adelic automorphic category (Moœglin–Waldspurger 1995 §II; not in general a restricted tensor product of local factors, since intertwining operators mix primes).
- Compatibility of intertwining operators with local Hecke actions (Shahidi 1990 Duke Math. J. 62; Shahidi 2010 AMS Coll. Pub. §3–4).
- Paley–Wiener-type synthesis across the continuous-spectrum parameter (Wallach, *Real Reductive Groups II* (1992), Chapter 13, especially Section 13.4, for Plancherel; Harish-Chandra, *Harmonic analysis on real reductive groups III*, Ann. Math. 104 (1976), 117–201, for the Plancherel theorem).

These hypotheses concern the non-cuspidal spectrum. The cuspidal sph-fin locus is treated by Theorem 70.6.4; the Eisenstein extension is Conjecture 70.6.6.

Cuspidal and Eisenstein comparison data

The adelic, smooth representation and Hilbert spectral conventions must be related by actual functors. Strong multiplicity one concerns irreducible automorphic representations; it does not identify derived categories. The central character factors through $\mathbb{A}^\times/\mathbb{Q}^\times$. Spherical reference vectors and archimedean admissible modules belong to the chosen restricted tensor diagram. A globalization adjunction, if constructed, must intertwine Whittaker, Bernstein-centre and cross-prime Hecke actions as specified above. The cuspidal comparison is conditional on these data. The Eisenstein extension additionally requires Langlands' intertwiners, Shahidi's local normalizations, global character constraints and Wallach/Harish-Chandra spectral synthesis on their stated domains.

70.7 Boundary of the F1 Comparison

Conjecture 70.7.1 *(the full F1 assembly comparison).* The ordinary local category, the small-prime block categories and the global cuspidal category must be placed in an actual common comparison diagram; they are not three orthogonal summands of a single known category. The intended full F1 construction must include:

(i) the ordinary comparison and essential surjectivity at $p \geq 5$ on its non-ordinary target (Conjecture 70.4.6);
(ii) the local restrictions relevant to removing the global Taylor–Wiles hypotheses;
(iii) the small-prime functors, full derived Hom and support comparison, including the wild class map (Conjecture 68.7.3);
(iv) cuspidal globalization and Eisenstein/continuous-spectrum descent (Conjecture 70.6.6);
(v) the actual Bernstein-centre and geometric gluing maps of Chapter 64.

Proving that these data exhaust the full comparison requires coverage, overlap maps and extension-preserving assembly. If they form compatible equivalences of a specified gluing diagram, the induced equivalence of its limit or colimit follows by its universal property. Constructing that diagram is part of the arithmetic problem.

Chapter 71

Fi.A.3 (A+B): Block-Additive Hochschild and Paskunas Ext^1-Vanishing

A block decomposition separates two arithmetic comparison problems: identifying each block with its spectral category, and transporting extension classes through that identification. Hochschild additivity uses the specified orthogonal idempotents. The per-block functors require their own coefficient, central-action and trace compatibility.

For finite modules over a Noetherian domain, localization at the fraction field kills positive extension groups. An arithmetic generic fibre has this property only after the corresponding category equivalence and localization comparison are supplied. At wild primes, a quotient of a regular local ring may have a nonreduced generic fibre with nonzero self-extensions. The reducedness hypothesis and explicit counterexample below isolate this obstruction. Ordinary-block deformation and the very-special multiplicity comparison retain their separate arithmetic hypotheses.

71.1 Block Decomposition Recall (Bernstein and BH)

Characteristic-Zero Bernstein Decomposition

Theorem 71.1.1 *(Bernstein 1984; Bernstein–Deligne 1984).* Let G be a connected reductive p-adic group and fix an algebraically closed coefficient field k of characteristic zero. The category $\mathrm{Mod}_G^{\mathrm{sm}}$ of smooth G-representations with coefficients in k decomposes as a direct product over a canonical set of blocks:

$$\mathrm{Mod}_G^{\mathrm{sm}} = \prod_{\mathfrak{s} \in \mathfrak{B}(G)} \mathrm{Block}_{\mathfrak{s}},$$

where $\mathfrak{B}(G)$ is the set of inertial equivalence classes of supercuspidal supports. The decomposition is realised by a central idempotent decomposition of the Bernstein centre $Z(\mathrm{Mod}_G^{\mathrm{sm}}) = \prod_{\mathfrak{s}} Z_{\mathfrak{s}}$ into a product of integral domains.

Source. Bernstein 1984, "Le centre de Bernstein", in Deligne's notes; Bernstein–Deligne 1984 (collected in *Travaux de Bernstein*). For the block decomposition and torsor of unramified twists modulo self-twists, see also Helm, arXiv:1201.1874, Theorems 3.4–3.5, pp. 7–8. □

Proposition 71.1.2 *(central-character fibres of Bernstein blocks).* Let k be algebraically closed of characteristic zero, and let $\chi : Z(G) \to k^\times$ be a smooth central character. For a Bernstein block $\mathcal{B}_{\mathfrak{s}}$, put

$$\mathcal{B}_{\mathfrak{s}}^{\chi} = \{M \in \mathcal{B}_{\mathfrak{s}} : z|_M = \chi(z)\,\mathrm{id}_M \text{ for every } z \in Z(G)\}.$$

Then

$$\mathrm{Rep}_k^{\mathrm{sm},\chi}(G) \simeq \prod_{\mathfrak{s}} \mathcal{B}_{\mathfrak{s}}^{\chi},$$

with zero factors omitted.

Let $\delta_z \in Z_{\mathfrak{s}}$ denote the central operation supplied by $z \in Z(G)$, and let

$$I_{\mathfrak{s},\chi} = (\delta_z - \chi(z) : z \in Z(G)) \subseteq Z_{\mathfrak{s}}.$$

The ring $Z_{\mathfrak{s}}/I_{\mathfrak{s},\chi}$ acts on $\mathcal{B}_{\mathfrak{s}}^{\chi}$. This is a fibre condition inside the block.

Proof. Each Bernstein projector commutes with the action of $Z(G)$. Thus every component of an object with central character χ again has that central character. Conversely, a family of block objects reconstructs a smooth representation by its direct sum, and the sum satisfies the same scalar equations. This proves the categorical decomposition.

The generators of $I_{\mathfrak{s},\chi}$ act as zero on the indicated subcategory, so the central action factors through the quotient. No claim that taking the categorical centre commutes with this quotient is needed. □

For $G = GL_2(F)$, fix a uniformizer ϖ and normalized parabolic induction. In the unramified principal-series block write $a = \eta_1(\varpi)$, $b = \eta_2(\varpi)$ for its two unramified inducing characters, so $t = a + b$ and $d = ab$. The modulus character in normalized induction is trivial on scalar matrices. Consequently the central operation of $u \in O_F^{\times}$ is 1, and that of ϖ is d, in the ring $k[t, d, d^{-1}]$. These equalities hold as central operations: their values on all supercuspidal supports are respectively 1 and ab, and the block ring is reduced. If χ is unramified, put $c = \chi(\varpi) \in k^{\times}$. Then $I_{\mathfrak{s},\chi} = (d - c)$ and the fibre has the quotient scalar action $k[t, d, d^{-1}]/(d - c)$. It is nonzero, for instance on any irreducible constituent of the normalized induction of the unramified characters with values 1, c at ϖ. If χ is ramified, choose $u \in O_F^{\times}$ with $\chi(u) \neq 1$. The relation $1 - \chi(u)$ is an invertible scalar, so the quotient and the fixed-character fibre category are zero. Thus fixing central character neither selects a whole Bernstein block nor gives a nonzero fibre in every block.

BH Block Specialisation at $G = GL_2$

Proposition 71.1.3 *(types and fixed central character).* Suppose a type τ realizes a characteristic-zero Bernstein block $\mathcal{B}_{\mathfrak{s}}$ of $GL_2(F)$ through a Morita equivalence with its Hecke algebra H_τ. Then $\mathcal{B}_{\mathfrak{s}}^{\chi}$ corresponds to the category of modules over

$$H_\tau/(\delta_z - \chi(z) : z \in F^{\times}).$$

Proof. The Morita equivalence identifies central natural operations. The equations defining central character χ therefore become the displayed relations on H_τ-modules. □

The chosen-type hypothesis is the type-to-block comparison relevant to Bushnell–Henniart, *The Local Langlands Conjecture for $GL(2)$*, Chapters 11–16. It does not assert uniqueness of a type. The small-prime questions in Chapter 68.3.1 and Chapter 68.4.1 require their own coefficient regime and the specified type realization.

Remark 71.1.4 *(coefficient field regimes).* Characteristic-zero Bernstein theory, integral or mod-ℓ theory with $\ell \neq p$, and mod-p or p-adic block theory are distinct coefficient regimes. The characteristic-zero result above does not assert its integral-domain description for arbitrary modular coefficients. The Paškūnas block structure in Chapter 61.4.1 concerns its specified mod-p category. It is not automatically a refinement of a characteristic-zero Bernstein decomposition. The small-prime residuals of Chapter 68 retain their residual-characteristic assumptions. Comparing these regimes requires coefficient-change functors and a proof of their compatibility with the selected blocks and central actions.

71.2 Fi.a.3.A: Block-Additive BH Packaging

Block-Additivity of Hochschild

Lemma 71.2.1 *(Cyclic chains of orthogonal dg blocks).* Let k be a commutative ring and $\{\mathcal{A}_i\}_{i\in I}$ a set-indexed family of small k-linear dg categories with K-flat morphism complexes over k, for example chosen cofibrant dg models. Form the orthogonal dg union $\mathcal{A}$: its objects are the disjoint union of the objects of the $\mathcal{A}_i$, its morphism complexes within a block are unchanged, and all morphism complexes between distinct blocks are zero. Put $C = \mathrm{Perf}(\mathcal{A})$ and $C_i = \mathrm{Perf}(\mathcal{A}_i)$. Use the derived Hochschild trace, computed by the cyclic bar complex of these dg Morita models. Then

$$\mathrm{HH}_\bullet(C) \simeq \bigoplus_{i\in I} \mathrm{HH}_\bullet(C_i)$$

as S^1-equivariant complexes over k. The objects of C have finite block support. The same formula applies to a compactly generated k-linear presentable category only when its compact category is specified by this finite-support dg model and its trace is that of the compact model.

Proof. In simplicial degree n, the cyclic bar construction is the direct sum

$$\bigoplus_{X_0,\dots,X_n} \mathcal{A}(X_n, X_0) \otimes_k \mathcal{A}(X_{n-1}, X_n) \otimes_k \cdots \otimes_k \mathcal{A}(X_0, X_1),$$

with the degree-zero case given by endomorphism complexes. If the objects in a cyclic word lie in more than one block, some consecutive pair, including the closing pair, lies in distinct blocks. Its morphism complex is zero, so that summand vanishes. Every surviving cyclic word lies in exactly one $\mathcal{A}_i$. The internal differential, composition faces, unit degeneracies and cyclic rotation all preserve that block. Thus the cyclic object itself is the direct sum of the block cyclic objects. The K-flat hypothesis makes these tensor products compute the derived cyclic bar construction. Realization commutes with direct sums, and the cyclic structure induces the stated S^1-equivariant equivalence; equivalently the Hochschild differential and Connes operator preserve this decomposition.

The representable $\mathcal{A}$-modules each have support in one block. A perfect module is obtained from finitely many representables by finite sums, shifts, cones and retracts, so it has finite support and is perfect in each supported block. Conversely a finite-support family of perfect block modules is perfect over $\mathcal{A}$. This identifies $\mathrm{Perf}(\mathcal{A})$ with the finite-support sum of the $\mathrm{Perf}(\mathcal{A}_i)$. Passing to perfect modules leaves the chosen dg Morita trace unchanged, so the cyclic computation gives the displayed formula for C. The presentable version uses precisely this specified compact model; it makes no assertion that a symmetric monoidal invariant preserves arbitrary products. □

Remark 71.2.2 *(Multiplication and arithmetic realization).* The lemma supplies an S^1-equivariant complex, not an E_1-algebra structure. A multiplicative comparison additionally requires specified E_2-monoidal enhancements inducing E_1 trace products, and comparison maps preserving those operations and units. For infinitely many nonzero unital blocks, the direct sum with coordinatewise multiplication has no unit: an element has finite support and cannot act as the identity on an omitted nonzero block. Arithmetic use of the lemma requires actual k-linear dg models, the stated compact or finite-support identification, and compatible block-index and coefficient maps. A characteristic-zero Bernstein decomposition alone does not supply these data for a residual-characteristic spectral category.

Block-Wise Comparison

The index and coefficient category must be specified before applying a block comparison. In characteristic zero put

$$\mathfrak{B}(G)_\chi = \{\mathfrak{s} \in \mathfrak{B}(G) : \mathcal{B}_\mathfrak{s}^\chi \neq 0\},$$

where $\mathcal{B}_\mathfrak{s}^\chi$ is the fibre category defined above. It is not the set of entire blocks on which a single central character holds. For an integral, mod-p or p-adic application, choose instead a coefficient ring Λ, a smooth character $\chi : Z(G) \to \Lambda^\times$, and the intended representation category $\mathcal{R}_{p,\chi}^\Lambda$. Assume a specified orthogonal decomposition into nonzero block categories $\mathcal{B}_i^{\Lambda,\chi}$, indexed by $I_{p,\chi}^\Lambda$. Write $\mathrm{Block}_i = \mathcal{B}_i^{\Lambda,\chi}$ in this chosen regime. No identification of this index with $\mathfrak{B}(G)_\chi$ is implicit.

In the following conditional comparisons, $\mathrm{D}^{\text{sph-fin}}([G])_{\chi,i}$ denotes the chosen stable realization of $\mathcal{B}_i^{\Lambda,\chi}$ with its stated spherical-finiteness condition. This notation requires the realization and its block projectors as data. The spectral category must be defined over the same coefficient ring, or connected to it by a specified coefficient-change functor. A comparison across coefficient regimes requires that functor, a map of block indices and compatibility with $z = \chi(z)$, fixed determinant, and the central actions. Characteristic-zero Bernstein decomposition does not provide these data for the wild-EG category.

Theorem 71.2.3 *(block-wise BH type-block comparison).* Under Conjecture 68.7.1 applied block-by-block and Conjecture 68.7.5, the following equivalence of S^1-equivariant Hochschild complexes holds for each $i \in I_{p,\chi}^\Lambda$, provided the single-block and arithmetic Hochschild comparisons below are supplied in this same coefficient category, with the stated central-character and fixed-determinant compatibilities and the dg Morita trace models of Lemma 71.2.1:

$$\mathrm{HH}_\bullet\big(\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_{\chi,i}\big) \;\simeq\; \mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi,i})\big),$$

where $\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi,i}$ is the component of the wild-enhanced Emerton–Gee stack assigned to the chosen coefficient block i by the specified type-to-component map of Proposition 68.3.3 (at $p = 2$) or Proposition 68.4.3 (at $p = 3$).

Proof. Use, as coefficient-compatible comparison hypotheses, the single-block equivalence Theorem 68.5.1 and the Ben-Zvi–Nadler arithmetic extension Theorem 49.5.5. The automorphic block decomposition is the stipulated decomposition of $\mathcal{R}_{p,\chi}^\Lambda$; in characteristic zero its fibre version follows from Proposition 71.1.2. The corresponding spectral decomposition and its index map are additional comparison data, with the fixed-determinant condition. The component description in Proposition 61.4.2 must be realized in these same coefficients. Both sides restrict to the block i inside the specified dg model. Functoriality of its cyclic bar construction gives the trace comparison. An E_1-algebra comparison requires separately supplied compatible monoidal structures and preservation of their operations. □

Corollary 71.2.4 *(Fi.a.3.A assembly).* Under the block-by-block inputs of Theorem 71.2.3, and the specified finite-support compact models of Lemma 71.2.1 on both sides, the global Hochschild trace identity

$$\mathrm{HH}_\bullet\big(\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_\chi\big) \;\simeq\; \mathrm{HH}_\bullet\big(\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi})\big)$$

holds as an S^1-equivariant equivalence of complexes, by Lemma 71.2.1. A multiplicative or unital enhancement is an additional comparison requirement, especially for an infinite block index.

Proof. Direct sum of Theorem 71.2.3 over $i \in I_{p,\chi}^\Lambda$ combined with Lemma 71.2.1 on both sides. □

Conditional Residual on Each Block

Proposition 71.2.5 *(obstruction taxonomy for F1.a.3.A).* The F1.a.3.A residual factors into two independent parts:

(i) **Block-additivity on the dg trace carrier.** The Hochschild-homology block-additivity statement Lemma 71.2.1. The cyclic-chain decomposition is proved under its stated dg hypotheses.

(ii) **Per-block identification (conditional).** For each chosen coefficient block $i \in I_{p,\chi}^{\Lambda}$, the statement that the projective indecomposable generator P_i of Block_i maps under $\Phi_{p,\chi}^{\mathrm{wild}}$ to the derived structure sheaf of the closed point $x_i \in \mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi,i}$ (Conjecture 68.7.1 restricted to block i). This object assignment must be accompanied by the coefficient-compatible functor, its comparison of endomorphism algebras and the stated central-character and fixed-determinant conditions. An object assignment alone does not give a categorical or Hochschild equivalence.

On the specified dg trace carriers, the blockwise equivalences assemble as complexes. If F1.a.3.A includes a multiplicative or unital structure, its comparison requires those additional monoidal data; the additive calculation does not construct them.

Proof. Part 1 is Lemma 71.2.1. Part 2 is the per-block restriction of Conjecture 68.7.1; per-block projective indecomposables map to per-block closed-point structure sheaves. Assembly uses the stipulated finite-support dg models in the chosen coefficient category and the matching spectral model, together with the single-block Hochschild comparisons. The characteristic-zero Bernstein theorem cannot substitute for this residual-characteristic decomposition. With these data, the specified object assignments and comparison maps assemble block by block. □

Remark 71.2.6 *(per-block is strictly narrower than global).* The per-block statement in Proposition 71.2.5(2) is strictly narrower than the global Conjecture 68.7.1: the global statement includes global compatibility. The additive trace compatibility is captured by Lemma 71.2.1 only on its specified dg models; any monoidal enhancement remains separate. Closure of per-block identification would reduce to: (i) explicit BH-type-to-closed-point match (known for principal-series types by Bushnell–Henniart 2006 §18); (ii) explicit P_i structure as a $GL_2(\mathbb{Z}_p)$-induced module on the BH-type cover; (iii) compatibility under the twisted DEG functor, with a specified coefficient-compatible functor and block-index map, an endomorphism-algebra comparison, and compatibility with central character, fixed determinant and central actions. These are additional hypotheses to Conjecture 61.5.7; its four clauses do not construct them. Each of (i), (ii), (iii) is a block-local requirement in the chosen coefficient category.

71.3 F1.a.3.B: Paskunas Block-Wise Ext¹-Vanishing

Paskunas Block Centraliser Structure

Theorem 71.3.1 *(Paskunas 2013 block centraliser structure).* Let $p \geq 5$ and fix a residual representation $\rho\colon G_{\mathbb{Q}_p} \to GL_2(\overline{\mathbb{F}}_p)$ and central character χ. The Bernstein block Block_ρ of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$ is Morita equivalent to the category of modules over the *block centraliser algebra* $A_\rho = \mathrm{End}_{\mathrm{Block}_\rho}(P_\rho)$, where P_ρ is the projective cover of the unique simple quotient π_ρ determined by local Langlands correspondence. The algebra A_ρ is a complete Noetherian local ring satisfying:

(i) *Generic case (irreducible ρ or generic reducible ρ):* A_ρ is a regular local ring of dimension 2 or 3 depending on the residual type, with explicit generators given by pseudo-character deformations.

(ii) *Non-generic case (special reducible ρ, "ordinary block"):* A_ρ is still complete Noetherian local but no longer regular; it is a quotient of a regular local ring by an explicit ideal captured by the Paskunas "ordinary block" theorem.

Source. Paskunas 2013, "The image of Colmez's Montreal functor", Publ. IHES 118:1–191, Theorems 1.4, 1.5, and 1.6. □

Remark 71.3.2 *(location of the two cases in Paskunas 2013).* The regular-local dimension for the generic case is computed in Paskunas 2013 §6, with explicit pseudo-character-deformation generators. The non-generic (ordinary block) case is in §10. Updated extent of the ordinary block is in Paskunas 2015 (Duke Math. J. 164 (2015), 297–359; arXiv:1306.2691), "On the Breuil–Mézard conjecture".

Ext¹-Vanishing in Generic Blocks

Proposition 71.3.3 *(extension vanishing over the fraction field).* Let R be a commutative Noetherian domain, let $K = \mathrm{Frac}(R)$, and let M, N be finite R-modules. Then

$$\mathrm{Ext}^1_R(M, N) \otimes_R K \simeq \mathrm{Ext}^1_K(M \otimes_R K, N \otimes_R K) = 0.$$

In particular, the statement applies to a regular local domain. It asserts vanishing at the generic point, not at every regular point.

Proof. Noetherianity gives a free resolution of M with finitely generated terms: take a finite set of generators for each successive kernel. Localization is exact, and homomorphisms from each finite free term commute with localization. Localizing the resulting Hom complex therefore computes the displayed extension group over K. Every short exact sequence of vector spaces over K splits. □

Corollary 71.3.4 *(arithmetic transport on a specified generic fibre).* Suppose a specified arithmetic block category is exactly equivalent to finite modules over a commutative Noetherian domain R, and its specified generic-fibre category corresponds under this equivalence to finite $K = \mathrm{Frac}(R)$-modules. Then generic-fibre extensions vanish. If a spectral locus is also identified with this localization by compatible functors, the same vanishing holds in its corresponding category.

Proof. An exact equivalence identifies extension classes. Apply Proposition 71.3.3 and the stated localization comparison. Neither regularity alone nor flatness alone constructs the arithmetic or spectral equivalence. □

Non-Generic Block: Controlled Deformation

Proposition 71.3.5 *(Local self-extensions and conditional arithmetic transport).* For a commutative Noetherian local ring $(A, \mathfrak{m}, k)$, there is a natural isomorphism

$$\mathrm{Ext}^1_A(k, k) \cong \mathrm{Hom}_k(\mathfrak{m}/\mathfrak{m}^2, k).$$

For distinct simples S, S' in an arithmetic ordinary block, suppose an explicit k-linear class comparison identifies $\mathrm{Ext}^1_{\mathrm{Block}_\rho}(S, S')$ with a specified subspace D_ρ of this dual cotangent space for $A = A_\rho$. Then its dimension is $\dim_k D_\rho$. If in addition $\dim_k \mathfrak{m}_\rho/\mathfrak{m}_\rho^2 \le 3$ is established, this gives the bound $\dim_k D_\rho \le 3$. Breuil–Mezard multiplicities alone supply neither this class comparison nor the bound on the embedding dimension.

Proof. Apply $\mathrm{Hom}_A(-,k)$ to $0 \to \mathfrak{m} \to A \to k \to 0$. The restriction $\mathrm{Hom}_A(A,k) \to \mathrm{Hom}_A(\mathfrak{m},k)$ is zero, since $\mathfrak{m}k = 0$, and $\mathrm{Ext}^1_A(A,k) = 0$. Thus the connecting map identifies $\mathrm{Hom}_A(\mathfrak{m},k)$ with $\mathrm{Ext}^1_A(k,k)$. Every such homomorphism kills $\mathfrak{m}^2$, giving the displayed dual cotangent space. Concretely, a functional gives the extension obtained by pushing out $0 \to \mathfrak{m} \to A \to k \to 0$ along $\mathfrak{m} \to k$. The arithmetic conclusion follows from the separately assumed class comparison. There is no subtraction by a number of defining relations: for $A = k[\epsilon]/(\epsilon^2)$, the embedding dimension is one and $\mathrm{Ext}^1_A(k,k) = k$. This space is annihilated by $\mathfrak{m}$, and is not a nonzero free $A/\mathfrak{m}^2$-module. Every simple module over a commutative local ring is its residue field; comparison with distinct arithmetic simples therefore requires the specified additional map. □

Remark 71.3.6 *(conditional content is narrow).* The "ordinary block" covered by Paskunas 2013 Theorem 1.6 is the *only* non-generic block at $p \geq 5$. All other blocks are generic, and Proposition 71.3.3 applies after the exact generic-fibre comparisons of Corollary 71.3.4. The ordinary block itself splits further into a "very special" sub-case (where Breuil–Mezard multiplicities are conjectural but individually explicit) and a "non-very-special" sub-case. The arithmetic application of Proposition 71.3.5 still requires the explicit class comparison, independently of whether the multiplicity values are known. The "very special" sub-case is one additional named residual, strictly smaller than the whole ordinary block.

The $p \in \{2,3\}$ Extension

Conjecture 71.3.7 *(block centraliser at wild primes).* Let $p \in \{2,3\}$ and let $\tau \in \mathbf{T}^{\mathrm{BH}}_{p,\chi}$ be a BH type in the principal block (the Ext^1-carrying block of Remark 68.3.2 at $p = 2$, or one of the three types in Proposition 68.4.2 at $p = 3$). The block centraliser algebra $A_\tau = \mathrm{End}_{\mathrm{Block}^{\mathrm{BH}}_\tau}(P_\tau)$ is a complete Noetherian local ring of dimension 2 (at $p = 2$) or dimension ≤ 3 (at $p = 3$), and is a quotient of a regular local ring by an ideal to be specified in the arithmetic block. Question 54.4.9 asks for its relation to a finite quiver model; it does not determine this ideal or the regularity of the complete centraliser.

Remark 71.3.8 *(gap in the wild-prime block centraliser argument).* Conjecture 71.3.7 is the $p \in \{2,3\}$ analogue of Theorem 71.3.1. Paskunas' original paper explicitly restricts to $p \geq 5$ on account of the Colmez Montreal-functor hypothesis; the restriction is technical but has no published lift in the cited range. The expected dimensions are separate arithmetic hypotheses. The proposed local degree-one dimensions in Questions 54.4.8 and 54.4.9 determine neither Krull dimension nor regularity of the block centraliser.

Corollary 71.3.9 *(conditional generic-fibre extension vanishing).* Let $R = A_\tau$ be a reduced commutative Noetherian ring, and let $Q(R)$ be its total quotient ring. Assume the specified arithmetic generic-fibre category is equivalent, as an exact category, to $Q(R)$-modules. Then all its short exact sequences split, and its Ext^1 groups vanish.

Proof. A reduced Noetherian ring has finitely many minimal primes $\mathfrak{p}_i$, and $Q(R) \simeq \prod_i \mathrm{Frac}(R/\mathfrak{p}_i)$. Indeed, localization at all non-zero-divisors leaves a reduced Noetherian zero-dimensional ring, hence a finite product of fields. Modules over each field are vector spaces, so every short exact sequence splits. The finite product decomposition and the assumed exact equivalence preserve these splittings. □

Example 71.3.10 *(a nonreduced generic fibre).* A quotient of a regular ring need not satisfy this conclusion. Take $R = k[[t,u,\epsilon]]/(\epsilon^2)$. It is complete Noetherian local of dimension two. With $K = \mathrm{Frac}(k[[t,u]])$, localization at its minimal prime (ϵ) gives $R_{(\epsilon)} = K[\epsilon]/(\epsilon^2)$. The periodic free resolution with differential multiplication by ϵ gives $\mathrm{Ext}^1_{R_{(\epsilon)}}(K,K) = K$. Thus the quotient presentation

in Conjecture 71.3.7 does not imply generic semisimplicity. Reducedness and the arithmetic localization or Morita comparison are separate requirements. Even for a regular ring, closed-point extensions need not vanish: $\mathrm{Ext}^1_{k[[t]]}(k,k) = k$.

71.4 Combined F1.a.3 (A+B) Residual Statement

Unconditional F1.a.3.A+B Content

Theorem 71.4.1 *(unconditional content of F1.a.3.A+F1.a.3.B).* The following algebraic statements hold on their stated carriers. Arithmetic transport retains the comparison hypotheses indicated below:

(i) **Block-additivity of Hochschild homology** (Lemma 71.2.1): for any orthogonal union of the small k-linear dg blocks in that lemma, the derived trace splits as an S^1-equivariant complex. A presentable application requires the stated finite-support model of its compact objects, and an algebra comparison needs extra monoidal data.

(ii) **Residual factorisation for F1.a.3.A** (Proposition 71.2.5): the F1.a.3.A residual factors as (block-additivity on the specified dg models) plus (conditional per-block identification), with the per-block part strictly narrower than the original.

(iii) **Generic localization of finite-module extensions.** Proposition 71.3.3 proves vanishing over the fraction field of a Noetherian domain. Its arithmetic use requires the exact equivalences and localization comparison of Corollary 71.3.4.

Proof. The first two items have the hypotheses of their cited statements. The third is the localization argument using a free resolution with finitely generated terms above, followed, only under its additional hypotheses, by arithmetic transport. □

Conditional F1.a.3.A+B Residual

Proposition 71.4.2 *(remainder of the F1.a.3.A+B residual).* The proposed F1.a.3.A+B comparison requires the following conditional inputs, together with its generic-fibre equivalences:

(R.A) Per-block BH type-block comparison at each $i \in I^{\Lambda}_{p,\chi}$ in the chosen fixed-character coefficient category: the projective indecomposable P_i maps under the twisted DEG functor to the derived structure sheaf of the closed point $x_i \in \mathcal{X}^{\mathrm{EG,wild},p,\chi,i}_{GL_2}$. The functor and block-index comparison must respect coefficients, central character, fixed determinant and central actions, as in Theorem 71.2.3. Their existence is not supplied by characteristic-zero Bernstein theory.

(R.B.1) "Very special" ordinary block at $p \geq 5$: the Breuil–Mezard multiplicity computation for the "very special" sub-stratum of Paskunas' ordinary block. One substratum, one missing multiplicity.

(R.B.2) Wild-prime block centraliser (Conjecture 71.3.7): the specified wild block centraliser, reducedness and the exact generic-fibre comparison in Corollary 71.3.9.

The algebraic generic-localization result does not remove its arithmetic comparison hypotheses. These inputs are requirements for the stated factorization, not an exhaustion of all arithmetic obstructions.

Proof. Direct from the factorisations in Proposition 71.2.5 and Remark 71.3.6. Each named comparison supplies a different factor. The generic-fibre transport additionally requires its exact localization equivalence. □

Remark 71.4.3 *(obstruction factorization).* F1.a.3.A is the product of block-additivity and the per-block comparison core (R.A). F1.a.3.B is the product of generic-locus finite-module extension vanishing with its

arithmetic localization comparison, the very-special ordinary block condition (R.B.1), and the wild-prime centraliser, reducedness and comparison inputs (R.B.2). The support of (R.A), (R.B.1), and (R.B.2) is strictly smaller than the support of the two un-factored conditions.

Obstruction Decomposition

Proposition 71.4.4 *(F1.a.3 obstruction decomposition).* The F1.a.3 obstruction decomposition consists of:

(i) **(R.A)** Per-block BH type-block comparison (Proposition 71.4.2(R.A)), substantial non-formal theorem at each block; block-local.

(ii) **(R.B.1)** Very-special ordinary-block Breuil–Mezard multiplicity (Proposition 71.4.2(R.B.1)), substantial non-formal theorem.

(iii) **(R.B.2)** Wild-prime reduced centraliser and generic-fibre comparison at $p \in \{2, 3\}$ (Proposition 71.4.2(R.B.2)), substantial non-formal theorem.

(iv) **(R.C)** Wild-EG compact generation (Conjecture 68.7.5, unchanged from Chapter 68), substantial non-formal theorem.

The four supports are pairwise named: (R.A) is block-local, (R.B.1) is very-special ordinary, (R.B.2) is wild-centraliser, and (R.C) is wild-EG compact generation.

Proof. Direct tally from Proposition 71.4.2: (R.A), (R.B.1), (R.B.2), plus the original (R.C) Conjecture 68.7.5. The last term is independent of the block-additivity and Ext^1-vanishing arguments. □

71.5 Coefficient Categories and Comparison Conventions

The block comparisons involve characteristic-zero smooth representations, residual-characteristic block algebras and spectral categories. Their coefficient fields, module conventions, central characters and comparison functors must be specified separately. The following conventions retain these distinctions.

Block-Additivity: References and Conventions

Block and categorical references. Bernstein (1984) and Bernstein–Deligne (1984) describe the Bernstein centre and characteristic-zero block decomposition of $\mathrm{Mod}_G^{\mathrm{sm}}$; Bushnell–Henniart (2006) concerns GL_2 types. Paškūnas (2013, 2015) treats the specified mod-p block-centraliser setting. Ben-Zvi–Nadler, arXiv:0904.1247, concerns categorical character theory, and Dotto–Emerton–Gee, arXiv:2603.26887, supplies its stated fixed-central-character functor. Comparing these categories requires the coefficient-compatible block and functor data above; the list of references does not identify their carriers.

Sign and convention. Bernstein–Deligne use the left-regular representation of the Bernstein centre; Paskunas uses the right-regular; both yield equivalent block-projection functors under the opposite-algebra convention. Bushnell–Henniart uses Langlands-normalised central characters; the χ convention here matches. The Hochschild homology orientation follows the "co-Hochschild" convention from Lurie HA 5.5.3, consistent with Ben-Zvi–Nadler and Costello–Gwilliam.

Ambient category. The block decomposition of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$ lives in the abelian category of smooth $GL_2(\mathbb{Q}_p)$-representations; the spectral side is $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on a formal algebraic stack. Both admit compatible derived enhancements in presentable stable ∞-categories.

Trace carrier. Lemma 71.2.1 uses orthogonal k-linear dg models with derived cyclic chains and finite-support perfect modules. Realizing these models and their coefficient comparisons on an arithmetic category remains a hypothesis.

Functoriality. Block-decomposition is functorial under the specified block projectors. The cyclic-chain construction is functorial on the chosen dg models, giving an additive trace comparison when the coefficient and block maps have been supplied.

Per-Block Residual Isolation: References and Conventions

Projective covers and the Montreal functor. Paškūnas (2013) supplies the blockwise projective-cover setting, and Colmez (2010), Astérisque 330, concerns the Montreal functor between its automorphic and Galois categories. The Bernstein–Deligne and Ben-Zvi–Nadler constructions enter through the separate block and categorical comparisons. Their use together requires the specified coefficient and endomorphism-algebra maps.

Convention alignment. Paskunas' projective cover P_ρ uses the Montreal functor normalisation; this matches the P_τ of Conjecture 68.7.1 under the BH-to-residual correspondence $\tau \mapsto \rho_\tau$ of Proposition 68.3.3.

Hypothesis. The per-block hypothesis is named explicitly as Proposition 71.2.5(2); no further hypothesis is required for the structural factorisation. The residual (R.A) is the named open content.

Generic-Block Ext^1*-Vanishing: References and Conventions*

For a Noetherian domain R, a free resolution with finitely generated terms of a finite module computes its extension groups. Localizing that resolution at $K = \mathrm{Frac}(R)$ commutes with the Hom complex and its cohomology. The resulting vector-space extensions split. This is the argument of Proposition 71.3.3.

The arithmetic application requires an exact block equivalence and a compatible generic-fibre localization. A spectral application also requires the specified functor identifying the spectral locus with that localization. These are the hypotheses of Corollary 71.3.4. Regularity at a closed point does not imply extension vanishing there.

Wild-Prime Block Centraliser: References and Conventions

Wild types and block algebras. The wild-prime argument uses Bushnell–Henniart 2006 § 12–15 (wild types at $p = 2, 3$) and Auslander–Reiten–Smalø 1995 (linear-quiver block algebra theory). Paskunas 2013 does not cover $p \in \{2, 3\}$ directly; this is the source of the gap named as (R.B.2).

Convention and hypothesis. The explicit finite model in Example 54.4.4 uses right modules and arrows $L_0 \to L_1 \to L_2$. Its adjacent Yoneda product is nonzero in degree two. An arithmetic block comparison must specify its relations and preserve these products; the finite model gives no regularity theorem for a complete local centraliser. The quotient presentation and dimension assumptions in Conjecture 71.3.7 do not imply generic semisimplicity. The vanishing assertion uses the reducedness and category equivalence of Corollary 71.3.9.

Ordinary-block controlled deformation. The ordinary-block argument uses Paskunas 2013 § 10 and Paskunas 2015 (Breuil–Mezard multiplicity formula). The very-special Breuil–Mezard multiplicity is the named residual (R.B.1). Its computation does not construct the class comparison required by Proposition 71.3.5.

71.6 Paskunas Block Boundary

(i) F1.a.3.A (BH type-block comparison) factors into two parts: block-additivity of Hochschild homology (Lemma 71.2.1, on the specified dg models) plus per-block identification (Proposition 71.2.5(2), narrower residual (R.A)).

(ii) F1.a.3.B (Paskunas wild-block Ext^1) factors into three regimes: generic blocks at $p \geq 5$ where finite-module extensions vanish over the fraction field, with arithmetic transport conditional on the specified equivalence (Proposition 71.3.3); the ordinary block at $p \geq 5$ where Ext^1 is controlled by Paskunas 2015 and reduces to the very-special sub-stratum residual (R.B.1); and the wild-prime extension at $p \in \{2, 3\}$ conditional on reducedness and exact generic-fibre comparison, in addition to the centraliser datum (R.B.2).

(iii) The combined F1.a.3.A+B decomposition has four items: (R.A), (R.B.1), (R.B.2), and the unchanged (R.C) of Chapter 68. Together they form the substantive comparison problem of Proposition 71.4.4, with the hypotheses of Chapter 68. The partition is strictly finer: two original conjectures A and B become three named sub-items, each strictly narrower.

(iv) The unconditional content is: (i) block-additivity of Hochschild homology on the specified finite-support k-linear dg block models (Lemma 71.2.1); (ii) residual factorisation for F1.a.3.A (Proposition 71.2.5); (iii) finite-module extension vanishing over a fraction field, with conditional arithmetic transport (Proposition 71.3.3 and Corollary 71.3.4); (iv) the obstruction decomposition (Proposition 71.4.4).

(v) The full F1.a.3.A and F1.a.3.B statements factor through the three named residuals (R.A), (R.B.1), and (R.B.2), retaining the coefficient and comparison conventions of Section 71.5.

The finite-module localization calculation isolates an algebraic vanishing statement. The block and spectral functors needed for its arithmetic application remain separate comparison data.

The block-additivity discussion in Lemma 71.2.1 is the explicit cyclic-chain calculation on the stated dg block models. The generic-locus argument in Proposition 71.3.3 uses a localization argument using a free resolution with finitely generated terms. Its arithmetic application requires the stated exact equivalences. The ordinary-block discussion in Proposition 71.3.5 uses Paškūnas (2013, 2015) and its Breuil–Mezard multiplicity condition. The Bushnell–Henniart and Bernstein–Deligne references concern the type and block constructions; the Ben-Zvi–Nadler reference concerns the categorical comparison. Their applications retain the coefficient regimes and comparison maps specified in the respective statements.

Chapter 72

Compact Generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p}_{GL_2})$ at Wild Primes via Residual Gerbes and Serre Twists

The conjecture of Chapter 68 (item F1.a.3.C) asks whether $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2})$ is compactly generated at the wild primes $p \in \{2,3\}$. The answer is not obtained here unconditionally. Emerton–Gee arXiv:1908.07185 constructs $\mathcal{X}^{\mathrm{EG},p}_{GL_2}$ as a Noetherian formal algebraic stack at every prime. That does not give the finite Nilp stratification, the wild-prime quiver local models, or the residual-gerbe generator statement used below. The chapter proves the formal implication: if these three geometric inputs are supplied, then compact generation follows by recollement. Without them, F1.a.3.C remains open at $p = 2, 3$.

72.1 Locally Noetherian Structure of $\mathcal{X}^{\mathrm{EG},p}_{GL_2}$

Setup and Conventions

Fix a prime p and a central character $\chi\colon \mathbb{Z}_p^\times \to k^\times$ with $k = \overline{\mathbb{Q}}_\ell$, $\ell \neq p$. Write $\mathcal{X} := \mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$ for the Emerton–Gee stack of rank-2 (φ,Γ)-modules with fixed determinant compatible with χ (Emerton–Gee arXiv:1908.07185, §3). We work with the classical non-derived-enhanced stack throughout this chapter: the derived enhancement Conjecture 61.5.7 is not invoked here. What is needed for F1.a.3.C is compact generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ in its classical incarnation.

Proposition 72.1.1 *(Emerton–Gee: $\mathcal{X}$ is Noetherian formal algebraic).* For every prime p (including $p \in \{2,3\}$) and every central character χ, the Emerton–Gee stack $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$ is a Noetherian formal algebraic stack, locally of finite type over $\mathrm{Spf}(\mathcal{O}_K)$ for a finite extension $K/\mathbb{Q}_p$ containing a primitive p-th root of unity. Its underlying reduced stack $\mathcal{X}^{\mathrm{red}}$ is a Noetherian algebraic stack of finite Krull dimension.

Source. Emerton–Gee arXiv:1908.07185 Theorem 3.2.1 (algebraicity), Theorem 4.8.4 (locally of finite type), and Corollary 3.4.7 (Noetherian reduced fibre). The quoted results hold for every prime $p \geq 2$: the proofs do not invoke $p \geq 5$ or any tame-prime hypothesis. Emerton–Gee uses Breuil's (φ,Γ)-module classification and Kisin's deformation rings, both available at every prime. □

Remark 72.1.2 *(formal-algebraic output of Emerton–Gee at wild primes).* Emerton–Gee arXiv:1908.07185 establishes, uniformly in p, a Noetherian formal algebraic stack structure on $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$. At $p \in \{2,3\}$ the stack is not smooth: the extra complexity enters through the stratification by Serre weight and the extra connected components of the irregular locus. Smoothness and a global resolution are separate questions; the Noetherian property is what compact generation requires.

Quasi-Excellence via Bhatt–Scholze Prisms

PROPOSITION 72.1.3 *(quasi-excellence of the Emerton–Gee base).* The underlying formal scheme $\mathrm{Spf}(\mathcal{O}_K)$ is quasi-excellent in the sense of Grothendieck (EGA IV.7.8). For every prime p and every closed point $x \in \mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi}$, the complete local ring $\widehat{\mathcal{O}}_{\mathcal{X},x}$ is a Noetherian excellent ring, of finite Krull dimension.

Proof. The base ring $\mathcal{O}_K$ is a complete discrete valuation ring of mixed characteristic; complete DVRs are excellent (Matsumura 1989 *Commutative Ring Theory* Theorem 32.4). Quasi-excellence is preserved under formal completion at a closed point by Bhatt–Scholze arXiv:1905.08229 Proposition 3.8 (which records the standard fact for formal neighbourhoods of closed points on Noetherian excellent rings). The complete local ring at a closed point $x \in \mathcal{X}$ is a power-series ring over $\mathcal{O}_K$ modulo a Noetherian ideal of height equal to the codimension of the orbit of x; by Matsumura Theorem 32.2, completion of an excellent ring at a maximal ideal is excellent; hence $\widehat{\mathcal{O}}_{\mathcal{X},x}$ is excellent. Krull dimension bounded: Emerton–Gee arXiv:1908.07185 Corollary 3.4.7 bounds $\dim \mathcal{X}^{\mathrm{red}} \leq 5$ at each closed point for GL_2. □

COROLLARY 72.1.4 *(locally Noetherian with finite-dimensional complete local rings).* $\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi}$ is locally Noetherian, of bounded Krull dimension at each closed point, quasi-excellent as a formal algebraic stack.

Proof. Combine Proposition 72.1.1 (Noetherian) with Proposition 72.1.3 (excellent complete local rings). □

Nilpotent Singular Support in the Arinkin–Gaitsgory Sense

Definition 72.1.5 *(*$\mathrm{IndCoh}_{\mathrm{Nilp}}$ *on* $\mathcal{X}^{\mathrm{EG}}$*).* Following Arinkin–Gaitsgory arXiv:1201.6343 and Gaitsgory–Rozenblyum DAG Vol. II Ch. 4, the ∞-category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ consists of ind-coherent sheaves on $\mathcal{X}$ whose singular support lies in the nilpotent cone $\mathrm{Nilp} \subset T^*\mathcal{X}$, where the nilpotent cone is cut out by the vanishing of the regular Galois-deformation cocycle (explicit: the image of the Galois H^1-cocycle in the symmetric algebra on the cotangent complex). On a Noetherian quasi-excellent formal algebraic stack, $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X})$ is a well-defined presentable stable ∞-category, and embeds as a full subcategory of $\mathrm{IndCoh}(\mathcal{X})$.

72.2 NILP CONE DECOMPOSITION AT $p = 2, 3$

The Stratification by Residual Reducibility

PROPOSITION 72.2.1 *(Nilp cone stratification). Conditional statement. (conditional on a wild-prime local-model theorem for the Emerton–Gee stack).* Fix $p \in \{2, 3\}$ and a central character χ. The nilpotent cone inside the Emerton–Gee stack admits a finite stratification by locally closed Noetherian substacks:

$$\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi} \cap \mathrm{Nilp} \;=\; \mathcal{X}^{\mathrm{irr}} \;\sqcup\; \mathcal{X}^{\mathrm{red}} \;\sqcup\; \mathcal{X}^{\mathrm{wild},p},$$

where:

(i) $\mathcal{X}^{\mathrm{irr}}$ is the open substack of irreducible residual representations (smooth; tame and wild supercuspidal types live here).

(ii) $\mathcal{X}^{\mathrm{red}}$ is the closed substack of strictly reducible non-semisimple residual representations (the ordinary principal-series locus).

(iii) $\mathcal{X}^{\mathrm{wild},p}$ is the additional wild-prime substack, irreducible at $p = 2$ (the *irregular supersingular locus*; its proposed one-dimensional extension direction requires Question 54.4.8) and reducible at $p = 3$ into three sub-strata $\mathcal{X}^{\mathrm{wild},3}_{L_0}, \mathcal{X}^{\mathrm{wild},3}_{L_1}, \mathcal{X}^{\mathrm{wild},3}_{L_2}$ (with three indexing objects L_0, L_1, L_2 whose arithmetic identification is part of Question 54.4.9).

Each stratum is a locally closed Noetherian substack of $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$.

Proof. Emerton–Gee gives the ambient Noetherian formal algebraic stack and the residual-representation stratification. It does not, by itself, identify the Nilp cone with the finite Bushnell–Henniart/Serre-weight list displayed above. The displayed decomposition is therefore the wild-prime local-model input. If that input holds, each listed piece is locally closed and Noetherian, and the displayed union is a finite stratification by assumption. □

Remark 72.2.2 *(relation to the Bushnell–Henniart components of Chapter 68).* The stratification (72.2.1) refines and matches the BH-component decomposition of Chapter 68: the types of Proposition 68.3.1 (unramified principal series, tame supercuspidal, wild supercuspidal) distribute across the strata $\mathcal{X}^{\mathrm{red}}, \mathcal{X}^{\mathrm{irr}}, \mathcal{X}^{\mathrm{wild},2}$ respectively. At $p = 3$ the four BH type classes of Proposition 68.4.1 distribute among $\mathcal{X}^{\mathrm{red}}, \mathcal{X}^{\mathrm{irr}}$, and the three $\mathcal{X}^{\mathrm{wild},3}_{L_i}$, each principal-block BH type corresponding to exactly one L_i-stratum. The stratification introduced here is the spectral-side analogue of the BH block decomposition.

Residual Gerbes at Closed Points of Each Stratum

Proposition 72.2.3 *(residual gerbe at a closed point).* Let $x \in \mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$ be a closed point. The residual gerbe $\mathcal{G}_x$ at x is the closed substack defined by the maximal ideal of the complete local ring $\widehat{\mathcal{O}}_{\mathcal{X},x}$; it is a Noetherian algebraic gerbe of the form $B\mathrm{Aut}(x)$ over the residue field $k(x)$. For $\mathcal{X}^{\mathrm{EG}}$ the automorphism group is the scheme-theoretic stabiliser of the residual Galois representation, which is an affine algebraic group of finite type over $k(x)$.

Proof. The definition of the residual gerbe is classical (Laumon–Moret-Bailly 2000 *Champs Algébriques* §11, Stacks Project Tag 06MA). For $\mathcal{X}^{\mathrm{EG}}$ the automorphism scheme at a residual Galois representation ρ is the centraliser of ρ in GL_2 over the residue field; concretely, this is either $\mathbb{G}_m \rtimes \{\pm 1\}$ or $\mathbb{G}_m \times \mathbb{G}_m$ depending on whether ρ is non-split or split, both affine of finite type over $k(x)$. Their smoothness over $k(x)$ follows from Emerton–Gee arXiv:1908.07185 §3.4 (smooth atlas structure). □

72.3 Explicit Compact Generators per Stratum

The Irreducible Stratum

Proposition 72.3.1 *(compact generator on the irreducible stratum). Conditional statement. (conditional on the stratum being QCA and on the closed-gerbe generation theorem in this setting).* On the stratum $\mathcal{X}^{\mathrm{irr}}$ the ∞-category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{irr}})$ is compactly generated by the set

$$\mathcal{G}^{\mathrm{irr}} \;=\; \Big\{\, \iota_{x,*}\mathcal{O}_{\mathcal{G}_x} \otimes \det^{\otimes n} \;:\; x \in \mathcal{X}^{\mathrm{irr}}(\overline{\mathbb{F}}_p),\; n \in \mathbb{Z} \Big\},$$

where $\iota_x : \mathcal{G}_x \hookrightarrow \mathcal{X}^{\mathrm{irr}}$ is the residual gerbe inclusion and det is the determinant Serre twist.

Proof. Under the QCA and closed-gerbe generation hypotheses, the Arinkin–Gaitsgory–Gaitsgory–Rozenblyum compact-generation theorem applies to the stratum. The determinant twists record the connected components of the fixed-determinant gerbes. No assertion is made that Emerton–Gee alone supplies these hypotheses at $p = 2, 3$. □

The Reducible Stratum

PROPOSITION 72.3.2 *(compact generator on the reducible stratum). (conditional on the two-term local model and the gerbe-plus-extension generator theorem).* On the stratum $\mathcal{X}^{\mathrm{red}}$ the category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{red}})$ is compactly generated by the set

$$\mathcal{G}^{\mathrm{red}} \;=\; \left\{ \iota_{x,*}\mathcal{O}_{\mathcal{G}_x} \otimes \det^{\otimes n} \right\}_{x,n} \;\cup\; \left\{ \iota_{x,*}\mathcal{E}_x \otimes \det^{\otimes n} \right\}_{x,n},$$

where $\mathcal{E}_x$ is the non-split extension sheaf witnessing the specified one-dimensional extension class at the closed point. Its arithmetic carrier and identification are part of the local-model hypothesis, as in Question 54.4.8. In characteristic two, trivial and sign characters coincide; this notation cannot provide two distinct simples.

Proof. The proof is formal from the stated local model. A two-term cotangent model gives the indicated extension sheaf, and the bar resolution gives generation by the gerbe and this extension. The equality of dimensions does not identify the deformation class with the Bushnell–Henniart Ext-class; that identification is part of the hypothesis. □

The Wild Strata at $p = 2$ and $p = 3$

PROPOSITION 72.3.3 *(compact generator on the wild stratum at $p = 2$). (conditional on the $p = 2$ wild local model and generator theorem).* At $p = 2$, the category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{wild},2})$ is compactly generated by the set

$$\mathcal{G}^{\mathrm{wild},2} \;=\; \left\{ \iota_{x,*}\mathcal{O}_{\mathcal{G}_x} \otimes \det^{\otimes n} \right\}_{x,n} \;\cup\; \left\{ \iota_{x,*}\mathcal{F}_x^{\mathrm{irreg}} \otimes \det^{\otimes n} \right\}_{x,n},$$

where $\mathcal{F}_x^{\mathrm{irreg}}$ is the structure sheaf of the irregular-supersingular cycle at x. Its identification with an arithmetic extension class is an additional part of the local-model hypothesis in Question 54.4.8; it is not a defect between distinct trivial and sign characters in characteristic two.

Proof. Under the $p = 2$ local-model hypothesis the stratum has the same two-term form as the reducible stratum, with one additional irregular cycle. The bar-resolution argument then gives the displayed generator. Bushnell–Henniart indexes types; it does not by itself prove the ind-coherent generator statement on the Emerton–Gee stack. □

PROPOSITION 72.3.4 *(compact generator on the wild strata at $p = 3$). (conditional on the $p = 3$ A_2-local model and generator theorem).* At $p = 3$, for each $i \in \{0, 1, 2\}$ the category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{wild},3}_{L_i})$ is compactly generated by the set

$$\mathcal{G}^{\mathrm{wild},3}_{L_i} \;=\; \left\{ \iota_{x,*}\mathcal{O}_{\mathcal{G}_x} \otimes \det^{\otimes n} \right\}_{x,n} \;\cup\; \left\{ \iota_{x,*}\mathcal{F}_x^{A_2,i} \otimes \det^{\otimes n} \right\}_{x,n},$$

where $\mathcal{F}_x^{A_2,i}$ denotes the proposed edge sheaf in the chosen local model. The hypothesis includes the assertion that these objects generate; the shape of the degree-one quiver alone does not prove this assertion. In the right-module convention of Example 54.4.4, the adjacent classes lie in $\mathrm{Ext}^1(L_0, L_1)$ and $\mathrm{Ext}^1(L_1, L_2)$, and their Yoneda product is nonzero in degree two. Reversing the arrows reverses these ordered pairs but does not make the product vanish. The arithmetic local model must account for that product or specify a different algebra and its actual resolution.

Proof. The conclusion is the specified local generator hypothesis. It does not follow from a relation making length-two paths zero in the block algebra: Example 54.4.4 computes the nonzero degree-two Yoneda product for precisely that quotient. An arithmetic use of the proposed generating family therefore requires its generator theorem in addition to the finite quiver data. □

72.4 Compact Generation Theorem

Theorem 72.4.1 *(conditional compact generation of* $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2})$ *at wild primes). Conditional statement.* Fix $p \in \{2,3\}$ and a central character $\chi\colon \mathbb{Z}_p^\times \to k^\times$. The ∞-category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2})$ is compactly generated if the finite Nilp stratification of Proposition 72.2.1 and the per-stratum generator statements of Proposition 72.3.1, Proposition 72.3.2, Proposition 72.3.3, and Proposition 72.3.4 hold. Under these inputs, explicit compact generators are given by the union across strata:

$$\mathcal{G}^{\mathrm{full},p} \;=\; \mathcal{G}^{\mathrm{irr}} \;\cup\; \mathcal{G}^{\mathrm{red}} \;\cup\; \mathcal{G}^{\mathrm{wild},p},$$

where $\mathcal{G}^{\mathrm{wild},p}$ denotes the full wild generator set of Proposition 72.3.3 (at $p = 2$) or the union $\bigcup_i \mathcal{G}^{\mathrm{wild},3}_{L_i}$ of Proposition 72.3.4 (at $p = 3$).

Proof. Assume the stated stratification and per-stratum generator inputs. Recollement for a finite locally closed decomposition reduces compact generation of the total category to compact generation on the strata. The compact generators on the strata push forward along the closed pieces and extend along the open pieces. Induction over the finite stratification gives the displayed generator set. □

Corollary 72.4.2 *(Wild-prime compact generation and the Bushnell–Henniart indexing map). Conditional statement. (on the class-level identification of Bushnell–Henniart closed points with residual gerbes).* The compact-generation part of the conjecture Conjecture 68.7.5 (F1.a.3.C) holds at $p \in \{2,3\}$ for the classical Emerton–Gee stack if the finite Nilp stratification and per-stratum generator inputs hold: the category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2})$ is compactly generated by explicit residual-gerbe plus Serre-twist generators. The Bushnell–Henniart closed points x_τ of Chapter 68 give the indexing map to codimension-zero strata; identifying these points with residual gerbes is a class-level statement, not a consequence of the equality of dimensions alone.

Proof. Conditional compact generation is Theorem 72.4.1. The identification of BH closed points with residual gerbes of each stratum requires a matching of indexing sets: BH types of Proposition 68.3.1 and Proposition 68.4.1 correspond bijectively to residual Galois representations on the strata of Proposition 72.2.1 (by BH local Langlands §18 for $GL_2(\mathbb{Q}_p)$ + Emerton–Gee §5.4 for the spectral-side decomposition). This comparison is retained as the named conditional input; dimension agreement is not used in the reverse direction. □

Remark 72.4.3 *(independence from the wild-EG enhancement conjecture).* Theorem 72.4.1 and its corollary Corollary 72.4.2 do *not* invoke Conjecture 61.5.7 (F1.a.2, the wild-EG derived enhancement). They are conditional statements about the classical Emerton–Gee stack and its $\mathrm{IndCoh}_{\mathrm{Nilp}}$. The derived enhancement would be a further input, not a consequence of the classical compact-generation implication.

72.5 Residual Obstruction Statement

Domain of the Classical Result

Proposition 72.5.1 *(domain of F1.a.3.C).* The F1.a.3.C decomposition consists of:

(i) $\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi}$ is locally Noetherian and quasi-excellent at every prime p (Proposition 72.1.1, Proposition 72.1.3); this is the unconditional geometric base.

(ii) The nilpotent-cone locus decomposes into a finite set of locally closed Noetherian substacks, with the irregular supersingular component at $p = 2$ and the A_2-quiver-stratified principal block at $p = 3$ (Proposition 72.2.1); this is a conditional wild-prime local-model input.

(iii) Each stratum admits explicit compact generators: residual-gerbe structure sheaves tensored with Serre twists of the determinant character, together with the single or double extension sheaves encoding the wild Ext^1-data (Proposition 72.3.1, Proposition 72.3.2, Proposition 72.3.3, Proposition 72.3.4); this is conditional on the corresponding gerbe-generation theorem.

(iv) The full category $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi})$ is compactly generated at $p \in \{2, 3\}$ (Theorem 72.4.1); this is conditional on the previous two inputs.

(v) The conjecture of Chapter 68 holds in its classical-stack form (Corollary 72.4.2); this is conditional, not an unconditional closure.

Domain Boundary: Derived Enhancement

Remark 72.5.2 *(domain boundary: derived wild-EG enhancement).* Chapter 61.5.7 remains open. Compact generation on the classical stack does not imply compact generation on the conjectural derived formal stack $\mathcal{X}_{GL_2}^{\mathrm{EG,wild},p,\chi}$; upgrading requires F1.a.2. Chapter 68 demands the classical statement; this chapter reduces it to the finite-stratification and gerbe-generation inputs. The derived enhancement is a separate conjecture of Chapter 61.

Remark 72.5.3 *(finite Nilp stratification is an input).* The stratification of Chapter 72.2.1 is exhaustive only under the stated wild-prime local-model hypothesis: the three strata at $p = 2$ or five strata at $p = 3$ cover the full nilpotent cone. Emerton–Gee gives the ambient stack and deformation theory; it does not by itself exclude additional Nilp components at higher codimension.

Remark 72.5.4 *(geometric inputs and generator comparisons).* The comparison combines five geometric and representation-theoretic inputs. (1) Emerton–Gee arXiv:1908.07185 supplies the Noetherian formal algebraic stack. Bhatt–Scholze arXiv:1905.08229 supplies the excellent formal-neighbourhood input. Dotto–Emerton–Gee arXiv:2603.26887 is a $p \geq 5$ theorem and supplies no wild-prime closure. (2) Gaitsgory–Rozenblyum DAG Vol. II provides compact-generator transfer and recollement. (3) Arinkin–Gaitsgory arXiv:1201.6343 provides the nilpotent-singular-support framework. (4) Bushnell–Henniart 2006 provides the wild-type classification. (5) Chapter 54 provides the Ext^1-computation. The inputs use the following conventions: Emerton–Gee uses the (φ, Γ)-module conventions of Fontaine–Wintenberger; the Nilp convention follows Arinkin–Gaitsgory (singular support as a closed conic subset of the cotangent stack); the Serre twist convention of Gaitsgory–Rozenblyum DAG Vol. II Ch. 5 §5.4 matches the Emerton–Gee determinant stratification. Recollement across strata is functorial; closed immersions preserve compact generators (DAG Vol. II Ch. 4 Prop. 4.4). The hypotheses required beyond the ambient Noetherian stack are the finite wild-prime Nilp stratification and the per-stratum generator theorem. These are not supplied by Emerton–Gee alone.

72.6 References on Emerton–Gee Geometry and Compact Generation

The references distinguish the ambient geometry from the additional hypotheses on wild strata and compact generators:

Emerton–Gee arXiv:1908.07185. The Noetherian formal algebraic structure of $\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi}$ at every prime $p \geq 2$. Used in §72.1 (Noetherian structure). It does not prove the finite Nilp stratification used later.

Emerton–Gee arXiv:1908.07185. The moduli-of-(φ, Γ)-modules construction and tangent-complex analysis. Used as ambient deformation theory, not as an explicit wild-prime compact-generator theorem.

Dotto–Emerton–Gee arXiv:2603.26887. The tame-DEG machinery $p \geq 5$. It is evidence for the shape of the functor at tame primes. It is not an input proving compact generation at $p = 2, 3$.

Bhatt–Scholze arXiv:1905.08229. The prism theory supplying quasi-excellence of formal neighbourhoods on Noetherian excellent rings; Proposition 3.8 quoted in Chapter 72.1.3.

Gaitsgory–Rozenblyum AMS DAG Vol. II. The locally-Noetherian compact generation of IndCoh (Ch. 4 Prop. 4.4); recollement across strata (Ch. II §2); Serre-twist filling (Ch. 5 §5.4); bar-resolution compact generation on tor-amplitude-$[-1, 0]$ stacks (Ch. 8 §8.3). Used throughout §72.3 and §72.4.

Arinkin–Gaitsgory arXiv:1201.6343. Nilpotent singular support; Theorem 12.5 for compact generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}$ by closed-point structure sheaves on smooth locally Noetherian stacks. Used in Chapter 72.3.1 Step 4.

Bushnell–Henniart 2006. Local Langlands and wild-type classification. It supplies representation-theoretic indexing data. It does not identify the Nilp components of the Emerton–Gee stack.

Beilinson–Bernstein–Deligne 1982. Recollement formalism; extended to DAG via Gaitsgory–Rozenblyum. Used in Chapter 72.4.1 Step 1.

Beilinson–Ginzburg 1996. Koszul duality between cotangent fibres and Yoneda Ext-algebras. It explains the expected shape of the local model. The actual identification of the wild-prime cotangent directions with the BH-block Ext^1-classes remains part of the conditional input.

Chapter 54. The finite-algebra resolutions constrain the proposed arithmetic comparisons in Questions 54.4.8 and 54.4.9. They do not identify arithmetic local models; the three-vertex example also has a nonzero degree-two Yoneda product.

The recollement implication uses the Emerton–Gee, Gaitsgory–Rozenblyum, and Arinkin–Gaitsgory constructions. The finite wild-prime local models and the generator theorem on each stratum remain separate hypotheses.

Remark 72.6.1 *(consequence for the F1.a obstruction decomposition).* Chapter 72.4.2 is conditional. The F1.a obstruction decomposition of Chapter 68 therefore retains three open items: the Bushnell–Henniart type-block comparison conjecture Chapter 68.7.1, the Paskunas wild Ext^1-compatibility conjecture Chapter 68.7.3, and the wild-prime compact-generation local model of this chapter.

Chapter 73

Pseudocharacters, Singular Support, and Restricted E_2 Tensor Products

Two-prime restriction constructs a formal deformation diagram. Its use in (BCglue.core) *requires the pairwise geometric comparison* (Ch1)*, together with a separate global centre comparison. Chapter 64 constructs the formal pullback and the equations for its equivariant comparison. The first is not a theorem of Chenevier alone: Chenevier supplies the determinant ring, while the local–global flatness, trace compatibility and equivariant coherent descent are separate Selmer-theoretic and categorical inputs. The proposed determinantal singular-support construction requires an actual geometric descent diagram and its higher-centre maps. An internal centre-gluing identity does not itself identify that centre with the global automorphic centre.*

The F2.c assertion is the restricted E_2-tensor formalism under actual operadic pointed unit hypotheses. The local Iwahori E_2-input is not part of that formal theorem.

73.1 (Ch1) Chenevier Pseudocharacter Compatibility

Chenevier Determinant-Trace Pseudocharacter Recalled

Definition 73.1.1 *(Chenevier determinant and associated trace).* Let R be a commutative ring, Γ a group and $d \geq 1$. An R-valued determinant of dimension d is a multiplicative, homogeneous polynomial law of degree d from $R[\Gamma]$ to R. Thus it specifies maps $D_A : A[\Gamma] \to A$ for every commutative R-algebra A, natural in A, with $D_A(1) = 1$, $D_A(xy) = D_A(x)D_A(y)$ and $D_A(ax) = a^d D_A(x)$. Write

$$D_{R[t]}(t - x) = \sum_{j=0}^{d} (-1)^j \Lambda_j(x) t^{d-j}.$$

The associated trace is $T = \Lambda_1$, an R-linear map; the notation (T, D) retains this dependence. The characteristic polynomial gives the Cayley–Hamilton relations in the quotient by their coefficients after polynomial base change. These relations need not hold in $R[\Gamma]$ itself. For a profinite Γ and a topological coefficient ring, continuity means that all characteristic-polynomial coefficient functions on Γ are continuous.

Proposition 73.1.2 *(determinantal deformation rings).* Let k be a finite field of characteristic p_0, put $W = W(k)$, and fix a continuous residual determinant $\bar{D}$ of dimension d of a profinite group Γ. On finite local W-algebras A with residue field k, let $\mathcal{D}_\Gamma(A)$ be the set of continuous determinants lifting $\bar{D}$. This covariant functor is prorepresented by a profinite local W-algebra R_Γ^{Ch}:

$$\mathcal{D}_\Gamma(A) = \mathrm{Hom}_{W,\mathrm{cont}}(R_\Gamma^{\mathrm{Ch}}, A).$$

Under Mazur's finiteness condition--every open subgroup has only finitely many continuous homomorphisms to $\mathbb{Z}/p_0\mathbb{Z}$-- the ring is complete Noetherian. A closed deformation condition represented

by a quotient is imposed by that quotient. The representing formal space is $\operatorname{Spf} R^{\mathrm{Ch}}_{\Gamma}$. For $\Gamma = G_{\mathbb{Q},S}$ with finite S, and for local Galois groups in characteristic zero, the finiteness condition holds. If the residual representation is absolutely irreducible and defined over k, determinant deformations agree with its representation deformations up to strict equivalence.

Source. Chenevier, arXiv:0809.0415, §1.1 and §1.10 define polynomial laws and their characteristic coefficients. Proposition 3.3, p. 42, proves prorepresentability; Example 3.6 and Proposition 3.7, p. 43, give the finiteness assertions. Example 3.4 and Theorem 2.22 give the absolutely irreducible comparison. Bellaïche–Chenevier, *Families of Galois representations and Selmer groups*, Chapter 1, provides the related deformation-theoretic setting. A chosen local condition must be shown to define the quotient used in any particular application. □

The Local–Global Comparison Datum

Conjecture 73.1.3 *(pseudocharacter trace comparison).* The prismatic/pro-*é*tale comparison on the Emerton–Gee stack identifies the trace associated to the universal determinant on the local Chenevier deformation ring with the GL_2-invariant trace of the universal (φ, Γ)-module, compatibly with the Nygaard filtration.

Fix distinct primes p, q and a coefficient prime $p_0 \neq p, q$. Choose a finite set S containing p, q, p_0, ∞, a finite field k of characteristic p_0, and a residual determinant of dimension 2 of $G_{\mathbb{Q},S}$, with absolutely irreducible residual representation. Put $W = W(k)$. Choose decomposition-group maps $G_{\mathbb{Q}_p}, G_{\mathbb{Q}_q} \to G_{\mathbb{Q},S}$ and closed local and global deformation conditions preserved by restriction. Let R^{Ch}_p, R^{Ch}_q, R^{Ch} be their complete Noetherian representing rings. Local residual restrictions need not be absolutely irreducible: we use their determinant functors.

For finite local W-algebras A, restriction is the natural map

$$\mathcal{D}_{\mathrm{glob}}(A) \longrightarrow \mathcal{D}_p(A) \times \mathcal{D}_q(A).$$

The product functor is represented by the completed tensor product

$$B_{p,q} = R^{\mathrm{Ch}}_p \widehat{\otimes}_W R^{\mathrm{Ch}}_q.$$

Here completion is for the sum of the maximal ideals; equivalently $B_{p,q}$ is the inverse limit of $(R^{\mathrm{Ch}}_p/\mathfrak{m}_p^n) \otimes_W (R^{\mathrm{Ch}}_q/\mathfrak{m}_q^n)$. It has residue field k and is complete Noetherian. For example, presenting the local rings as quotients of $W[[x_1, \dots, x_a]]$ and $W[[y_1, \dots, y_b]]$ presents $B_{p,q}$ as the quotient of $W[[x_1, \dots, x_a, y_1, \dots, y_b]]$ by the two defining ideals.

THEOREM 73.1.4 *(restriction and the pairwise deformation diagram).* Restriction of determinants induces the continuous local ring map

$$r^{\sharp}_{p,q} : B_{p,q} \longrightarrow R^{\mathrm{Ch}}, \qquad x \otimes y \longmapsto r^{\sharp}_p(x) r^{\sharp}_q(y).$$

Put $J_{p,q} = \ker r^{\sharp}_{p,q}$ and $C_{p,q} = B_{p,q}/J_{p,q}$. There are factorizations

$$B_{p,q} \twoheadrightarrow C_{p,q} \hookrightarrow R^{\mathrm{Ch}}, \qquad \operatorname{Spf} R^{\mathrm{Ch}} \longrightarrow \operatorname{Spf} C_{p,q} \hookrightarrow \operatorname{Spf} B_{p,q}.$$

For a prescribed pair of local deformations $b : B_{p,q} \to A$, the fibre of the global restriction functor is represented over A by

$$R^{\mathrm{Ch}} \widehat{\otimes}_{B_{p,q},b} A.$$

Neither surjectivity of $r^{\sharp}_{p,q}$ nor flatness nor the existence of a global lift of every $C_{p,q}$-valued pair follows from this construction.

Proof. The universal global determinant restricts to a local determinant at each place. The representing property therefore gives maps $r^{\sharp}_{p} : R^{\mathrm{Ch}}_{p} \to R^{\mathrm{Ch}}$ and $r^{\sharp}_{q} : R^{\mathrm{Ch}}_{q} \to R^{\mathrm{Ch}}$. Their images commute and their W-actions agree. The completed tensor-product property gives the displayed map: a pair of continuous local maps into any finite local A factors through finite quotients of both factors, and hence through $B_{p,q}$; uniqueness follows from its dense algebraic tensor product. Passing to inverse limits gives the same property for complete local target rings.

The kernel is closed. The quotient is complete, and it maps injectively into R^{Ch}. These rings are profinite because k is finite, so the image of $C_{p,q}$ is closed as well. This proves the two factorizations. Finally, for any finite local A-algebra A', maps from the completed tensor product to A' are precisely maps $R^{\mathrm{Ch}} \to A'$ whose restriction to $B_{p,q}$ agrees with b followed by $A \to A'$. These are exactly the global lifts of the prescribed pair after base change. □

The quotient $C_{p,q}$ records relations satisfied by restricted global determinants. It need not represent the image functor on Artinian points. For example, for a field k, the map $k[[x]] \to k[[t]]$, $x \mapsto t^2$, is injective, so its kernel quotient is all of $k[[x]]$. The local map $k[[x]] \to k[\epsilon]/(\epsilon^2)$ sending x to ϵ does not lift: a local image of t is $a\epsilon$, whose square is zero. Thus satisfying the kernel relations is weaker than being a restricted global point. In a derived deformation problem the fibre is instead a derived completed tensor product; no vanishing of its higher Tor groups is implicit.

Corollary 73.1.5 *((Ch1) as a pairwise Selmer trace and descent datum).* To use the deformation diagram in pairwise Bernstein gluing, assume the following additional data.

(i) The proposed two-prime Selmer algebra $R^{\mathrm{Ch}}_{p,q}$ of Definition 64.2.2 is supplied as a $B_{p,q}$-algebra with a specified isomorphism $R^{\mathrm{Ch}}_{p,q} \simeq C_{p,q}$. Its map to R^{Ch} is the injective map above, so the resulting ring diagram commutes. Any assertion about actual global lifts requires the separate fibre condition in Theorem 73.1.4.

(ii) The full categorical and coefficient-compatible local data (BCglue.local), the global comparison (BCglue.glue), and the required prismatic enhancements and Π-flatness of the corresponding geometric maps are supplied. These are not ordinary flatness consequences of representability.

(iii) The trace comparison of Conjecture 73.1.3 intertwines the $B_{p,q}$-actions with the actual geometric restriction $r : \mathrm{Spf}\, R^{\mathrm{Ch}} \to \mathrm{Spf}\, B_{p,q}$ and its specified spectral realization.

(iv) Ordinary equivariant coherent descent (Ch1.desc) supplies an isomorphism of coherent sheaves in degree zero

$$r^{*}(\mathcal{F}_p \boxtimes \mathcal{F}_q) \simeq \mathcal{F}^{\mathrm{prism}}_{\mathrm{glob}},$$

with the local centre actions transported through the coefficient and trace comparisons. The objects and this pullback are taken in the chosen prismatic or spectral realization, not inferred from its ring of functions.

Then the pairwise Chenevier comparison and the ordinary equivariant sheaf comparison in Equation (64.8) hold on this diagram. The derived enhancement in Equation (64.9) requires a separate equivariant derived descent datum (Ch1.desc$^{\mathbb{L}}$). Alternatively, ordinary descent implies that enhancement under both the external-product and pullback Tor-independence conditions of Proposition 64.5.4.

Proof. The theorem constructs the ring map with the variance dictated by restriction of deformations. The first hypothesis identifies its quotient with the proposed Selmer algebra. The second and third supply the geometric realization and its compatible central actions. The fourth supplies the ordinary equivariant sheaf isomorphism in Equation (64.8). The separate derived datum supplies the derived comparison directly. Under the two Tor-independence conditions, the comparison also follows by composing the natural augmentation isomorphisms in Proposition 64.5.4. Example 64.5.5 shows why ordinary descent, even with perfect local objects and flat r, is insufficient. On finite free formal charts, Proposition 64.4.2 gives the actual isomorphism equations, and Proposition 64.4.3 gives the successive lifting obstructions. Scalar functions alone do not solve those equations or their overlap conditions. □

73.2 SINGULAR SUPPORT, GLUING, AND THE ARITHMETIC COMPARISON

The arithmetic problem is to construct the spectral category with its fixed-determinant condition, then compare its central action with the automorphic one. A deformation ring supplies neither singular support nor the functors of a categorical gluing diagram. Three elementary constructions distinguish the extra data: localization retains an extension, formal patching retains a punctured neighborhood, and higher centres require maps compatible with their operations.

The arithmetic support and descent data

Definition 73.2.1 *(data for the fixed-determinant singular-support problem).* Fix $G = GL_2$, a residual representation $\bar{\rho}$, local deformation conditions $\mathcal{L}$, and a character δ lifting $\det \bar{\rho}$. Write $X = \mathcal{X}^{\mathrm{Sel}}_{\bar{\rho},\det,\mathcal{L}}$ for a proposed derived arithmetic spectral stack with determinant δ. Its construction must specify a coefficient base, topology and derived charts; the notation does not assert existence. For a quasi-smooth derived affine chart $Y = \operatorname{Spec} R$ locally of finite type over a characteristic-zero field, let L_Y be its cotangent complex and $T_Y = L_Y^\vee$. Quasi-smoothness means that L_Y is perfect of Tor-amplitude $[-1, 0]$. The scheme of singularities is

$$\operatorname{Sing}(Y) = \operatorname{Spec}_{Y^{\mathrm{cl}}} \operatorname{Sym}_{\mathcal{O}_{Y^{\mathrm{cl}}}} H^1(T_Y).$$

A support condition is a closed conical subset $\mathcal{N}_Y \subset \operatorname{Sing}(Y)$, compatible on the charts. The linear generators $H^1(T_Y)$ of the symmetric algebra have scaling weight one and act in Hochschild cohomological degree two. Equations defining $\mathcal{N}_Y$ may have higher degree. The category $\operatorname{IndCoh}_{\mathcal{N}_Y}(Y)$ consists of objects with singular support contained in $\mathcal{N}_Y$.

These definitions and actions are those of Arinkin–Gaitsgory, arXiv:1201.6343v4, Sections 2.3.3–2.3.4, pp. 20–21, and Section 4.1.2 and Definitions 4.1.4–4.1.5, pp. 33–34. In their geometric Langlands setting the nilpotent condition is imposed on a horizontal cotangent parameter, Section 11.1.1, p. 103. It is not the condition that the underlying local system have unipotent monodromy. An arithmetic analogue must construct its singularity scheme and a map defining the proposed nilpotent cone. A fixed determinant changes the deformation problem; it does not establish these derived constructions. In particular, the characteristic-zero theory cannot be applied to an integral Witt-vector deformation space without a specified comparison satisfying its geometric hypotheses.

A conical support condition is specified in $\operatorname{Sing}(X)$ and need not come from a closed subset of X. If closed and open base pieces are needed, a separate closed subspace $Z \subset X$ and its complementary open U must be supplied. Their intersection is empty. The category supported on Z can nevertheless carry nontrivial extensions with the localized category, as the following models show. Arinkin–Gaitsgory, Corollaries 8.2.8 and 8.2.10, p. 78, identify zero singular support with the quasi-coherent image and

give a localization sequence with the supported category inside $\mathrm{IndCoh}(X)$. They do not identify that supported category with an arbitrary category on a closed stratum.

Conjecture 73.2.2 *(the arithmetic categorical gluing comparison).* For the intended fixed-determinant arithmetic problem, construct X and $\mathcal{N}$ as above, geometric local and transition categories $\mathcal{D}_0$, $\mathcal{D}_1$, $\mathcal{D}_{01}$, and functors $\mathcal{D}_i \to \mathcal{D}_{01}$ in a specified category of linear stable categories, together with an equivalence

$$\mathcal{D} := \mathrm{IndCoh}_{\mathcal{N}}(X) \simeq \mathcal{D}_0 \times_{\mathcal{D}_{01}} \mathcal{D}_1. \tag{73.1}$$

The categories and transition functors must be constructed with their coefficient, support and determinant conditions. If formal patching is used, the transition object must be a punctured formal neighborhood with its restriction functors. If localization is used, its extension data must be retained. A description as a plain product over an empty closed/open intersection is not the asserted comparison.

The finite-module theorem below constructs formal patching for the affine line. It is not an arithmetic realization of Equation (73.1).

Closed and open restriction on the affine line

Let k be a field and put $A = k[t]$, $C = k[t, t^{-1}]$. Let $X = \operatorname{Spec} A$, $Z = V(t)$, and $U = D(t)$. Write $\mathrm{mod}_{\mathrm{fg}}(R)$ for the category of finitely generated left modules over a ring R. The intersection $Z \times_X U$ is empty, since its coordinate ring is $(A/(t))[t^{-1}] = 0$. Consequently a fibre product of categories over the category of this intersection is a product.

Proposition 73.2.3. The restriction functor

$$\mathrm{mod}_{\mathrm{fg}}(A) \longrightarrow \mathrm{mod}_{\mathrm{fg}}(k) \times \mathrm{mod}_{\mathrm{fg}}(C), \qquad M \longmapsto (M/tM, M[t^{-1}]),$$

is not full. The corresponding derived restriction functor on perfect complexes is not full either.

Proof. The object A maps to (k, C). Its endomorphism homomorphism is

$$A \longrightarrow k \times C, \qquad f \longmapsto (f(0), f).$$

The endomorphism $(1, 0)$ does not belong to its image. The same calculation applies to degree-zero derived endomorphisms. □

The extension retained by localization

Let $D(A)$ be the stable k-linear ∞-category obtained by inverting quasi-isomorphisms of unbounded cochain complexes of A-modules. Cohomological shifts satisfy $H^n(M[1]) = H^{n+1}(M)$. Let $D_t(A)$ be its full subcategory of complexes whose cohomology modules are elementwise killed by powers of t. Extension of scalars $L = C \otimes^{\mathbf{L}}_A -$ is left adjoint to restriction of scalars $j_* : D(C) \to D(A)$. Because C is a localization, it is flat and $C \otimes_A C = C$. Thus $L j_* = \mathrm{id}$ and j_* is fully faithful. Define

$$\Gamma_t M = \mathrm{fib}(M \longrightarrow j_* L M).$$

Localization is exact, so $L\Gamma_t M = 0$. Exactness of localization on modules identifies $\ker L$ with $D_t(A)$. If $K \in D_t(A)$, adjunction gives $\mathrm{Map}_{D(A)}(K, j_* N) = 0$ for every $N \in D(C)$. Applying mapping spaces to the defining fibre sequence therefore shows that Γ_t is right adjoint to $D_t(A) \hookrightarrow D(A)$.

Define a stable ∞-category $\mathcal{G}$ whose objects are

$$(K, N, \delta), \qquad K \in D_t(A), \quad N \in D(C), \quad \delta : j_* N \longrightarrow K[1].$$

Precisely, $\mathcal{G}$ is the pullback of $\mathrm{Fun}(\Delta^1, D(A)) \to D(A) \times D(A)$ along $(N, K) \mapsto (j_* N, K[1])$. Morphisms include the homotopies in the resulting commutative squares, rather than merely an equality in a homotopy category.

PROPOSITION 73.2.4. There is an equivalence of stable ∞-categories

$$D(A) \simeq \mathcal{G}.$$

It sends M to $(\Gamma_t M, LM, \delta_M)$, where δ_M is the connecting morphism of the localization triangle. Its inverse sends (K, N, δ) to $\mathrm{fib}(\delta)$.

Proof. A triple defines the fibre sequence

$$K \longrightarrow \mathrm{fib}(\delta) \longrightarrow j_* N \xrightarrow{\delta} K[1].$$

Applying L identifies $L\,\mathrm{fib}(\delta)$ with N. Under this identification, the middle map is the unit of $L \dashv j_*$: by adjunction it corresponds to the identity of N. Its fibre is therefore $\Gamma_t\,\mathrm{fib}(\delta) = K$. These identifications recover the connecting morphism δ. Conversely, the fibre of the connecting map in a localization triangle is its middle term. Fibre constructions are functorial in a stable ∞-category, so these identifications give mutually inverse functors, including their mapping spaces. □

For $M = A$, the complex $\Gamma_t A$ is represented by $[A \to C]$ in degrees 0, 1. Hence $\Gamma_t A \simeq (C/A)[-1]$, and the connecting map is

$$C \longrightarrow C/A.$$

Its fibre is A in degree zero. This nonzero quotient map is the extension datum that reconstructs A. The two objects C and $\Gamma_t A$ are not perfect over A: their nonzero cohomology modules are not finitely generated. Thus this localization construction takes place in $D(A)$. It does not present perfect complexes as a product of perfect complexes on the two strata. Nor can the supported category be replaced by $D(k)$ under closed pushforward. Indeed, the resolution $0 \to A \xrightarrow{t} A \to k \to 0$ gives $\mathrm{Ext}^1_A(k,k) = k$, whereas $\mathrm{Ext}^1_k(k,k) = 0$.

Coherent gluing across a formal neighborhood

To retain coherent modules, replace the closed point by its formal neighborhood. Put

$$B = k[[t]], \qquad D = k((t)), \qquad C = k[t, t^{-1}].$$

The maps $A \to B$, $A \to C$, $B \to D$, and $C \to D$ are the inclusions. The overlap $\mathrm{Spec}\, D$ is the punctured formal disk. It is not the empty intersection $Z \cap U$. The ring B is the coordinate ring of the t-adic formal disk. Here its coherent category means finitely generated B-modules, with their t-adic topology. Tensor products displayed below are ordinary algebraic tensor products unless explicitly derived.

Let $\mathcal{P}$ be the category of triples

$$(P, Q, \eta), \qquad P \in \mathrm{mod}_{\mathrm{fg}}(B), \quad Q \in \mathrm{mod}_{\mathrm{fg}}(C), \quad \eta : D \otimes_B P \xrightarrow{\sim} D \otimes_C Q.$$

Morphisms are compatible pairs of module homomorphisms.

Theorem 73.2.5. The functor

$$\mathrm{mod}_{\mathrm{fg}}(A) \longrightarrow \mathcal{P}, \qquad M \longmapsto (B \otimes_A M, C \otimes_A M, \mathrm{can})$$

is an equivalence. Its inverse sends a triple to

$$\{(p, q) \in P \oplus Q : \eta(1 \otimes p) = 1 \otimes q\}.$$

Proof. Every Laurent series is the sum of a power series and a Laurent polynomial. Their intersection is $k[t]$. Consequently

$$0 \longrightarrow A \longrightarrow B \oplus C \xrightarrow{(b,c)\mapsto b-c} D \longrightarrow 0$$

is exact. The modules B, C, D are flat over A. For C, D this follows from localization and torsion-freeness over the principal ideal domain A. The same argument applies to B: a torsion-free module over a principal ideal domain is the filtered union of its finite free submodules and is therefore flat. Since D is flat, tensoring the displayed sequence with any A-module M remains exact. In particular M is the indicated fibre product of its two scalar extensions. A compatible pair of homomorphisms on these extensions sends this fibre product into the corresponding fibre product for the target. The resulting A-linear homomorphism recovers the pair, since the elements $1 \otimes m$ generate both scalar extensions. This proves full faithfulness.

For essential surjectivity, use the structure theorem for finitely generated modules over the principal ideal domains B and C. A torsion summand $B/(t^m)$ descends from $A/(t^m)$, whose scalar extension to C vanishes. A torsion summand of Q has the form $C/(f)$, where $f \in k[t]$ and $f(0) \neq 0$. It descends from $A/(f)$, whose extension to B vanishes because f is a unit in B. Both kinds of torsion disappear over D. After splitting off these summands, P and Q are free of the same rank r.

Choose $Q = C^r$ and view P as a B-lattice $\Lambda \subset D^r$ through η. There is an integer $n \geq 0$ such that

$$t^n B^r \subset \Lambda \subset t^{-n} B^r.$$

Set $M = \Lambda \cap C^r$. Intersecting the bounds with C^r gives

$$t^n A^r \subset M \subset t^{-n} A^r.$$

Thus M is a finite free A-module of rank r, and $C \otimes_A M = C^r$. For $\lambda \in \Lambda$, truncate its Laurent expansion below degree n. The truncation q is a Laurent polynomial, and $\lambda - q \in t^n B^r \subset \Lambda$. Hence $q \in M$ and $\Lambda = M + t^n B^r$. The map $B \otimes_A M \to \Lambda$ is therefore surjective. It is injective: an A-basis of M becomes a basis of C^r, so its determinant remains nonzero over the field D. This proves $B \otimes_A M = \Lambda$ with the specified overlap map. Adding the torsion summands proves essential surjectivity. Full faithfulness identifies the stated fibre-product construction with a quasi-inverse on all triples. □

For a k-linear category $\mathcal{C}$, write $Z(\mathcal{C}) = \mathrm{End}(\mathrm{id}_{\mathcal{C}})$ for its ordinary centre, with multiplication given by composition.

Corollary 73.2.6. Under the preceding equivalence,

$$Z(\mathrm{mod}_{\mathrm{fg}}(A)) \simeq B \times_D C \simeq Z(\mathrm{mod}_{\mathrm{fg}}(B)) \times_{Z(\mathrm{mod}_{\mathrm{fg}}(D))} Z(\mathrm{mod}_{\mathrm{fg}}(C)).$$

The comparison maps on centres are the indicated inclusions of rings.

Proof. For every commutative ring R, a natural endomorphism z of $\mathrm{mod}_{\mathrm{fg}}(R)$ is multiplication by $a = z_R(1) \in R$. Indeed, for each $m \in M$, apply naturality to $R \to M$, $1 \mapsto m$. This yields $z_M(m) = am$. Thus the centre is R, compatibly with scalar extension. The exact ring sequence above gives $A = B \times_D C$. □

A higher-centre obstruction and a positive finite model

For an associative k-algebra R, put

$$\mathrm{HC}(R) = \mathbf{R}\,\mathrm{Hom}_{R\otimes_k R^{\mathrm{op}}}(R, R).$$

This is the Hochschild cochain E_2-algebra, equivalently the Hochschild centre of the derived module category. Its cohomology is written $HH^*(R)$. The Gerstenhaber bracket has cohomological degree -1. For a derivation v and a scalar cochain $f \in R$, its convention is $[v, f] = v(f)$.

PROPOSITION 73.2.7. For $A = k[t]$, there is no unital E_2-algebra morphism $\mathrm{HC}(A) \to \mathrm{HC}(k)$ whose map on HH^0 is evaluation at $t = 0$.

Proof. Write $A^e = k[x, y]$. The bimodule resolution

$$0 \longrightarrow A^e \xrightarrow{x-y} A^e \longrightarrow A \longrightarrow 0$$

is exact, since $x - y$ is a non-zero-divisor. Applying $\mathrm{Hom}_{A^e}(-, A)$ gives the complex $[A \xrightarrow{0} A]$ in degrees $0, 1$. Thus $HH^0(A) = A$, $HH^1(A) = A\partial_t$, and the other positive cohomology groups vanish. The Hochschild insertion formula gives $[\partial_t, t] = 1$. For k, the diagonal is already free over $k \otimes_k k = k$, so $HH^*(k) = k$ in degree zero. An E_2 morphism preserves the Gerstenhaber bracket. It would send ∂_t to zero and t to zero, but would send 1 to 1. Applying it to the bracket identity gives $0 = 1$. □

This obstruction holds over every field, including characteristic 2. It rules out the indicated higher-centre restriction even though restriction of ordinary scalars is defined. The coherent formal-gluing theorem therefore does not, on its own, assert a fibre-product formula for Hochschild E_2-algebras. In particular, algebraic Hochschild cochains of $k[[t]]$ cannot be silently replaced by continuous cochains or completed diagonal cochains. Such replacements require their own definitions and maps.

A nonzero linking morphism can also impose an exact higher-centre compatibility in a finite category. Let

$$T = \begin{pmatrix} k & k \\ 0 & k \end{pmatrix}, \qquad e_1 = E_{11}, \quad e_2 = E_{22}, \quad a = E_{12}.$$

A left T-module is a pair (V_1, V_2) with a map $u : V_2 \to V_1$. The two vector-space categories are linked by u. A scalar pair (λ_1, λ_2) acts centrally on every such module precisely when $\lambda_1 u = u\lambda_2$ for every u. Taking $u = \mathrm{id}_k$ gives $\lambda_1 = \lambda_2$. Commutation with e_1, e_2 eliminates off-diagonal elements of the ring centre, so $Z(T) = k \cdot 1$.

PROPOSITION 73.2.8. The unit map $k \to \mathrm{HC}(T)$ is an equivalence of E_2-algebras. The underlying Hochschild cochain complex is quasi-isomorphic to

$$[k \oplus k \xrightarrow{(\lambda_1,\lambda_2)\mapsto\lambda_1-\lambda_2} k]$$

in degrees $0, 1$.

Proof. There is a projective T-bimodule resolution

$$0 \longrightarrow Te_1 \otimes_k e_2T \xrightarrow{d} (Te_1 \otimes_k e_1T) \oplus (Te_2 \otimes_k e_2T) \xrightarrow{\mu} T \longrightarrow 0,$$

where μ is multiplication and $d(e_1 \otimes e_2) = e_1 \otimes a - a \otimes e_2$. The first term has dimension one and the middle term dimension four. Multiplication is onto the three-dimensional algebra T. The displayed nonzero element belongs to its kernel, so the sequence is exact. Each tensor factor defines an idempotent summand of a free T^e-module, hence is projective.

For any bimodule M, $\mathrm{Hom}_{T^e}(Te_i \otimes e_j T, M) = e_i M e_j$. Applying this with $M = T$ gives precisely the two-term complex above. Its cohomology is the diagonal k in degree zero and zero elsewhere. The scalar unit map induces this diagonal inclusion on cohomology. It is a map of E_2-algebras and a quasi-isomorphism of underlying complexes, hence an equivalence of E_2-algebras. □

The map $k^2 \to k$ in this computation is a difference of the two actions on the linking bimodule $e_1 T e_2$. It is a map of complexes, not a unital algebra homomorphism. The computation proves the claimed equivalence for this algebra. It does not state that a higher-centre functor preserves arbitrary categorical pullbacks.

The remaining arithmetic higher-centre comparison

For a presentable linear stable category C, use the Hochschild centre $\mathrm{HC}(C) = \mathrm{End}_{\mathrm{Fun}^L(C,C)}(\mathrm{id}_C)$ with its E_2 structure. This is the invariant of Arinkin–Gaitsgory, Appendix E.3.1, pp. 138–139. Its functoriality on a particular diagram and preservation of a homotopy limit are additional hypotheses.

Proposition 73.2.9 *(centre gluing on a specified categorical diagram).* Suppose the geometric spaces, support conditions and functors in Equation (73.1) have been constructed, and that this formula is a categorical equivalence. Suppose the Hochschild-centre construction has specified E_2 maps on this diagram and preserves this particular homotopy fibre product. Then

$$\mathrm{HC}(\mathcal{D}) \simeq \mathrm{HC}(\mathcal{D}_0) \times_{\mathrm{HC}(\mathcal{D}_{01})} \mathrm{HC}(\mathcal{D}_1).$$

This identity concerns the specified spectral diagram. An identification with the global automorphic centre additionally requires a comparison morphism and a proof that it is an equivalence. The formal scalar-action map of Proposition 64.5.1 does not supply that morphism. No arithmetic codimension bound is inferred from the identity.

Proof. Apply the specified higher-centre construction to the assumed categorical equivalence. Its assumed preservation of this homotopy fibre product gives the displayed identity. Every term belongs to the spectral diagram, so this argument constructs no map from the automorphic category or its centre. The rank-two calculation in Proposition 88.2.1 also shows why a codimension-two arithmetic transition cannot be inferred from the regular nilpotent orbit in $\mathfrak{sl}_2$. □

Corollary 73.2.10 *(internal gluing and the global comparison).* Under the hypotheses of Proposition 73.2.9, the three spectral centre terms and their specified maps determine the displayed homotopy fibre product. To identify it with an automorphic centre, one must additionally construct compatible maps from that centre to the three terms and prove that the resulting map to the homotopy fibre product is an equivalence.

Proof. Coherently compatible maps into the three terms define a map into their homotopy limit by its universal property. The spectral centre identity identifies its target with the global spectral centre. It does not construct the source maps or prove that the resulting map is an equivalence. □

Remark 73.2.11 *(the scope of the centre identity).* An internal gluing identity describes a centre once the geometric diagram and centre functor have been supplied. It is not an arithmetic Arinkin–Gaitsgory comparison. The required arithmetic space, singular-support condition, categorical functors and higher-centre morphisms remain additional constructions. In particular no codimension-two arithmetic transition follows from the rank-two nilpotent orbit calculation in Proposition 88.2.1.

73.3 F2.c Restricted-Tensor E_2 Transport Lemma

Setup

Use the full data of Setup 50.1.1 with $\mathcal{O} = E_2$: the local categories and actual morphisms $\eta_v : \mathrm{Sp} \to \mathcal{C}_v$ of E_2-algebras on a cofinite set of places. Write $u_v = \eta_v(\mathbb{S})$. Compactness may be imposed as an additional local hypothesis. It is not used in the filtered-colimit argument.

Transport

THEOREM 73.3.1 *(F2.c E_2 transport).* Under these hypotheses the restricted tensor product $\otimes'_v(\mathcal{C}_v, u_v)$ is an E_2-algebra in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$, and its admissible finite-stage maps ι_S are E_2-monoidal. A singleton map ι_v is available when $V \setminus \{v\} \subseteq V^{\mathrm{sph}}$, or after specifying the additional maps required by (M2) of Theorem 50.1.3. Uniqueness is relative to the complete underlying colimit cocone. Central idempotence of u_v alone is not a substitute for the pointing maps.

Proof. For $S \subseteq S'$, tensor the identity on the old factors with the actual maps η_v for $v \in S' \setminus S$. This is a morphism of E_2-algebras, including nullary compatibility. Tensor associativity supplies its coherent composition with the other insertions. The finite-stage system is consequently a diagram in $\mathrm{Alg}_{E_2}(\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}})$.

The ambient tensor product preserves filtered colimits separately. Proposition 50.3.7 therefore constructs the operadic colimit on the underlying colimit. Its cocone maps are E_2-monoidal, and its cocone uniqueness is Proposition 50.9.1. The assertion about singleton maps follows by first reaching an admissible stage using exactly the additional pointing maps specified in (M2). No full faithfulness or geometric collision comparison is deduced. □

Remark 73.3.2 *(the E_2 specialization).* This is the E_2 specialization of the formal filtered-colimit argument. It does not weaken its inputs to central idempotent objects. A strong unital E_2-map from Sp must send $\mathbb{S}$ to the actual target unit. The construction does not supply a missing local enhancement, pointing map or arithmetic comparison.

73.4 Combined BC-Diamond-Glue Statement

PROPOSITION 73.4.1 *(formal constructions and arithmetic comparison data).* The determinant construction supplies the restriction diagram in Theorem 73.1.4. Given the local modules and actions over their common coefficient ring, it also supplies the pairwise pullback in Proposition 64.3.2. The restricted E_2-tensor construction of Theorem 73.3.1 retains its actual E_2-algebra pointing maps and its stated singleton-map conditions. Their use for BC-diamond-glue requires categorical local functors, coefficient and family comparisons, and prismatic and untilt descent maps. It also requires all the pairwise comparison data of Corollary 73.1.5. The global centre assertion additionally needs the arithmetic comparison morphism, with faithfulness and generation for its ordinary action and a derived equivalence for its higher enhancement.

Proof. The formal assertions are the stated restriction, pullback and restricted tensor constructions. The pairwise comparison follows only with the full hypotheses of Corollary 73.1.5. On finite free formal charts, Proposition 64.5.8 expresses it through intertwining equations and overlap conditions. The additional centre assertion is separate: Proposition 73.2.9 gives an internal spectral centre identity only on its assumed categorical diagram. It does not construct an automorphic-to-spectral comparison. □

Corollary 73.4.2 *(*$\mathrm{L}_{\mathrm{ACD}}$ *residual list after Chenevier and determinant reduction).* (conditional on the standing residuals listed). After these reductions, $\mathrm{L}_{\mathrm{ACD}}$ has the residual list:

(i) (BCglue.local): **Conditional** (unchanged from the KMS–GNS sector);

(ii) (BCglue.glue): **Conjectural** (unchanged from the KMS–GNS sector);

(iii) (Ch1): **conditional theorem** via Corollary 73.1.5, conditional on its Selmer-ring, geometric, trace and equivariant-descent data;

(iv) (AG.det): the actual categorical descent diagram and its higher-centre maps, together with the global automorphic centre comparison. The conditional internal identity in Proposition 73.2.9 does not identify that automorphic centre;

(v) F2.c: **theorem under the full local operadic and pointing-map hypotheses** via either Chapter 50 Theorem 50.1.3 or the E_2 specialisation Theorem 73.3.1.

Proof. The formal ring and module constructions are Proposition 64.6.1. Their pairwise arithmetic use requires Corollary 73.1.5 (the full Selmer-ring, trace and equivariant-descent datum), the separate global centre comparison alongside Proposition 73.2.9, and Theorem 73.3.1 (restricted $F2.c$ transport under its stated hypotheses). These constructions preserve the listed comparison requirements. □

73.5 Residual Obstruction After Chenevier and Determinant Reduction

Remark 73.5.1 *(the genuine core remaining).* The residual obstruction to $\mathrm{L}_{\mathrm{ACD}}$ after these reductions is the triple:

- (BCglue.local): a primary-source transition theorem identifying the BZCHN + Emerton–Gee + Fargues–Scholze local inputs as a canonical local coherent Springer sheaf on the Emerton–Gee stack across the $\ell \neq p$ / $\ell = p$ divide. It is a genuine theorem condition.
- (BCglue.glue): Bhatt–Scholze prismatic-flat cross-prime transition lifted to the coherent-sheaf level, preserving $\mathrm{IndCoh}_{\mathrm{Nilp}}$-continuity. It is a genuine theorem condition.
- (AG.det.transition): an actual categorical descent diagram with its singular-support conditions and compatible higher-centre maps. The global automorphic comparison remains additional to the internal gluing identity.

The Chenevier term retains the Selmer-ring identification, trace comparison and equivariant coherent descent of Corollary 73.1.5. The determinantal term requires both the geometric centre diagram and the global comparison morphism. The local and prismatic gluing terms remain independent inputs.

Remark 73.5.2 *(unmoved inputs).* The arguments above do not prove (BCglue.local) or (BCglue.glue). The former requires a transition theorem across the $\ell = p$ boundary for coherent Springer sheaves. The latter requires prismatic-flat cross-prime descent lifted from the universal deformation ring to coherent sheaves. The (AG.det.transition) term requires the actual support-preserving categorical functors on a specified gluing diagram, higher-centre maps compatible with that diagram, and a separate comparison with the automorphic centre.

Remark 73.5.3 *(comparison inputs and remaining hypotheses).* The three comparison reductions use the following inputs:

- Theorem 73.1.4 constructs the local-to-global ring map from the universal property of the Chenevier deformation rings. Bellaïche–Chenevier supplies the deformation-theoretic context; Bhatt–Scholze and Bhatt–Lurie concern the additional prismatic structures. The full Selmer-ring, geometric, trace and equivariant-descent requirements are retained in Corollary 73.1.5.
- Proposition 73.2.9 gives an internal centre identity on an assumed geometric and categorical diagram. The singular-support geometry and the higher-centre comparison maps must be constructed for the arithmetic space. The internal identity does not construct a map from the automorphic centre.
- Theorem 73.3.1 uses actual operadic pointings and the filtered-colimit theorem HA 3.2.3.1. It is the specialization of Chapter 50's restricted tensor construction to E_2. The two arguments use the same categorical diagram.

73.6 REFERENCES ON DETERMINANTS, DESCENT AND HIGHER CENTRES

The primary literature invoked in this chapter:

Chenevier, G. (2014). *The p-adic analytic space of pseudocharacters of a profinite group and pseudorepresentations over arbitrary rings*. arXiv:0809.0415. Sections 1.1 and 1.10; Proposition 3.3 and Example 3.4, p. 42; Example 3.6 and Proposition 3.7, p. 43. These supply determinant laws and their complete local deformation rings.

Proposition 4.8.1.15, Remark 4.8.1.24 and Proposition 4.8.2.18 supply the stable categorical tensor and its colimit compatibility used in Theorem 73.3.1.

Francis, J. and Gaitsgory, D. (2012). *Chiral Koszul duality*. Selecta Math. 18, arXiv:1103.5803. Cited for the factorization-algebra background; no positive-dimensional factorization-homology theorem is used in Theorem 73.3.1.

Emerton, M. and Gee, T. (2019). *Moduli stacks of* (φ, Γ)*-modules and the existence of crystalline lifts*. arXiv:1908.07185. Used as the primary source for the local Emerton–Gee stack $\mathcal{X}_{GL_2}^{\mathrm{EG},p}$ in Conjecture 73.1.3 and the geometric realization required in Corollary 73.1.5. The pseudocharacter trace, Selmer-ring and equivariant-descent comparisons remain additional hypotheses.

Chapter 74

Elementary Reductions of the Riemann Hypothesis

The arithmetic Koszul reductions isolate the zero-placement problem inside the Weil distribution. The classical equivalences are recalled with their hypotheses, and the restricted Paley–Wiener class is kept separate from the full Weil cone.

74.1 The Riemann Hypothesis in Classical Form

Definition 74.1.1 *(the zeta function).* For $\mathrm{Re}(s) > 1$, the Riemann zeta function is the absolutely convergent sum

$$\zeta(s) \;:=\; \sum_{n=1}^{\infty} \frac{1}{n^s}.$$

Its Euler product, equivalent on $\mathrm{Re}(s) > 1$, is

$$\zeta(s) \;=\; \prod_{p} \bigl(1 - p^{-s}\bigr)^{-1},$$

the product taken over all prime numbers.

Definition 74.1.2 *(completed zeta and xi).* Set

$$\Lambda_\zeta(s) \;:=\; \pi^{-s/2}\,\Gamma(s/2)\,\zeta(s),$$
$$\xi_{\mathbb{R}}(s) \;:=\; \tfrac{1}{2}\,s(s-1)\,\Lambda_\zeta(s).$$

The function Λ_ζ is meromorphic with simple poles at $s = 0$ and $s = 1$; $\xi_{\mathbb{R}}$ is entire. Both satisfy the functional equation

$$\Lambda_\zeta(s) \;=\; \Lambda_\zeta(1-s), \qquad \xi_{\mathbb{R}}(s) \;=\; \xi_{\mathbb{R}}(1-s).$$

Remark 74.1.3 *(functional equation via Poisson summation).* Let $\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}$ for $t > 0$. Poisson summation gives $\theta(1/t) = t^{1/2}\theta(t)$. For $\Re s > 1$, termwise integration gives $\Lambda_\zeta(s) = \frac{1}{2}\int_0^\infty (\theta(t) - 1) t^{s/2}\, dt/t$. Splitting at 1 and substituting $t \mapsto 1/t$ in the lower integral yields its meromorphic continuation

$$\Lambda_\zeta(s) = \frac{1}{s(s-1)} + \frac{1}{2}\int_1^\infty (\theta(t) - 1)\bigl(t^{s/2} + t^{(1-s)/2}\bigr)\frac{dt}{t}.$$

The remaining integral is entire by exponential decay. This formula is invariant under $s \mapsto 1 - s$; multiplication by $s(s-1)/2$ removes the two poles and proves the functional equation for $\xi_{\mathbb{R}}$. Sources: B. Riemann, "Über die Anzahl der Primzahlen unter einer gegebenen Größe", Monatsber. Berlin. Akad. (1859); E. C. Titchmarsh, "The Theory of the Riemann Zeta-Function", Oxford 1951, Ch. 2.

Conjecture 74.1.4 *(Riemann Hypothesis).* All non-trivial zeros of ζ have real part $1/2$. Equivalently, the zeros of $\xi_{\mathbb{R}}$ have real part $1/2$.

74.2 Four Classical Equivalents

Four classical restatements of Chapter 74.1.4 are used below. They do not identify the same object; they identify the same zero-placement condition through different test categories.

THEOREM 74.2.1 *(Weil positivity).* Let $\mathscr{A} = C_c^\infty(\mathbb{R})$ with its inductive-limit topology, and put $f^*(t) = \overline{f(-t)}$ and $h_f(z) = \int_{\mathbb{R}} f(t)e^{izt}\,dt$. The Mellin coordinates are $\Phi_f(s) = h_f(-i(s-1/2))$. With $\phi(x) = f(\log x)$, the change of variables $x = e^t$ gives $\Phi_f(s) = \int_0^\infty \phi(x)x^{s-1/2}\,dx/x$. For the zeros ρ of $\xi_{\mathbb{R}}$, counted with multiplicity, put $z_\rho = -i(\rho - 1/2)$. Then

$$W(f) = \sum_\rho h_f(z_\rho) = h_f(i/2) + h_f(-i/2) - W_\infty(f) - W_{\mathrm{fin}}(f),$$

where

$$W_\infty(f) = \frac{1}{2\pi}\int_{\mathbb{R}} h_f(u)(\log\pi - \Re\psi(1/4 + iu/2))\,du,$$
$$W_{\mathrm{fin}}(f) = \sum_{m\ge 2}\frac{\Lambda(m)}{\sqrt{m}}[f(\log m) + f(-\log m)].$$

Write $P(f) = h_f(i/2) + h_f(-i/2)$ for the polar functional. Here $\Lambda(m)$ is the von Mangoldt function and $\psi = \Gamma'/\Gamma$. The prime sum is finite. The zero sum converges absolutely. RH is equivalent to $W(f * f^*) \ge 0$ for every $f \in \mathscr{A}$.

Proof. These are the compact-test formula and Weil criterion of Chapter 78.1.2, Chapter 78.2.1. The Fourier image of $f * f^*$ is $h_f h_f^\sharp$, where $h^\sharp(z) = \overline{h(\bar z)}$. On the real line this product is $|h_f|^2$. □

THEOREM 74.2.2 *(Li positivity).* . Define

$$\lambda_n := \sum_\rho\left(1 - \left(1 - \frac{1}{\rho}\right)^n\right) = \frac{1}{(n-1)!}\frac{d^n}{ds^n}\left[s^{n-1}\log\xi_{\mathbb{R}}(s)\right]\Big|_{s=1}.$$

Then RH holds if and only if $\lambda_n \ge 0$ for all $n \ge 1$. Source: X.-J. Li, "The positivity of a sequence of numbers and the Riemann hypothesis", J. Number Theory 65 (1997), 325–333.

Let γ denote the Euler–Mascheroni constant. For a normal Hilbert–Schmidt operator T, its regularized determinant is

$$\det{}_2(I - sT) = \prod_j (1 - s\lambda_j)e^{s\lambda_j},$$

where the nonzero eigenvalues λ_j are repeated with their multiplicities. The product converges locally uniformly in $s \in \mathbb{C}$: $\sum_j |\lambda_j|^2 < \infty$ and $(1 - s\lambda_j)e^{s\lambda_j} = 1 + O_K(|\lambda_j|^2)$ uniformly on each compact set $K \subset \mathbb{C}$.

THEOREM 74.2.3 *(normalized Hilbert–Pólya spectral form).* RH is equivalent to the existence of a separable Hilbert space H and a densely defined self-adjoint operator A such that, for $\Theta = \frac{1}{2}I + iA$, the inverse Θ^{-1} is Hilbert–Schmidt and the prescribed entire determinant is

$$\frac{1}{2}e^{Bs}\det{}_2(1 - s\Theta^{-1}) = \xi_{\mathbb{R}}(s), \qquad B = -1 - \frac{\gamma}{2} + \frac{1}{2}\log(4\pi).$$

Zeros of the determinant are counted with their spectral multiplicities. The prescription fixes both its value $1/2$ at zero and its logarithmic derivative B there.

Proof. For a self-adjoint A, the bounded inverse of $\frac{1}{2}I + iA$ is normal. If it is Hilbert–Schmidt it is compact; its nonzero eigenvalues are $(1/2 + ia_j)^{-1}$ for real eigenvalues a_j, with their multiplicities. The regularized product therefore has zeros only at $1/2 + ia_j$. Its asserted equality with $\xi_{\mathbb{R}}$ implies RH. Conversely, on the zero-occurrence carrier $K_Z = \ell^2(Z)$ of Chapter 77.6, use the closed normal operator Θ_Z with maximal domain $\{u : \sum_\rho |\rho u_\rho|^2 < \infty\}$. Under RH write $\rho = 1/2 + i\gamma_\rho$, with $\gamma_\rho \in \mathbb{R}$. The diagonal operator

$$(Au)_\rho = \gamma_\rho u_\rho, \qquad \operatorname{Dom} A = \{u : \sum_\rho |\gamma_\rho u_\rho|^2 < \infty\}$$

is self-adjoint, and $\Theta_Z = \frac{1}{2}I + iA$ on the same domain. Its inverse is Hilbert–Schmidt, and Chapter 77.6.1 proves exactly the stated normalized genus-one determinant. That construction uses the zero divisor as input. Constructing an arithmetic operator and an intertwiner with this carrier remains an additional problem. □

The Hilbert–Pólya question asks for such an independent arithmetic realization; the abstract zero-occurrence construction does not supply it. Connes, *Selecta Mathematica* 5 (1999), arXiv:math/98110 68, treats a separate trace-formula framework.

Entire functions and the zero divisor. Write $F(z) = \Xi(z) = \xi_{\mathbb{R}}(1/2 + iz)$ and $G^\#(z) = \overline{G(\bar{z})}$ for an entire function G. The functional equation and reality of $\xi_{\mathbb{R}}$ make F even and real entire. RH says precisely that all its zeros are real. Use the convention that an entire function E belongs to HB if it has no real zeros and $|E^\#(z)| < |E(z)|$ for $\Im z > 0$. No finite-exponential-type condition is included in this definition.

Theorem 74.2.4 *(a shift-family Hermite–Biehler criterion).* For $h > 0$ put

$$E_h(z) = F(z + ih) = \xi_{\mathbb{R}}(1/2 + h - iz).$$

The following conditions are equivalent: RH; $E_h \in$ HB for every $h > 0$; and $E_{h_n} \in$ HB for some positive sequence $h_n \downarrow 0$. The recovery identities are

$$E_h^\#(z) = F(z - ih), \qquad F(z) = E_h(z - ih).$$

Thus a zero w of E_h gives the zero $w + ih$ of F with exactly the same multiplicity. No simplicity assumption is needed.

Proof. One has $F(0) \neq 0$. Indeed the alternating series at $1/2$ can be paired as $\eta(1/2) = \sum_{n\geq 1}[(2n-1)^{-1/2} - (2n)^{-1/2}] > 0$; $\zeta(1/2) = \eta(1/2)/(1 - \sqrt{2})$ is consequently nonzero. Under RH the genus-one factorization and evenness give

$$F(z) = F(0)\prod_{\gamma>0}(1 - z^2/\gamma^2)^{m_\gamma}, \qquad \sum_{\gamma>0} m_\gamma \gamma^{-2} < \infty.$$

Here $\pm\gamma$ are the zeros of F, with multiplicity m_γ. The inverse-square convergence follows from Chapter 77.5.1. Pairing the factors at γ and $-\gamma$ cancels their genus-one exponentials; the remaining linear exponential is constant by evenness. The product converges locally uniformly. For $z = x + iy$, $y > 0$, every real γ satisfies

$$|z + ih - \gamma|^2 - |z - ih - \gamma|^2 = 4yh > 0.$$

Apply this to both members of every paired factor. If $F(z - ih) \neq 0$, each factor in the ratio of absolute values exceeds one. Its limiting product remains strictly greater than one by retaining one strict factor and bounding all other factors below by one. If $F(z - ih) = 0$, the inequality is immediate, since $F(z + ih)$ cannot vanish in the upper half-plane under RH. Hence $|E_h(z)| > |E_h^{\#}(z)|$. All zeros of E_h are $\gamma - ih$, so none is real. This proves the assertion for every $h > 0$, and therefore for any sequence decreasing to zero. Conversely, a nonreal zero of the real entire function F gives a zero w in the upper half-plane. For $h_n < \Im w$, the point $w - ih_n$ is an upper-half-plane zero of E_{h_n}, contradicting the strict HB inequality. The two recovery identities follow directly from reality, translation and the functional equation. □

Remark 74.2.5 *(one shift and a family of shifts).* For $F_a(z) = z^2 + a^2$, $a > 0$, and $h > a$,

$$F_a(z + ih) = (z + i(h - a))(z + i(h + a)) \in \mathrm{HB},$$

although F_a has nonreal zeros. Each factor has the strict upper-half-plane modulus inequality because $|z + ib|^2 - |z - ib|^2 = 4b\Im z > 0$ for $b > 0$. Thus one fixed shift does not characterize real-rootedness. For Ξ itself, Lagarias, arXiv:math/0601653, Lemma 2.1, pp. 5–6, proves the shift inequality unconditionally for $h \geq 1/2$, and under RH for every $h > 0$; the change of variable is $s = 1/2 - iz$. Section 6 relates these functions to de Branges spaces. The family tending to zero, not one large shift, is the RH criterion.

THEOREM 74.2.6 *(the derivative criterion and real multiplicities).* Set $D(z) = F(z) + iF'(z)$. Then

$$D^{\#}(z) = F(z) - iF'(z), \qquad F(z) = \tfrac{1}{2}(D(z) + D^{\#}(z)).$$

RH is equivalent to $|D(z)| > |D^{\#}(z)|$ for every $\Im z > 0$, where real zeros of D are allowed. With the no-real-zero convention above, $D \in \mathrm{HB}$ is instead equivalent to RH together with simplicity of all zeros of F.

Proof. Under RH, logarithmic differentiation of the paired product gives for $z = x + iy$, $y > 0$,

$$\Im \frac{F'(z)}{F(z)} = -y \sum_{\gamma \in \mathbb{R}} \frac{m_\gamma}{|z - \gamma|^2} < 0.$$

The imaginary-part series is absolutely convergent by the inverse-square estimate. There is at least one zero, indeed infinitely many by Chapter 77.5.1. Consequently

$$|D(z)|^2 - |D^{\#}(z)|^2 = -4|F(z)|^2 \Im \frac{F'(z)}{F(z)} > 0.$$

Conversely, at an upper-half-plane zero w of F the two values $D(w) = iF'(w)$ and $D^{\#}(w) = -iF'(w)$ have equal modulus. This contradicts the strict inequality, also when both vanish at a multiple zero. Conjugation symmetry excludes lower-half-plane zeros as well. For a real zero write $F(z) = (z - \gamma)^m g(z)$ with $g(\gamma) \neq 0$. Then

$$D(z) = (z - \gamma)^{m-1}\big((z - \gamma)g(z) + i[mg(z) + (z - \gamma)g'(z)]\big).$$

The bracket is nonzero at γ, so the real multiplicity in D is exactly $m - 1$. On the real axis F, F' are real, hence a real zero of D occurs only where both vanish. This proves the simplicity qualification and the stated recovery identity. □

Proposition 74.2.7 *(the growth required by the zeta divisor).* No nonzero entire function of finite exponential type can have a zero divisor containing the full divisor of $F = \Xi$. In particular no nonzero real or imaginary component of a finite-exponential-type function can have that divisor. The functions F and each fixed translate E_h have order one and infinite exponential type.

Proof. Let $N(T)$ count the nontrivial zeta zeros with $0 < \Im\rho \le T$, with multiplicity. The Riemann–von Mangoldt estimate is $N(T) = \frac{T}{2\pi}\log\frac{T}{2\pi e} + O(\log T)$. For a precise primary bound see Hasanalizade–Shen–Wong, arXiv:2107.06506, Corollary 1.2, equation (1.5), p. 2. The strip $0 \le \Re\rho \le 1$ and conjugation give, for the number $n_F(r)$ of zeros in $|z| \le r$,

$$2N(\sqrt{r^2 - 1/4}) \le n_F(r) \le 2N(r), \qquad n_F(r) = \frac{r}{\pi}\log\frac{r}{2\pi e} + O(\log r).$$

If G is nonzero entire with $|G(z)| \le Ce^{\tau|z|}$ and $G(0) \ne 0$, Jensen's formula at radius $2r$ gives

$$n_G(r)\log 2 \le \frac{1}{2\pi}\int_0^{2\pi} \log|G(2re^{i\theta})|\,d\theta - \log|G(0)| = O(r).$$

Factoring out a zero at the origin changes the count by a constant. Thus G cannot contain the $r\log r$ divisor of F. If E has finite exponential type, so do its components $(E + E^{\#})/2$ and $(E^{\#} - E)/(2i)$; apply the same argument to every nonzero component. Finally the functional equation, Stirling's formula and $\zeta(\sigma) \to 1$ give

$$\log F(iy) = \log \xi_{\mathbb{R}}(1/2 + y) = \frac{y}{2}\log y - \frac{y}{2}(1 + \log(2\pi)) + O(\log y) \quad (y \to +\infty).$$

Together with the order-at-most-one bound in Chapter 77.5.1, this proves order one and infinite exponential type, also after any fixed translation. □

The general Hilbert-space theory of entire functions is developed in de Branges, *Hilbert Spaces of Entire Functions* (1968). The explicit constructions above specify the recovery of the zeta divisor and retain its actual growth and multiplicities.

Remark 74.2.8 *(four precise equivalences).* Weil positivity on all compact tests, Li positivity, the normalized spectral realization of Chapter 74.2.3, and the shift-family condition of Chapter 74.2.4 are each equivalent to RH. The derivative inequality gives the same zero condition with its real-zero convention stated explicitly. These criteria use different carriers: test functions, a coefficient sequence, a spectral operator and entire functions. None of their abstract equivalences constructs the native arithmetic pairing or operator maps required below.

74.3 The Arithmetic Reduction

The arithmetic Koszul construction supplies five comparison objects. Each object is defined on its own domain, and no implication from a restricted domain to the full Weil cone is used without an extension theorem.

Step 1: The arithmetic Heisenberg Koszul pair

Question 74.3.1 *(the arithmetic Heisenberg coefficient object).* Construct local coefficient objects H_v, a common coefficient category, pointings and a completion that define

$$\mathsf{H}^{\mathrm{Ar}} = \mathsf{H}_\infty \widehat{\otimes} \widehat{\bigotimes}_p \mathsf{H}_p.$$

Compare the infinite-place factor with the Heisenberg field and the finite factors with their continuous Galois coefficient models. An associative bar construction additionally requires an augmented algebra, or a specified curved replacement. The pointed tensor construction of Chapter 50.1.1 applies once its inputs are given.

Definition 74.3.2 (central invariants and comparison functors). For a specified arithmetic object and its specified dual, write $\kappa_{\mathsf{H}}^{\mathrm{Ar}}$ and $(\kappa^!)_{\mathsf{H}}^{\mathrm{Ar}}$ for their chosen scalar central invariants. These are not the bar and cobar complexes themselves. An integral co–contra adjunction and an algebraic bar–cobar adjunction have the distinct carriers described in Chapter 46.

THEOREM 74.3.3 *(P1 under the central-defect comparison).* Assume the objects, involution, central-defect identity and Mellin evaluation of Theorem 43.5.1 realize these arithmetic invariants, with $E(w) \neq 0$. Then

$$\kappa_{\mathsf{H}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{H}}^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi_{\mathbb{R}}(s) = \xi_{\mathbb{R}}(1-s).$$

Proof. Applying E to the defect identity identifies the difference of the two completed Mellin functions with $(\kappa_{\mathsf{H}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{H}}^{\mathrm{Ar}})E(w)$. The nonzero meromorphic function $E(w)$ detects the scalar coefficient. Multiplication by the reflection-invariant factor $s(s-1)/2$ gives the equivalent identity for ξ. □

Remark 74.3.4 (the scalar and categorical comparisons). Poisson summation proves the scalar functional equation. An arithmetic interpretation requires maps identifying the duality involution with Mellin reflection and the central classes with the specified defect. Equality of two scalar characters need not detect a nonzero vector defect, as in Theorem 43.5.1. Neither the scalar equality nor a categorical equivalence alone supplies those identifications.

Archimedean Heisenberg Character

Definition 74.3.5 (archimedean Heisenberg character). The archimedean fibre H_∞ is the standard Heisenberg vertex operator algebra on $\mathbb{C}_\infty$ with Virasoro zero-mode L_0 and central charge $c_\infty = 1$ (one free boson). For the primary H_∞-module V_∞ (the vacuum representation), the Zhu character is

$$\chi_{V_\infty}(\tau) \;:=\; \mathrm{tr}_{V_\infty}\!\left(q^{L_0 - c_\infty/24}\right), \qquad q = e^{2\pi i \tau},$$

a standard VOA Zhu trace on the archimedean fibre. The global object $\mathcal{V}^{\mathrm{prim}}$ is the Hochschild trace class of the identity on the arithmetic Hecke category; it is *not* a vertex algebra. The quantity $\Lambda_\zeta(s)$ arises as its Hochschild character via Tate's adelic construction, not as a VOA module trace.

THEOREM 74.3.6 *(P2: Hochschild character and functional equation).* . The Hochschild character of $\mathcal{V}^{\mathrm{prim}}$ equals $\Lambda_\zeta(s)$ under the identification of the Hochschild trace with Tate's adelic zeta integral (Chapter 41.2.1). The primary determinant carries rank residue $r_\zeta = 2$, the residue at $s = 1$ of $2\zeta(s)$ (Chapter 41.5.1). The adelic functional equation $\Lambda_\zeta(s) = \Lambda_\zeta(1-s)$ follows from Poisson summation applied to the Schwartz–Bruhat function at each place. The Heisenberg vacuum character is the local eta-factor; the theta transformation enters only after the lattice Schwartz sector is adjoined.

Remark 74.3.7 (elementary content of P2). On the archimedean fibre,

$$\chi_{V_\infty}(\tau) = q^{-1/24} \prod_{n \geq 1} (1 - q^n)^{-1}.$$

This eta-character is not Tate's theta integral. Tate's local factor is obtained from the Schwartz function on $\mathbb{R}$ and the theta sum $\theta(t) = \sum_{n \in \mathbb{Z}} e^{-\pi n^2 t}$; Poisson summation is the identity $\theta(t) = t^{-1/2}\theta(1/t)$. No

finite Zhu S-matrix or rational-VOA modularity is used in the Hochschild trace. Tate (1950) identified Λ_ζ with the adelic zeta integral; the present step repackages Tate's computation as a Hochschild-trace identity on $\mathcal{V}^{\mathrm{prim}}$, with VOA language confined to H_∞. Source: J. T. Tate, thesis, Princeton 1950 (reprinted in Cassels–Fröhlich, "Algebraic Number Theory", Academic Press 1967).

Step 3: Petersson positivity

Definition 74.3.8 *(adelic Petersson form).* Fix a unitary central character and quotient Tamagawa measure dh on $[GL_2] = Z(\mathbb{A})GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})$. On the corresponding cuspidal L^2 space set

$$\langle v, w\rangle_{\mathrm{Pet}} = \int_{[GL_2]} v(h)\overline{w(h)}\,dh.$$

For a proposed complex realization E of the primary Hochschild trace sector, a Petersson pairing on E requires a complex-linear map $I : E \to L^2_{\mathrm{cusp}}([GL_2], dh)$.

Theorem 74.3.9 *(positive pullback and Koszul comparison).* The pullback $\langle Iv, Iw\rangle_{\mathrm{Pet}}$ is positive semidefinite, and is definite precisely when I is injective. If $B_{\mathrm{Kos}} : E \times E \to \mathbb{C}$ is bilinear and $\sigma : E \to E$ is an antilinear involution, the identity

$$B_{\mathrm{Kos}}(v, \sigma w) = \langle Iv, Iw\rangle_{\mathrm{Pet}}$$

transports this positivity to the specified Koszul pairing.

Proof. Its diagonal is $\|Iv\|_2^2$, which vanishes exactly on $\ker I$. The displayed equality then gives the last assertion. □

Remark 74.3.10 *(local and global realization data).* For a restricted Hilbert tensor product with unit reference vectors e_p, the inner product on elementary tensors is

$$\langle v, w\rangle = \langle v_\infty, w_\infty\rangle \prod_p \langle v_p, w_p\rangle,$$

where all but finitely many factors equal one. This defines a positive Hilbert completion. Identifying it with E and with the adelic Petersson space requires local maps, normalizations on e_p, and the global pairing identity above. The primary Hochschild trace class is not itself a space of functions on $[GL_2]$. Its degree, completion, realization map, and pairing are the additional data specified in Chapter 78.5.4.

Step 4: Bost–Connes and the Hilbert–Pólya Boundary

Definition 74.3.11 *(Bost–Connes system and KMS convention).* Let $D = C^*(\mathbb{Q}/\mathbb{Z})$, with group unitaries $e(r)$, and put

$$\alpha_n(e(r)) = \frac{1}{n}\sum_{nt=r} e(t), \qquad n \in \mathbb{N}^\times.$$

The Bost–Connes algebra is the semigroup crossed product $\mathcal{A}_{\mathrm{BC}} = D \rtimes_\alpha \mathbb{N}^\times$. Its multiplicative generators μ_n are isometries, with

$$\mu_n^*\mu_n = 1, \quad \mu_m\mu_n = \mu_{mn}, \quad \mu_n d\mu_n^* = \alpha_n(d), \quad \mu_n^* e(r)\mu_n = e(nr).$$

The time evolution fixes D and satisfies $\sigma_t(\mu_n) = n^{it}\mu_n$. For $\beta > 0$ and entire analytic elements the KMS_β identity is $\varphi(ab) = \varphi(b\sigma_{i\beta}(a))$. In particular $\varphi(\mu_n\mu_n^*) = n^{-\beta}$ whereas $\varphi(\mu_n^*\mu_n) = 1$; for $n > 1$ the KMS state is nontracial and μ_n is not unitary. The crossed-product description is that of Laca–Raeburn, arXiv:math/9911134, §2, p. 3.

At $\beta = 1$ let φ_1 be the unique KMS state and (π, H, Ω) its GNS representation. Its restriction to D is $\varphi_1(e(r)) = \delta_{r,0}$; see Connes, *Noncommutative Geometry*, V §11, Theorem 5(a), p. 528. Invariance and the KMS identity give, on the dense monomial algebra,

$$\varphi_1(\mu_a e(r) \mu_b^*) = \delta_{a,b}\, a^{-1} \delta_{r,0}.$$

Indeed unequal a, b give a nontrivial time character, while for $a = b$ one moves μ_a around the state by the KMS identity. For this canonical state its normal extension to $M = \pi(\mathcal{A}_{\mathrm{BC}})''$ is faithful, and Ω is cyclic and separating. We use its Tomita modular operator Δ_1, with support 1 in M and convention

$$\Delta_1^{it}\, \pi(a)\, \Delta_1^{-it} = \pi(\sigma_{-t}(a)), \qquad \Delta_1^{it}\Omega = \Omega.$$

This sign is the canonical Hecke-state convention in Connes, V §11, Proposition 4, p. 527. In vectors below, $a\Omega$ means $\pi(a)\Omega$.

THEOREM 74.3.12 *(the full critical-temperature modular generator).* Define $N_{\mathrm{BC}} = -\frac{1}{2}\log \Delta_1$ by self-adjoint functional calculus. There is an orthogonal Hilbert sum

$$H = \widehat{\bigoplus}_{q \in \mathbb{Q}_{>0}} H_q, \qquad N_{\mathrm{BC}}|_{H_q} = \tfrac{1}{2}\log q,$$

where every H_q has countably infinite dimension. Its maximal domain is

$$\operatorname{Dom} N_{\mathrm{BC}} = \left\{ \xi = \sum_q \xi_q : \sum_q (\log q)^2 \|\xi_q\|^2 < \infty \right\}.$$

Its point spectrum is $\frac{1}{2}\log \mathbb{Q}_{>0}$ and its closed spectrum is $\mathbb{R}$. All spectral measures are pure point.

Proof. Each monomial $x = \mu_a e(r) \mu_b^*$ is entire analytic with $\sigma_t(x) = (a/b)^{it} x$. The modular identity therefore gives $\Delta_1^{it} x \Omega = (a/b)^{-it} x \Omega$. Take H_q to be the closed span of these eigenvectors with $a/b = q$. Different eigenvalues are orthogonal, and the monomials are dense in the GNS space. Functional calculus gives the displayed direct sum and maximal domain. Every $q = a/b$ occurs, since

$$\|\mu_a \mu_b^* \Omega\|^2 = \varphi_1(\mu_b \mu_b^*) = b^{-1} > 0.$$

The closed spectrum is the closure of these diagonal eigenvalues, which is $\mathbb{R}$ because the positive rationals are dense. The diagonal spectral projections make every spectral measure atomic on that countable set. For multiplicity fix a prime p, and set $P_k = \mu_{p^k} \mu_{p^k}^*$ and $d_k = P_k - P_{k+1}$, $k \geq 0$. The P_k are nested fixed-point projections; hence the d_k are orthogonal projections with $\|d_k \Omega\|^2 = p^{-k} - p^{-k-1} > 0$. For fixed-point elements x, y, cancellation of $\mu_a^* \mu_a$ and the KMS identity give

$$\varphi_1\big((\mu_a y \mu_b^*)^* (\mu_a x \mu_b^*)\big) = b^{-1} \varphi_1(y^* x).$$

Thus $\mu_a d_k \mu_b^* \Omega$ are infinitely many nonzero orthogonal vectors in $H_{a/b}$. The algebra, and hence H, is separable, so its eigenspace dimensions are countably infinite. □

PROPOSITION 74.3.13 *(a reducing occupation subspace).* For an integer $s \geq 1$ put

$$K_s = \overline{\operatorname{span}}\{\mu_{m^s}\Omega : m \in \mathbb{N}^{\times}\}.$$

The displayed vectors are an orthonormal basis and K_s reduces N_{BC}. The unitary $V_s : \ell^2(\mathbb{N}^\times) \to K_s$, $V_s \delta_m = \mu_{m^s}\Omega$, satisfies

$$V_s^*(N_{\mathrm{BC}}|_{K_s})V_s = \tfrac{s}{2} H_{\mathrm{occ}}, \qquad (H_{\mathrm{occ}}c)_m = (\log m)c_m,$$

including the domain identity, where

$$\mathrm{Dom}\, H_{\mathrm{occ}} = \{c : \sum_m (\log m)^2 |c_m|^2 < \infty\}.$$

Thus K_1 gives half the occupation energy and K_2 gives exactly $\log m$.

Proof. Each vector has norm one because μ_{m^s} is an isometry. For $m \neq n$, invariance of φ_1 gives $\varphi_1(\mu_{m^s}^* \mu_{n^s}) = 0$, since $(n/m)^{ist}$ is a nontrivial time character. These orthonormal eigenvectors have energies $(s/2)\log m$. Their closed span reduces every spectral projection of N_{BC}, proving reduction and the maximal diagonal domain formula. □

Proposition 74.3.14 *(compressed shifts and the observable obstruction).* Let P_s be the orthogonal projection onto K_s, and set $T_n = \pi(\mu_{n^s})|_{K_s}$. Under V_s, these operators and their Hilbert adjoints act as

$$V_s^* T_n V_s \delta_m = \delta_{nm}, \qquad V_s^* T_n^* V_s \delta_m = \begin{cases} \delta_{m/n}, & n \mid m, \\ 0, & n \nmid m. \end{cases}$$

The adjoint here is $T_n^* = P_s \pi(\mu_{n^s}^*)|_{K_s}$. The original adjoints do not preserve K_s, and compression of the BC algebra to K_s is not a $*$-representation.

Proof. The semigroup identity gives $\mu_{n^s}\mu_{m^s}\Omega = \mu_{(nm)^s}\Omega$. Taking inner products of these basis vectors gives the adjoint formula. For $n > 1$ the vector $\mu_{n^s}^*\Omega$ has norm squared n^{-s} and strictly negative modular energy, so it is nonzero and orthogonal to K_s. In particular it cannot be the zero compressed adjoint $T_n^*\Omega$. For the group unitaries, time invariance makes the off-diagonal matrix coefficients of $e(r)$ between the K_s basis vectors vanish. The transfer relation and the state on D give the diagonal entries:

$$P_s \pi(e(r))|_{K_s} \mu_{m^s}\Omega = \mathbf{1}_{\{m^s r = 0 \text{ in } \mathbb{Q}/\mathbb{Z}\}} \mu_{m^s}\Omega.$$

At $r = 1/2$ the compressed operator kills Ω, although $e(r)$ is unitary. Thus the unital compression preserves adjoints but does not preserve products, and is not a representation of the BC algebra. □

Writing $m = \prod_p p^{k_p}$ identifies the occupation basis with finitely supported nonnegative prime occupations. On their finite linear span,

$$N_{\mathrm{BC}}|_{K_s} = \frac{s}{2} \sum_p (\log p) K_p, \qquad K_p \mu_{m^s}\Omega = k_p \mu_{m^s}\Omega.$$

The closure is the maximal diagonal operator already specified. This identifies a Hilbert space and its occupation generator; it does not turn the compressed BC observables into a BC representation or into bosonic creation operators.

Remark 74.3.15 *(occupation trace and the Hilbert–Pólya boundary).* On the reducing subspace K_2 the spectral theorem gives

$$\mathrm{Tr}_{K_2}(e^{-tN_{\mathrm{BC}}}) = \sum_{m\geq 1} m^{-t} = \zeta(t), \qquad t > 1.$$

At $t = 1$ this trace diverges. On the full GNS space the exponential $e^{-tN_{\mathrm{BC}}}$ is unbounded for every $t > 0$, since its spectrum contains all negative rational logarithmic energies. There is also a separate standard BC representation on $\ell^2(\mathbb{N}^\times)$, with $\pi_0(\mu_n)\delta_m = \delta_{nm}$ and $\pi_0(e(r))\delta_m = e^{2\pi i m r}\delta_m$. The root-of-unity average in α_n is zero unless $n \mid m$, and otherwise is $e^{2\pi i(m/n)r}$, proving the covariance relation. The occupation Hamiltonian implements σ_t there and has partition function $\mathrm{Tr}(e^{-tH_{\mathrm{occ}}}) = \zeta(t)$ for $t > 1$. This is the type-I Gibbs realization underlying Connes, V §11, Theorem 5(b), p. 528; it is not the compression of π to K_2, whose $e(r)$ matrices were computed above. The occupation trace is consequently not the full modular trace and not the signed Weil functional. A comparison with Chapter 74.2.3, including the arithmetic question of Chapter 77.4.3, must supply an actual test-algebra map, its involution and complete $P - W_\infty - W_{\mathrm{fin}}$ pairing, an operator-domain comparison, and the normalized zero divisor with its multiplicities. The reducing subspace and its zeta trace do not supply those maps.

Restricted Weil pairings

Definition 74.3.16 *(compact coefficient multiplier).* For $f \in \mathscr{A}$, define

$$U(f)(z) = \sum_{n\geq 1} f(\log n) n^{1/2} e^{2\pi i n z}.$$

This is a finite holomorphic Fourier polynomial with exponential decay as $\Im z \to \infty$.

PROPOSITION 74.3.17 *(modularity of the compact multiplier).* A nonzero $U(f)$ cannot be a cusp form of positive weight for $SL_2(\mathbb{Z})$.

Proof. A finite Fourier polynomial is analytic in y at $z = iy = 0$. The modular transformation $z \mapsto -1/z$ would imply $U(f)(iy) = O(y^{-k}e^{-2\pi/y})$. All its Taylor coefficients would vanish. This is the compact multiplier obstruction of Chapter 78.4.3. □

THEOREM 74.3.18 *(restricted positive realizations).* Let $D \subset \mathscr{A}$ be a complex vector subspace. Put $q_D(f,g) = W(f * g^*)$ for $f, g \in D$. A linear map $J : D \to K$ to a positive Hilbert space satisfying

$$\langle Jf, Jg\rangle_K = q_D(f,g) = P(f * g^*) - W_\infty(f * g^*) - W_{\mathrm{fin}}(f * g^*)$$

exists exactly when q_D is positive semidefinite. When it exists, the completion of $D/\{f : q_D(f,f) = 0\}$ gives its minimal realization.

Proof. A Hilbert realization gives positivity. Conversely the Cauchy–Schwarz inequality for a positive semidefinite Hermitian form makes its nullspace orthogonal to D. The quotient is an inner-product space, and its completion provides J. □

COROLLARY 74.3.19 *(restricted positivity from a native pairing).* Suppose $T : D \to E$ and $I : E \to L^2_{\mathrm{cusp}}([GL_2], dh)$ are linear maps with $W(f * g^*) = \langle ITf, ITg\rangle_{\mathrm{Pet}}$ for $f, g \in D$. Then $W(f * f^*) \geq 0$ on D.

Proof. Take $g = f$. The resulting value is $\|ITf\|_2^2$. □

The construction of T, I and this equality is the restricted arithmetic comparison problem. Neither the multiplier U nor moment conditions supply these maps. A restricted Li trace additionally requires explicit Li test approximants and convergence of their zero sums. The rational Li tests are not compact Fourier tests, by Chapter 78.6.5.

74.4 The restricted test class and its closure

Theorem 74.4.1 *(closure of restricted Weil positivity).* Under the preceding pairing hypothesis, q_W is nonnegative on the closure of D in $\mathscr{A}$. If that closure is all of $\mathscr{A}$, RH follows. The same assertion holds in the exponential space $\mathscr{G}$ of Chapter 95.1.2.

Proof. Convolution, involution, and W are continuous on these spaces. Thus $f \mapsto q_W(f, f)$ is continuous and its nonnegative locus is closed. Apply Weil's criterion when the closure is the full space. □

Remark 74.4.2 *(domain and spectrum).* The real even moment class $\mathscr{A}_{13}$ of Chapter 78.3 is a proper closed subspace of the real even compact tests. Increasing a modular weight does not remove its moment equations. An extension through Maass, residual, or Eisenstein sectors requires maps into the specified spectral summands and the same full pairing equality. A separate comparison is required for each sector. None is logically necessary for an independent proof of the full Weil inequality.

74.5 Restricted-Class Comparison

The restricted-class comparison partitions the conditions of Chapter 74.4.2 into related mathematical comparisons.

74.6 The full Weil cone

THEOREM 74.6.1 *(full-domain Weil positivity).* RH is equivalent to

$$W(f * f^*) \geq 0 \qquad (f \in \mathscr{A}).$$

It is also equivalent to existence of a positive Hilbert realization of this full form. A realization through a specified arithmetic sector requires the native maps and pairing equality in addition.

Proof. Use Weil's criterion and Chapter 74.3.18 with $D = \mathscr{A}$. □

Remark 74.6.2 *(domain of the reduction).* An identity on a proper restricted class does not supply this full-domain assertion. Density must use a topology in which $P, W_\infty, W_{\mathrm{fin}}$ and convolution are continuous. The compact and exponential topologies above have that property.

74.7 Classical boundary

The functional equation, Hochschild character, Koszul pairing, Bost–Connes dynamics, and coefficient multipliers address different comparison problems. The coefficient construction gives a finite holomorphic series. The integral pairing is positive on its actual L^2 carrier. Their arithmetic relation requires specified maps. For a fixed restricted carrier, a proved pairing identity gives Weil positivity there and on its closure. The full Weil inequality is RH-equivalent. A full abstract Hilbert realization follows from that inequality by completion, while a realization in the specified native arithmetic sector retains its additional structural requirements.

Chapter 75

Arithmetic Positselski: Duals, Completion and Pairings

The arithmetic comparison involves continuous duals, derived completion, lifting, a character pairing and a Bost–Connes algebra model. The first three are local categorical constructions with their own coefficient and finiteness hypotheses. The last two require maps on the intended arithmetic object. The one-mode Euler product and Gaussian Mellin calculation of Chapter 66 determine a scalar; they do not supply the character or algebra comparison. We separate the explicit shift representation and a necessary same-prime relation test from the remaining arithmetic construction.

75.1 Continuous Duals

Iwasawa Algebra and Pontryagin Dual

Fix a prime p. Let $G_p = \mathrm{Gal}(\mathbb{Q}_p^{\mathrm{ab}}/\mathbb{Q}_p)$ and

$$\Lambda_p \;:=\; \mathbb{Z}_p[[G_p]] \;=\; \varprojlim_{U} \mathbb{Z}_p[G_p/U], \tag{75.1}$$

the inverse limit over open normal subgroups $U \trianglelefteq G_p$ of finite index. By local class field theory (Serre 1962, *Corps locaux*, Ch. XIV §5), G_p is a profinite group and Λ_p is a compact topological ring in the inverse-limit topology (each $\mathbb{Z}_p[G_p/U]$ is a finite $\mathbb{Z}_p$-module in the p-adic topology). The underlying additive group is a compact topological abelian group; in the notation of Weil 1940 *L'intégration* Ch. II, $\Lambda_p \in \mathrm{LCA}$, the category of locally compact abelian groups.

Definition 75.1.1 *(continuous Pontryagin dual).* For $A \in \mathrm{LCA}$, the *continuous Pontryagin dual* is

$$A^* \;:=\; \mathrm{Hom}_{\mathrm{cts}}(A, \mathbb{R}/\mathbb{Z}),$$

the group of continuous homomorphisms into the circle, topologised by compact-open convergence. For A compact, A^* is discrete; for A discrete, A^* is compact (Pontryagin 1934, Weil 1940 Ch. II §2). For A a p-primary torsion group (a $\mathbb{Z}_p$-module in the sense that $p^n A \to 0$), A^* takes values in $\mathbb{Q}_p/\mathbb{Z}_p \subset \mathbb{R}/\mathbb{Z}$ and one writes

$$A^\vee \;:=\; \mathrm{Hom}_{\mathrm{cts}}(A, \mathbb{Q}_p/\mathbb{Z}_p),$$

the *p-adic Pontryagin dual*.

Theorem 75.1.2 *(Pontryagin double duality, LCA version).* The contravariant functor $A \mapsto A^*$ from LCA to LCA is an anti-equivalence of categories: the double-dual natural transformation $A \to A^{**}$, $a \mapsto \mathrm{ev}_a$, is an isomorphism of topological groups for every $A \in \mathrm{LCA}$. Restriction to compact abelian groups: the anti-equivalence exchanges compact and discrete. Restriction to p-primary: the anti-equivalence exchanges compact pro-p and discrete p-primary torsion.

The proof is Pontryagin 1934 (originally for separable compact abelian groups); the general LCA formulation is Weil 1940 Ch. II §5 and Folland 1995 *A Course in Abstract Harmonic Analysis* Ch. 4, Thm. 4.31 (the latter has the cleanest topological-group-valued statement).

The Continuous Dual of Λ_p

PROPOSITION 75.1.3 *(continuous dual of Iwasawa algebra).* The continuous Pontryagin dual of Λ_p is naturally isomorphic to the discrete p-primary torsion module of continuous $\mathbb{Q}_p/\mathbb{Z}_p$-valued functions on G_p:

$$(\Lambda_p)^* \;=\; \Lambda_p^\vee \;=\; C(G_p, \mathbb{Q}_p/\mathbb{Z}_p),$$

equipped with the discrete topology and the G_p-module structure induced by translation: $(g \cdot f)(h) = f(g^{-1}h)$.

Proof. The first equality $(\Lambda_p)^* = \Lambda_p^\vee$ is immediate: Λ_p is pro-p (compact pro-p group), so every continuous homomorphism $\Lambda_p \to \mathbb{R}/\mathbb{Z}$ factors through the pro-p part $\mathbb{Q}_p/\mathbb{Z}_p$ of the circle (Definition 75.1.1 ad finem).

The second equality $\Lambda_p^\vee = C(G_p, \mathbb{Q}_p/\mathbb{Z}_p)$ is the content. Write $\Lambda_p = \varprojlim_U \mathbb{Z}_p[G_p/U]$ as an inverse limit of finite $\mathbb{Z}_p$-modules. The dual of a cofiltered inverse limit of compact groups is the filtered direct limit of duals (Weil 1940 Ch. II §5 Prop. 7; Bourbaki *TG* III §3.5 Prop. 7):

$$\Lambda_p^\vee \;=\; \Big(\varprojlim_U \mathbb{Z}_p[G_p/U]\Big)^\vee \;=\; \varinjlim_U \mathbb{Z}_p[G_p/U]^\vee.$$

At each finite level, $\mathbb{Z}_p[G_p/U]$ is a finitely generated free $\mathbb{Z}_p$-module of rank $|G_p/U|$; its p-adic Pontryagin dual is

$$\mathbb{Z}_p[G_p/U]^\vee \;=\; \mathrm{Hom}(\mathbb{Z}_p[G_p/U], \mathbb{Q}_p/\mathbb{Z}_p) \;=\; \mathrm{Maps}(G_p/U, \mathbb{Q}_p/\mathbb{Z}_p),$$

the group of all maps on the finite coset space G_p/U with values in $\mathbb{Q}_p/\mathbb{Z}_p$; no continuity hypothesis because G_p/U is finite discrete. Taking the direct limit over $U \trianglelefteq G_p$:

$$\varinjlim_U \mathrm{Maps}(G_p/U, \mathbb{Q}_p/\mathbb{Z}_p) \;=\; \mathrm{Maps}_{\mathrm{loc.cst.}}(G_p, \mathbb{Q}_p/\mathbb{Z}_p) \;=\; C(G_p, \mathbb{Q}_p/\mathbb{Z}_p),$$

the space of locally constant $\mathbb{Q}_p/\mathbb{Z}_p$-valued functions on G_p. The last equality uses that on a profinite group, continuous = locally constant for $\mathbb{Q}_p/\mathbb{Z}_p$-values (compactness plus discreteness of the target: every continuous function from a compact to a discrete space has finite image and therefore factors through a finite quotient, Bourbaki *TG* I §10 Prop. 8).

The G_p-action on Λ_p by right translation induces an action on $\Lambda_p^\vee$ by the dual (left) translation, recovering the standard G_p-module structure on $C(G_p, \mathbb{Q}_p/\mathbb{Z}_p)$. □

Compact Modules and Discrete Comodules for the Dual Tensor Product

Let $D = \mathbb{Q}_p/\mathbb{Z}_p$. Compact $\mathbb{Z}_p$-modules and discrete p-primary torsion modules are exchanged by $M \mapsto M^\vee = \mathrm{Hom}_{\mathrm{cts}}(M, D)$. On compact modules use the completed tensor product, the inverse limit of tensor products of finite quotient modules. On discrete modules define

$$M \odot N = (M^\vee \mathbin{\widehat{\otimes}_{\mathbb{Z}_p}} N^\vee)^\vee.$$

The unit for $\odot$ is D, since $D^\vee = \mathbb{Z}_p$. Associativity, symmetry and the unit maps are the duals of those for the completed tensor product, using the natural double-dual isomorphisms.

Theorem 75.1.4 *(continuous duality with its monoidal carrier).* Let Λ be a compact unital $\mathbb{Z}_p$-algebra with continuous multiplication, and put $C = \Lambda^\vee$. Multiplication and unit dualize to

$$\Delta : C \longrightarrow C \odot C, \qquad \varepsilon : C \longrightarrow D.$$

These make C a counital coalgebra for $\odot$. Continuous compact right Λ-modules are contravariantly equivalent to discrete right C-comodules for $\odot$, by exact Pontryagin duality. For $\Lambda = \Lambda_p, C = C(G_p, D)$. On bounded derived categories the equivalence is

$$\mathrm{D}^b(\mathrm{Mod}^{\mathrm{comp}}\text{-}\Lambda_p) \simeq \mathrm{D}^b(\mathrm{Comod}_\odot(C(G_p, D)))^{\mathrm{op}}. \tag{75.2}$$

This statement concerns the dual tensor product, not ordinary $\mathbb{Z}_p$-coalgebras.

Proof. At finite p-group level evaluation identifies every module with its double dual. Pontryagin duality exchanges the inverse limits of finite compact quotients with the direct limits of their discrete duals. It is exact: at finite level a character on a subgroup extends because D is divisible, and passage through these dual limits preserves the resulting short exact sequences.

Dualize associativity and the unit identities of Λ. The resulting diagrams are precisely coassociativity and the counit identities for C with respect to $\odot$. For a compact right module M, dualizing its action gives

$$(M \widehat{\otimes} \Lambda \longrightarrow M)^\vee : M^\vee \longrightarrow M^\vee \odot C.$$

The module axioms become the comodule axioms. Conversely, dualize a coaction and use double duality to recover the continuous action. The two constructions are inverse on objects and morphisms, so give an exact anti-equivalence.

For a bounded cochain complex $M^\bullet$, use $(M^\vee)^n = (M^{-n})^\vee$ with differential $d(f) = (-1)^{n+1} f\, d_M$. Exactness gives $H^n(M^\vee) = H^{-n}(M)^\vee$, so acyclic complexes and quasi-isomorphisms are preserved. Passing to the bounded derived categories proves (75.2). □

Remark 75.1.5 *(ordinary tensor obstruction and reduction modulo p).* Already for $\Lambda = \mathbb{Z}_p$, the dual is D, and $D \otimes_{\mathbb{Z}_p} D = 0$: if $p^n x = 0$, write $y = p^n z$, so $x \otimes y = p^n x \otimes z = 0$. Also $\mathrm{Hom}_{\mathbb{Z}_p}(D, \mathbb{Z}_p) = 0$. Thus this nonzero module admits no ordinary counital $\mathbb{Z}_p$-coalgebra structure. The counit above has target D, the unit of the correct dual monoidal category.

For a compact module there is the elementary natural identity

$$(M/pM)^\vee \cong M^\vee[p].$$

A character factors through M/pM exactly when it is killed by p. This degree-zero identity supplies neither a derived base-change equivalence nor the ordinary field-coalgebra comodule–contramodule correspondence. To use continuous duality in the arithmetic Positselski comparison of Remark 46.1.6, one must construct the appropriate completed monoidal carrier, its bar and cobar functors, and their compatibility with the stated Selmer and pairing data. The compact/discrete duality above is a concrete input to that construction, not its completion.

75.2 Derived Completion

Derived Completion over a Noetherian Ring

Let R be a commutative Noetherian ring and $I \subset R$ an ideal. For $M \in \mathrm{D}(R)$, put

$$\mathrm{L}\Lambda_I(M) = \mathrm{Rlim}_n\big(M \otimes^{\mathbb{L}}_R R/I^n\big).$$

The tensor product and inverse limit are both derived. A complex N is derived I-complete when $\mathrm{RHom}_R(R[1/f], N) = 0$ for every $f \in I$. For the Noetherian ring considered here, the displayed construction is the reflection into these complexes. Without the Noetherian hypothesis, that identification needs additional conditions on the ideal.

THEOREM 75.2.1 *(Noetherian derived completion).* The functor $\mathrm{L}\Lambda_I$ is left adjoint to the inclusion of derived I-complete complexes in $\mathrm{D}(R)$. If every $H^j(M)$ is finitely generated over R, then

$$H^j(\mathrm{L}\Lambda_I M) \cong \varprojlim_n H^j(M)/I^n H^j(M).$$

In particular, the natural map from M to its derived completion is an equivalence when these finite cohomology modules are already I-adically complete.

Proof. The adjunction is Stacks Project, Tag 0922. Its proof compares the towers of Koszul complexes and ideal quotients using the Noetherian hypothesis.

The cohomology assertion is Tag 0A06. For a bounded above complex with finite cohomology, choose finite free resolutions. Completion is exact on the finite modules occurring in their kernels and images, by Artin–Rees. It therefore commutes with their cohomology. Truncation and the finite cohomological dimension of derived completion give the stated unbounded version. □

This theorem concerns cohomology modules and derived quotients. It does not identify completion of every chosen complex term by term with its derived completion. The following calculation records exactly the inverse-limit term that must be controlled.

Tor Amplitude and Reduction Towers

Definition 75.2.2 *(bounded Tor amplitude).* A complex $A \in \mathrm{D}(R)$ has *bounded Tor amplitude* if there are integers $a \le b$ such that $H^j(A \otimes^{\mathbb{L}}_R N) = 0$ outside $[a, b]$ for every R-module N in degree zero. For an ordinary flat algebra A, this interval is $[0, 0]$. For a dg algebra the condition refers to its underlying complex. It does not assert a Tor bound for every A-module.

THEOREM 75.2.3 *(cohomology of a reduction tower).* For $M \in \mathrm{D}(R)$, write $K_n = M \otimes^{\mathbb{L}}_R R/I^n$. There is a natural exact sequence

$$0 \longrightarrow \varprojlim_n{}^1 H^{j-1}(K_n) \longrightarrow H^j(\mathrm{L}\Lambda_I M) \longrightarrow \varprojlim_n H^j(K_n) \longrightarrow 0.$$

If the transition maps on $H^{j-1}(K_n)$ are surjective, the left term vanishes. More generally it vanishes under the Mittag–Leffler condition: for each fixed n, the images from all sufficiently large indices in $H^{j-1}(K_n)$ are equal.

Proof. Choose a complex model of the tower. Its derived limit has the defining triangle

$$\mathrm{Rlim}_n K_n \longrightarrow \prod_n K_n \xrightarrow{1-s} \prod_n K_n \longrightarrow (\mathrm{Rlim}_n K_n)[1],$$

where the n-th component of s is the transition map applied to the $(n+1)$-st component. Products of R-modules are exact, so the cohomology of these products is the product of their cohomologies. The long exact sequence identifies the outer terms with the kernel and cokernel of $1 - s$. These are $\varprojlim$ and $\varprojlim{}^1$, respectively.

For a surjective tower, one solves $(1 - s)x = y$ recursively, choosing each next component by surjectivity. Thus its cokernel vanishes. The same vanishing for a Mittag–Leffler tower is Stacks Project, Tag 07KV, Lemma 15.88.1. Consequently, under the stated hypothesis,

$$H^j(\mathrm{L}\Lambda_I M) \cong \varprojlim_n H^j(K_n).$$

□

Flatness of the coefficient algebra does not imply surjectivity on this cohomology tower. Take $R = A = \mathbb{Z}_p$ and $M = [R \xrightarrow{p} R]$, in degrees zero and one. Then

$$H^0(M \otimes^{\mathbb{L}}_R R/p^n) = p^{n-1}R/p^n \cong \mathbb{F}_p.$$

Every transition on these groups is zero, hence is not surjective. The tower is nevertheless Mittag–Leffler, with eventual image zero. This example separates surjectivity from the weaker condition actually used in the theorem.

Ordinary quotients can also miss the entire answer. For $D = \mathbb{Q}_p/\mathbb{Z}_p$, multiplication by p^n is surjective with kernel $D[p^n] \cong \mathbb{Z}/p^n$. Thus $D/p^n D = 0$, whereas

$$D \otimes^{\mathbb{L}}_{\mathbb{Z}_p} \mathbb{Z}/p^n \simeq D[p^n][1], \qquad \mathrm{L}\Lambda_{(p)} D \simeq \mathbb{Z}_p[1].$$

The transition on the kernels is multiplication by p. Writing an element as a/p^n identifies this transition with reduction $\mathbb{Z}/p^{n+1} \to \mathbb{Z}/p^n$. Its inverse limit is $\mathbb{Z}_p$, and its first derived limit vanishes by surjectivity. The coefficient algebra $A = \mathbb{Z}_p$ is flat in this example as well.

Remark 75.2.4 *(the arithmetic bar requires its coefficient model).* To apply these results to an arithmetic bar construction, one must specify its complex over the chosen Noetherian ring. Its residue, differential, and completed tensor operations must be actual maps on that complex. Torsion-freeness over $\mathbb{Z}_p$ does not imply flatness over $\mathbb{Z}_p[[T]]$: the module $\Lambda/(T)$ has $\mathrm{Tor}^{\Lambda}_1(\Lambda/(T), \Lambda/(T)) = \Lambda/(T)$. The arithmetic coefficient modules cannot be replaced by free oscillator coefficients without a comparison.

For a chosen procyclic $\Gamma \cong \mathbb{Z}_p$, $\mathbb{Z}_p[[\Gamma]]/p \cong \mathbb{F}_p[[T]]$. The full local group G_p in (75.1) is a different input. A map to a procyclic quotient does not identify its completed group algebra with the one-variable power-series ring.

Corollary 75.2.5 *(complete finite coefficient complexes).* Let $R = \mathbb{Z}_p[[T]]$, and suppose $M \in \mathrm{D}(R)$ has finitely generated cohomology in every degree. Then $M \to \mathrm{L}\Lambda_{(p)} M$ is an equivalence. The same holds for its derived reduction $M \otimes^{\mathbb{L}}_R R/p$.

Proof. The ring R is Noetherian and p-adically complete. Finite R-modules are therefore p-adically complete. Apply Theorem 75.2.1 to the cohomology of M. The two-term free resolution of R/p shows that the reduced complex also has finite cohomology in every degree. The same theorem applies to it. □

For a coderived or contraderived arithmetic recipient, completion must instead be checked internally, as in Theorem 46.1.5. A comparison with ordinary derived complexes must detect the unit and counit cofibers before the preceding corollary can be used there. These remain requirements of Remark 46.1.6(2).

75.3 Reduction and Lifting

Matlis Duality on the Compact Heart

Let R be a complete Noetherian local ring with maximal ideal $\mathfrak{m}$ and residue field $k = R/\mathfrak{m}$. The *Matlis dual* of an R-module M is

$$M^{\mathrm{M}} := \mathrm{Hom}_R(M, E(k)),$$

where $E(k)$ is the injective hull of k as R-module (Matlis 1958 Pacific J. Math. 8, §3).

THEOREM 75.3.1 *(Matlis duality).* Let R be a complete Noetherian local ring with residue field k. The Matlis dual $(-)^{\mathrm{M}}$ is a contravariant exact functor $R\text{−mod} \to R\text{−mod}$, and restricts to an anti-equivalence between the categories of finitely generated (Noetherian) R-modules and Artinian R-modules. $(-)^{\mathrm{MM}}$ is the identity on both categories: finitely generated modules are reflexive, and Artinian modules are reflexive, under Matlis dualisation.

The proof is Matlis 1958 Thm. 4.2 and Thm. 5.2; modern accounts in Bruns–Herzog 1993 *Cohen–Macaulay Rings* Ch. 3 §2, and Enochs–Jenda 2000 *Relative Homological Algebra* Ch. 5.

Lifting from Mod-p to Characteristic Zero

Let $\Lambda_p \to \mathbb{F}_p$ be the augmentation to the residue field (reduction modulo p combined with augmentation of the group algebra). A *mod-p representation* of Λ_p is an $\mathbb{F}_p$-vector space $\overline{V}$ with a continuous Λ_p-action factoring through $\mathbb{F}_p$. A *lift* of $\overline{V}$ to characteristic zero is a continuous Λ_p-module V with $V \otimes_{\Lambda_p} \mathbb{F}_p = \overline{V}$.

THEOREM 75.3.2 *(conservativity on a regular local coefficient model).* Let $R = \mathbb{Z}_p[[T]]$, with maximal ideal $\mathfrak{m} = (p, T)$ and residue field $k = \mathbb{F}_p$. On bounded complexes with finitely generated cohomology,

$$- \otimes^{\mathbb{L}}_R k : \mathrm{D}^b_{\mathrm{fg}}(R) \longrightarrow \mathrm{D}^b_{\mathrm{fg}}(k)$$

is conservative: it detects equivalences. It is not faithful on morphisms.

Proof. The resolution bound of Proposition 46.3.3 makes these complexes perfect, so the displayed functor has its stated target. Let K be the cone of a map whose reduction is an equivalence. If $K \neq 0$, choose the largest n with $H^n(K) \neq 0$. The top cohomology of $K \otimes^{\mathbb{L}}_R k$ is $H^n(K) \otimes_R k$. Its vanishing contradicts Nakayama's lemma for the nonzero finite module $H^n(K)$. Thus $K = 0$.

For failure of faithfulness, multiplication by p on R is nonzero and becomes zero after reduction. □

This is a theorem about the specified regular local ring. Applying it to an arithmetic completed group algebra requires its actual coefficient model and a comparison of recipients. Its residue field is obtained by killing both p and T. Under Matlis duality, the dual of $M/\mathfrak{m}M$ is the $\mathfrak{m}$-annihilated submodule, not merely the p-torsion submodule.

COROLLARY 75.3.3 *(detection for a supplied comparison map).* A supplied map in $\mathrm{D}^b_{\mathrm{fg}}(R)$ is an equivalence if its derived reduction to k is. For intrinsic derived p-complete recipients, the corresponding criterion is Proposition 46.4.5.

Proof. Apply the preceding theorem to the map in the first case, and the cited proposition to its complete cofiber in the second. □

Neither statement constructs a lift of an arbitrary residual representation. For instance, $R/(T)$ and $R/(T-p)$ are distinct $\mathbb{Z}_p$-free lifts of the same module modulo p. Completion of an inflated residual module also does not remove its p-torsion. The arithmetic adjunction and the comparison of its reduced unit and counit remain required in Remark 46.1.6(3).

75.4 Koszul-Dual Bost–Connes

Bost–Connes System

On $\mathcal{K} = \ell^2(\mathbb{N}_{>0})$ define $\mu_n \delta_N = \delta_{nN}$ and $e(r)\delta_N = \exp(2\pi i r N)\delta_N$ for $r \in \mathbb{Q}/\mathbb{Z}$. Use the concrete operator algebra

$$\mathcal{A}_{\mathrm{rep}} = C^*(\mu_n, e(r) : n \geq 1, r \in \mathbb{Q}/\mathbb{Z}) \subset \mathcal{B}(\mathcal{K}). \tag{75.3}$$

The shifts are isometries, $\mu_m \mu_n = \mu_{mn}$, and

$$\mu_n^* e(r) \mu_n = e(nr), \qquad \mu_n e(r) \mu_n^* = \frac{1}{n} \sum_{ns=r} e(s).$$

The first identity follows on each δ_N; for the second the sum of the n roots of unity vanishes unless $n \mid N$, in which case both sides multiply δ_N by $\exp(2\pi i r N/n)$. For $H\delta_N = \log N\, \delta_N$, conjugation by e^{itH} fixes $e(r)$ and sends μ_n to $n^{it}\mu_n$. The heat trace is $\sum_N N^{-\beta} = \zeta(\beta)$ for $\beta > 1$. These formulas specify the bounded operator model needed for the local comparison. They do not identify an arithmetic cobar algebra with it, or assert a classification of KMS states or a group-algebra presentation. Write $\mathbb{A}^{\mathrm{BC}}$ for an intended Bost–Connes algebra only after specifying its presentation and representation comparison.

Adele Class Space and Enveloping Sheaf

The *adele class space* of Connes 1999 (Selecta Math. 5, §1.4; Consani–Marcolli 2006 *Noncommutative Geometry, Arithmetic, and Related Topics* §2) is

$$X_{\mathrm{AC}} := \mathbb{A}_{\mathbb{Q}}/\mathbb{Q}^*,$$

the quotient of the full adele ring by the diagonal multiplicative action. Its non-Hausdorff quotient geometry is different from the occupation-basis representation of (75.3). A comparison with a noncommutative algebra model requires the specified site, algebra, representation and trace maps. A common zeta scalar does not construct a Hilbert duality between these models.

Definition 75.4.1 *(sheaf comparison data).* A sheaf comparison requires a specified site on the adele-class object, a sheaf of algebras $\mathcal{E}^{\mathrm{BC}}$ on that site, and an identification of its appropriate global sections with the chosen operator algebra. It also requires a sheaf model of the arithmetic cobar construction and a map preserving multiplication, differential, coefficients and the stated completion. These are hypotheses on a comparison. A phrase such as support on an adelic fibre does not define restriction maps or such an identification.

Koszul-Dual Description

Question 75.4.2 *(arithmetic cobar and Bost–Connes comparison).* Specify the coefficients, differential and topology of the primary arithmetic cobar algebra A_{prim}. Construct a comparison with a specified dg model of the intended Bost–Connes algebra whose chosen operator representation is compatible with (75.3). The desired quasi-isomorphism is

$$A_{\mathrm{prim}} \simeq B_{\mathrm{BC}} \qquad \text{in a common specified category of dg algebras.} \tag{75.4}$$

The problem includes coefficient comparison and completion; a C^*-algebra is not automatically a dg $\mathbb{Z}_p[[\Gamma]]$-algebra. The sheaf data in Definition 75.4.1 are additional requirements for a geometric realization of this comparison.

There is a necessary test on the proposed prime-power generator map. The equality of energies $\log(p^k) = k \log p$, using Convention 28.7.1(ii), permits the proposed association $b_{p,k} \mapsto \mu_{p^k}$. It does not prove the algebra relation. For an explicit algebraic example, let $Q = \mathbb{Q}[b_{p,k} : p \text{ prime}, k \geq 1]$. Its map to $\mathbb{Q}[t_p : p \text{ prime}]$, $b_{p,k} \mapsto t_p^k$, has kernel

$$(b_{p,k} - b_{p,1}^k : p \text{ prime}, k \geq 2).$$

Indeed quotienting by these relations leaves a polynomial ring freely generated by the classes of $b_{p,1}$; the evident inverse sends t_p to that class. Thus this map is surjective but not injective. Graded commutativity alone does not impose these relations. In a dg model one would instead need explicit boundaries or homotopies and a proof that the induced map is a quasi-isomorphism. The restricted-dual calculation $\eta_1^k = k!\eta_k$ of Theorem 46.5.1 also shows the effect of integral normalization. Phase operators, adjoints and their covariance require further generators and relations beyond the commuting shift subalgebra.

Remark 75.4.3 *(pairing compatibility).* If the comparison in (75.4) is constructed together with compatible pairing maps, those maps transport the specified pairing. This formal consequence does not construct the comparison or its compatibility. In particular, the numerical energy match does not settle the Koszul-dual Bost–Connes requirement of Remark 46.1.6(5).

75.5 Local Constructions and Arithmetic Comparison Hypotheses

Combined Theorem

Remark 75.5.1 *(distinct comparison inputs).* The continuous-dual, derived-completion and lifting constructions have their stated coefficient and finiteness hypotheses. Their application to an arithmetic object must verify those hypotheses. The scalar calculation in Chapter 66 concerns a selected one-mode Euler product and a Gaussian Mellin pairing. It does not identify the arithmetic cobar character or its pairing. The Bost–Connes comparison remains Question 75.4.2; it is not reduced to a match of generator energies or to an unnamed sheaf duality.

Arithmetic Positselski Comparison

Question 75.5.2 *(equivalence on the intended arithmetic carrier).* For the specified arithmetic dg coalgebra and completed dual, establish

$$\mathrm{D}^{\mathrm{co}}_{\Lambda_p}(C\text{-comod}) \simeq \mathrm{D}^{\mathrm{ctr}}_{\Lambda_p}(C^\vee\text{-contramod})$$

with the coefficient, topology and finiteness hypotheses required by Theorem 46.1.5. Its comparison with the Bost–Connes representation additionally requires (75.4), and the character and pairing intertwiners. Neither a scalar Euler product nor the local divisor substitution supplies these maps.

Question 75.5.3 *(central classes and Tate duality).* The intended arithmetic relation is

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s).$$

The right side is the classical functional equation. A proof relating it to the left side must identify the arithmetic obstruction classes under a compatible pairing. Energy-zero evaluation on a polynomial restricted dual does not provide this identification. The noncommutative Iwahori extension requires its own additional comparisons.

The Five Comparison Requirements

Input	Construction	Arithmetic requirement
(1)	Continuous duals	Specified topology and duality
(2)	Derived completion	Applicable hypotheses and base change
(3)	Lifting	Existence and the required morphism properties
(4)	Selected scalar character	Character and pairing comparison maps
(5)	Bost–Connes comparison	dg algebra, coefficients and completion

Table 75.1: The constructions required on the intended arithmetic carrier. The scalar one-mode calculation does not supply the last two comparisons.

Remark 75.5.4 *(domain and comparison).* The local compactness, completion and duality results must be used on their actual carriers. Even when those local hypotheses hold, an arithmetic identification must preserve the operators and pairings in question. These requirements remain in the abelian sector; they are not all consequences of excluding the nonabelian Iwahori case.

Remark 75.6.1 *(roles of the constructions).* Continuous duals, derived completion, lifting, and arithmetic operator comparison answer different questions. A scalar identity obtained from Tate's Mellin transform and the one-mode Euler product does not establish an algebra or pairing comparison. The missing maps remain the objects of Question 75.4.2.

Chapter 76

Full $\mathcal{V}^{\mathrm{prim}}$ P3 and the Koszul–Petersson Compatibility on the Discrete Core

The prime Gibbs model of Chapter 67 constructs a state, its Hilbert–Schmidt GNS space, closed modular operators and an actual comparison with a global state's prime cyclic subspace. The Koszul–Petersson problem additionally asks for the arithmetic placement and pairing maps of Hypothesis 67.1.1. This chapter describes conditional transport across the cuspidal sectors once those maps are supplied. Classical temperedness results identify some of the relevant domains; they do not prove the pairing comparison. The full arithmetic comparison remains Question 67.1.2.

76.1 Tempered Cuspidal Pairing Comparison

Throughout the pairing consequences below, the notation $\langle v, w\rangle^{\mathrm{Pet}}$ means the pullback $\langle \iota v, \iota w\rangle^{\mathrm{Pet}}$ along the specified injective arithmetic placement. No placement is inferred from a spectral decomposition of the automorphic target.

Theorem 76.1.1 *(conditional tempered cuspidal comparison).* Assume Hypothesis 67.1.1, including all local ramified comparisons and the adelic extension, on the chosen tempered cuspidal arithmetic domain $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$. Then

$$\langle v, w\rangle^{\mathrm{Pet}} = \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}$$

on that domain. Temperedness alone is not the comparison hypothesis.

Proof. The local maps identify the pairings with the same normalized Hilbert forms. Their identities multiply on elementary restricted tensors and extend by the explicitly assumed continuity or regularization, as proved in Theorem 67.3.8. The prime cyclic unitary in Theorem 67.2.5 intertwines only the specified prime algebra and state. It does not replace the arithmetic or Whittaker comparison maps. □

Remark 76.1.2 *(temperedness and modular domains).* Temperedness is a representation-theoretic condition on the selected automorphic sector. It is not a boundedness hypothesis for modular theory. In the actual one-prime Gibbs GNS model, $\Delta E_{ij} = p^{-\beta(i-j)} E_{ij}$, and both Δ and its inverse are unbounded; their maximal domains are given in Lemma 67.2.3. The GNS space is $\mathrm{HS}(\ell^2(\mathbb{N}_0))$. The proved unitary reaches a prime cyclic subspace, without identifying the full critical GNS representation, the phase operators or a Petersson space with an occupation tensor product.

76.2 Non-Tempered Cuspidal Representations: Deligne and Kim–Shahidi

The Non-Tempered Locus

Cuspidal automorphic representations of $GL_2/\mathbb{Q}$ decompose as $\pi = \otimes'_v \pi_v$, with archimedean component π_∞ of one of three types: a holomorphic discrete series D_k of weight $k \geq 2$; a Maass cusp form with Laplace eigenvalue $\lambda = 1/4 + r^2$ ($r \in \mathbb{R}$ tempered, $r \in i\mathbb{R}$ non-tempered); or a character twist.

Finite places carry Satake parameters (α_p, β_p) with $\alpha_p\beta_p = 1$ (unitarity) and $\max(|\alpha_p|, |\beta_p|) = p^{\theta_p}$. Temperedness is the condition $\theta_p = 0$ at all p; the Ramanujan conjecture asserts temperedness for all cuspidal π.

- **Holomorphic sector.** $\pi_\infty = D_k$ for $k \geq 2$. Deligne 1974 *Publ. IHES* 43, La conjecture de Weil I, gives the Ramanujan bound unconditionally: $|a_p| \leq 2p^{(k-1)/2}$ for the Hecke eigenvalue a_p of a holomorphic weight-k newform, which is temperedness $|\alpha_p| = |\beta_p| = p^{(k-1)/2} \cdot 1$ after normalisation (in the analytic normalisation π unitary, $|\alpha_p| = |\beta_p| = 1$). Weight-1 holomorphic forms are covered by Deligne–Serre 1974 *Ann. Sci. ENS. 7*, via the Artin conjecture for two-dimensional odd Galois representations attached to weight-1 newforms.
- **Maass sector.** π_∞ is a Maass cusp form with complementary-series parameter $r = it$, $0 < t \leq 1/2$, at ∞; temperedness at ∞ is $t = 0$. At finite places, non-temperedness is $\theta_p > 0$. The Ramanujan conjecture for Maass forms is open: the best current bound is Kim–Sarnak 2003 Duke Math. J. 119 $\theta_p \leq 7/64$, improving earlier Luo–Rudnick–Sarnak 1995 and Kim–Shahidi 2002 *Ann. Math.* 155, which used the symmetric-square and symmetric-fourth-power lifts to bound $\theta_p \leq 1/9$ via Jacquet–Piatetski-Shapiro–Shalika 1983.

Holomorphic Temperedness and the Pairing Comparison

Theorem 76.2.1 *(conditional Koszul–Petersson comparison on the holomorphic sector).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. Let $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}} \subset \mathcal{V}^{\mathrm{prim}}$ denote the subspace spanned by holomorphic cuspidal automorphic representations of $GL_2/\mathbb{Q}$, namely those π with $\pi_\infty = D_k$ for some $k \geq 1$. For all $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}.$$

The identification is conditional on the arithmetic comparison maps.

Proof. By Deligne 1974 (weight $k \geq 2$) and Deligne–Serre 1974 (weight $k = 1$), every holomorphic cuspidal representation of $GL_2/\mathbb{Q}$ is tempered at every finite place: $|\alpha_p| = |\beta_p| = 1$ at each p. Temperedness at ∞ for $\pi_\infty = D_k$ is automatic (discrete-series representations are tempered by Harish-Chandra's definition). The holomorphic cuspidal sector is therefore a subsector of the tempered cuspidal sector: $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}} \subset \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$. Theorem 76.1.1 gives (76.2.1) under its arithmetic comparison hypotheses. Deligne's bound supplies temperedness, not those maps. □

Remark 76.2.2 *(domain of Deligne 1974: holomorphic sector only).* Deligne 1974 establishes the Ramanujan–Petersson bound for the Hecke eigenvalues of a holomorphic weight-k cusp form via the Riemann hypothesis for ℓ-adic cohomology of a suitable Kuga–Sato variety. The bound transfers to temperedness of the associated automorphic representation at every finite prime. Deligne 1974 applies to holomorphic cuspidal forms; for Maass cusp forms, no algebraic variety whose Frobenius eigenvalues give the Hecke eigenvalues is available, and the Ramanujan bound in the Maass sector is an open problem. The current state of the art on the Maass sector is Kim–Sarnak 2003 $\theta \leq 7/64$; this is a sub-convex Ramanujan bound, strictly weaker than full temperedness.

The Maass Sector: Conditional on Ramanujan

Theorem 76.2.3 *(Koszul–Petersson on the Maass cuspidal sector, conditional).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. *(on*

the Ramanujan bound for Maass cusp forms of $GL_2/\mathbb{Q}$). Let $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}} \subset \mathcal{V}^{\mathrm{prim}}$ denote the subspace spanned by Maass cuspidal automorphic representations of $GL_2/\mathbb{Q}$. Assume the Ramanujan bound $\theta_p = 0$ at every finite prime, and assume archimedean temperedness for every Maass form in the chosen domain. For all $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}.$$

Proof. Under the stated finite-place and archimedean temperedness assumptions, $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}} \subset \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$; Theorem 76.1.1 then applies. □

Proposition 76.2.4 *(local error bounds and adelic summability).* The Satake exponent bound $\theta_p \le 7/64$ gives $|\alpha_p|, |\beta_p| \le p^{7/64}$ in the unitary unramified normalization. An estimate of the arithmetic pairing discrepancy such as

$$\left|\langle v_p, w_p\rangle_p^{\mathrm{Pet}} - \langle v_p, \sigma_p(w_p)\rangle_p^{\mathrm{Koszul}}\right| \le C_p\, p^{-25/64}$$

requires separate control of the actual comparison maps and their local norms. Even a uniform bound on C_p would not make this majorant summable over all primes.

Proof. The first inequality restates the exponent bound. The series $\sum_p p^{-25/64}$ diverges, since $p^{-25/64} \ge p^{-1}$ and the prime harmonic series diverges. Thus this proposed majorant cannot justify absolute adelic summability. No estimate of the displayed pairing difference is deduced from the Satake bound alone. □

Remark 76.2.5 *(the selected residual sector).* A chosen residual line with a normalized vector gives a direct one-dimensional pairing calculation once its arithmetic placement and Koszul normalization have been specified. This does not identify every residual automorphic representation with one Fock vacuum. The full discrete comparison requires a placement and orthogonal pairing decomposition for every included residual summand, in addition to the cuspidal comparisons.

76.3 The Eisenstein Density Mismatch and Domain Restriction

The Mismatch

We recall the mismatch identified in Chapter 67:

Proposition 76.3.1 *(the fixed scalar continuum models).* On the domain U of Definition 67.5.1, the proposed scalar coefficients, with $d(s) = |\xi(2s)|^{-2} > 0$, are

$$P(s) = (1 + |M(s)|^2)|\xi(2s)|^{-2} = 2d(s),$$
$$K(s) = \frac{\xi(2s)}{\xi(2s-1)}|\xi(2s)|^{-2} = M(s)^{-1}d(s).$$

They satisfy $d(s) \le |P(s) - K(s)| \le 3d(s)$. Their realization as coefficients of actual continuous pairings is an additional construction, not part of this scalar calculation.

Proof. This is Theorem 67.5.3, using the functional equation, conjugation and triangle inequalities. □

Domain Restriction

Definition 76.3.2 (discrete-spectrum core of $\mathcal{V}^{\mathrm{prim}}$). Fix the placement of Hypothesis 67.4.2 and a specified residual line with normalized vector. The *selected discrete-spectrum core* is

$$\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \;:=\; \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp}} \;\oplus\; \mathcal{V}^{\mathrm{prim}}_{\mathrm{res}},$$

the chosen arithmetic carrier placed inside $L^2_{\mathrm{disc}}([GL_2]) = L^2_{\mathrm{cusp}} \oplus L^2_{\mathrm{res}}$ under the placement map ι of Hypothesis 67.4.2. No full arithmetic placement into a continuous automorphic spectrum is inferred from this chosen discrete placement.

Theorem 76.3.3 *(Koszul–Petersson identity on the discrete-spectrum core).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. *(conditional on the arithmetic comparison maps on every sector; with the additional Ramanujan assumption on the Maass sector).* For all $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}. \tag{76.1}$$

The identification holds:

- on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$ under the comparison hypotheses (Theorem 76.1.1);
- on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}} \subset \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$ under the comparison hypotheses (Theorem 76.2.1);
- on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$ conditional on Ramanujan (Theorem 76.2.3);
- on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{res}}$ (one-dimensional, vacuum-generated) by direct calculation at the Fock vacuum.

Proof. $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} = \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp}} \oplus \mathcal{V}^{\mathrm{prim}}_{\mathrm{res}}$ decomposes orthogonally under the adelic inner product (Langlands 1966 §6; Moeglin–Waldspurger Ch. II). On $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp}}$, split by archimedean type: $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp}} = \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}} \oplus \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$ (Gelfand–Fomin–Piatetski-Shapiro 1969 *Representation Theory and Automorphic Functions* Ch. II). The holomorphic piece is closed by Theorem 76.2.1 under the comparison hypotheses; the Maass piece by Theorem 76.2.3 under Ramanujan. For the specified residual line, let v_0 be its chosen unit vector and assume the arithmetic comparison sends its normalized vacuum to v_0. Then $\langle a v_0, b v_0\rangle = a\overline{b}$, and the stipulated Koszul normalization gives the same value. This calculation uses the unit-vector datum, not an assertion that the whole automorphic quotient has volume one. □

Remark 76.3.4 (discrete and continuous domains). The conditional identity (76.1) concerns the selected discrete carrier with its assumed placement. It makes no assertion about the continuous automorphic spectrum. The scalar models P and K above differ in the fixed convention; identifying them with actual pairings and constructing a measure transport remain separate continuous-spectrum requirements.

Sufficiency for Li's Criterion

Proposition 76.3.5 *(domain restriction for the Li trace). (conditional on the H-P^{Ar} determinant-trace realisation and on the trace map placing Li's zero sum in the discrete sector).* Li's coefficients $\lambda_n = \sum_\rho (1 - (1 - 1/\rho)^n)$ (Theorem 44.3.1) sum over the discrete non-trivial zeros of ζ. The non-trivial zeros of ζ contributing to the Li sum are exactly the zeros of $\xi_{\mathbb{R}}$, all of which are discrete; the Eisenstein continuous spectrum contributes no term once the H-P^{Ar} trace has been identified with this zero sum. Eisenstein-series poles in ξ at $s = 0, 1$ are Tate poles (Remark 44.3.7), cancelled by the factor $s(s-1)/2$

in $\xi_{\mathbb{R}} = (1/2)s(s-1)\Lambda_\zeta$. The Hilbert–Pólya operator Θ_ξ of Hypothesis 44.3.2, if it exists, has regularised determinant divisor equal to the non-trivial zero divisor, whose ordinate multiset is discrete. The regularised trace $\mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n)$ of Proposition 44.3.8 then integrates against the discrete zero distribution: the Eisenstein continuous spectrum is not in the domain of the trace.

Proof. Li's sum is over non-trivial zeros of ζ, equivalently zeros of $\xi_{\mathbb{R}}$. The non-trivial zeros are a countable discrete set of density $\sim T\log T/(2\pi)$ in $[0,T]$ (von Mangoldt–Riemann; Titchmarsh 1986 Ch. II). No Eisenstein-series pole contributes to this set: Eisenstein poles at $s=0,1$ in Λ_ζ are exactly the Tate poles eliminated by the factor $s(s-1)/2$ in the Li normalisation (Remark 44.3.7). The zero divisor of $\xi_{\mathbb{R}}$ is therefore discrete. Under the H-P^{Ar} hypothesis it identifies with the determinant divisor and Weil–Connes trace of Θ_ξ (Hypothesis 44.3.2). The Li-transform trace $\mathrm{Tr}_{\mathrm{reg}}(\mathcal{L}_n)$ equals the sum over this discrete distribution only after that determinant-trace identification. □

Corollary 76.3.6 *(conditional Li path on the discrete core).* Assume also the determinant-trace realization and the explicit trace-placement comparison of Proposition 76.3.5, placing the Li trace on this same discrete domain. Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. *(conditional on Ramanujan for Maass forms at the cuspidal Maass boundary, on the H-P^{Ar} determinant-trace realisation, and on the Tamagawa-regularised assembly; with arithmetic pairing comparisons also assumed on the holomorphic and residual sectors).* The sufficient RH path of Theorem 44.6.1 receives a conditional P3 input from $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$ (Theorem 76.3.3); the Li criterion draws on discrete zero sums (Proposition 76.3.5) from the same domain, and the Eisenstein continuum is outside the domain of both inputs.

Proof. P3 on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$ is the conditional identity of Theorem 76.3.3. The Li path of Theorem 44.3.10 uses λ_n which are discrete-zero sums after the H-P^{Ar} spectral identification (Proposition 76.3.5). The Eisenstein continuum is outside the resulting trace domain. □

76.4 Langlands–Shahidi Normalisation

The Koszul–Petersson identity can be extended to the full $\mathcal{V}^{\mathrm{prim}}$, including the Eisenstein continuum, only after the Koszul pairing on principal-series inductions is identified with the positive Langlands–Shahidi Plancherel measure. The scalar N^{LS} of Definition 76.4.1 is not by itself such an identification. The discrete-core reduction of Section 76.3 is the construction used for the Li trace; the present section records the conditional continuum extension.

The Langlands–Shahidi Normalisation Factor

Definition 76.4.1 *(Langlands–Shahidi correction factor).* The *Langlands–Shahidi normalisation factor* on the principal-series induction $\mathrm{Ind}_B^G(\chi_s)$ is

$$N^{\mathrm{LS}}(s) \;:=\; \frac{\xi(2s-1)}{\xi(2s)} \qquad (\mathrm{Re}(s)=1/2).$$

On U, $|N^{\mathrm{LS}}(s)|=1$. In the scalar models above, $N^{\mathrm{LS}}K = d = P/2$; multiplication by the phase alone does not identify the two coefficients. The scalar coming from the Maass–Selberg truncation is part of the Plancherel convention, not part of the Langlands–Shahidi normalising operator.

Proposition 76.4.2 *(Koszul normalisation absorption). (on the identification of the bar–cobar Koszul spectral measure on the Eisenstein continuum with the Shahidi 2010 normalised Eisenstein measure;*

see Remark 76.4.3). Under the substitution $\langle\cdot,\cdot\rangle^{\mathrm{Koszul}} \to \langle\cdot,\cdot\rangle^{\mathrm{Koszul,LS}} = N^{\mathrm{LS}}(\cdot)\cdot\langle\cdot,\cdot\rangle^{\mathrm{Koszul}}$ on the Eisenstein continuum and the independent identification of the resulting quadratic form with the Shahidi L^2-normalised measure, the corrected Koszul normalisation is transported to the Maass–Selberg Plancherel normalisation:

$$\mathsf{Sh}_{\mathrm{LS}}\Big(\mathrm{lead}^{\mathrm{Koszul}}_{\mathrm{cont}}(s)\Big) \;=\; \mathrm{lead}^{\mathrm{Pet}}_{\mathrm{cont}}(s).$$

Here $\mathsf{Sh}_{\mathrm{LS}}$ denotes the Shahidi Plancherel transport. No raw equality of scalar densities is asserted before this transport is supplied.

Proof. On $\mathrm{Re}(s) = 1/2$, $|M(s)| = 1$ (Moeglin–Waldspurger §IV.3.10) gives $|N^{\mathrm{LS}}(s)| = 1$. Hence the Langlands–Shahidi factor changes the scattering phase but does not by itself turn the Koszul coefficient into a positive Plancherel density. The equality (76.4.2) is exactly the additional identification of the bar–cobar Eisenstein measure with the Shahidi 2010 L^2-normalised Eisenstein measure (Shahidi 2010 Thm 3.5.1). The scalar $1 + |M(s)|^2$ belongs to the Maass–Selberg truncation convention and is not inserted into N^{LS}. □

Remark 76.4.3 (Koszul–Shahidi measure identification). The ratio $\xi(2s)/\xi(2s-1)$ is a non-constant unit-modulus function on $\mathrm{Re}(s) = 1/2$; it equals $1/M(s)$ with $|M(s)| = 1$. The equality of Plancherel normalisations holds only when the Koszul Eisenstein measure is identified with the Shahidi 2010 L^2-normalised measure. Whether the bar–cobar Koszul definition (Beilinson–Drinfeld 2004 §3.5) assigns exactly this normalisation to the Eisenstein sector is an open problem. This gap does not affect Theorem 76.6.1: the main theorem uses the domain restriction of Section 76.3, not the Langlands–Shahidi extension.

Theorem 76.4.4 *(full-$\mathcal{V}^{\mathrm{prim}}$ Koszul–Petersson compatibility via Langlands–Shahidi).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. *(on the Ramanujan bound for Maass cusp forms of $GL_2/\mathbb{Q}$; on the identification of the bar–cobar Koszul spectral measure on the Eisenstein sector with the Shahidi 2010 L^2-normalised Eisenstein measure (Remark 76.4.3); and on the Langlands–Shahidi correction N^{LS} as a canonical ingredient of the arithmetic Koszul pairing on principal-series inductions).* Assume Ramanujan for Maass forms. For all $v, w \in \mathcal{V}^{\mathrm{prim}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul,LS}},$$

with $\langle\cdot,\cdot\rangle^{\mathrm{Koszul,LS}}$ the Langlands–Shahidi-corrected Koszul pairing of Proposition 76.4.2. The identification extends the discrete-core identity (76.1) to the Eisenstein continuum.

Proof. On the discrete core, $N^{\mathrm{LS}}|_{\mathrm{disc}} = 1$ (the correction factor is supported on the Eisenstein continuum), so Theorem 76.3.3 applies without modification. On the Eisenstein continuum, Proposition 76.4.2 gives the conditional Plancherel-normalisation match. Adelic extension on the continuous carrier is part of the assumed measure transport and factorization datum. It is not deduced from the scalar identity for N^{LS}. □

Remark 76.4.5 (domain of the Langlands–Shahidi correction). The full $\mathcal{V}^{\mathrm{prim}}$ identity (76.4.4) extends the domain of the Koszul pairing to the Eisenstein sector only under the measure identification of Remark 76.4.3; it is not obtained by the bare insertion of N^{LS}. The factor N^{LS} is the Langlands–Shahidi normalised intertwining operator (Shahidi 2010 Ch. 2–3; Moeglin–Waldspurger §IV.3), the natural normalisation for the Eisenstein functional equation, and its insertion is a definitional addition to the arithmetic Koszul pairing of Chapter 33, which uses the Bost–Connes involution alone. The

domain restriction of Section 76.3 requires no such addition and is sufficient only for the discrete trace normalisation of the Li path under the hypotheses of Proposition 76.3.5.

76.5 Full $\mathcal{V}^{\mathrm{prim}}$ P3 on the Discrete Core

Proposition 76.5.1 *(Pullback of the discrete Petersson form).* Let $i : V \to L^2_{\mathrm{disc}}([GL_2])$ be a specified injective linear placement. Then $h(v,w) = \langle i(v), i(w)\rangle_{L^2}$ is positive definite. If V has a specified bilinear form B and antilinear map J with $B(v,Jw) = h(v,w)$, this transported Koszul form is positive definite as well. No temperedness assumption is needed for this implication.

Proof. For $v \neq 0$, injectivity gives $i(v) \neq 0$, and hence $h(v,v) = \|i(v)\|^2_{L^2} > 0$. The form identity gives the second assertion. Constructing i, B, J and the identity is the separate arithmetic comparison problem. □

Theorem 76.5.2 *(P3 on the discrete core).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. The comparison maps are assumed on every sector, including the Maass sector, with the specified adelic assembly. The discrete-spectrum core $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \subset \mathcal{V}^{\mathrm{prim}}$ carries a positive-definite Hermitian form

$$\langle\,\cdot\,,\,\cdot\,\rangle^{\mathrm{Pet}} : \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \otimes \overline{\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}} \to \mathbb{C}$$

given by the adelic Petersson–Tamagawa inner product, compatible with arithmetic Koszul self-duality via

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}$$

on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \otimes \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$. The Eisenstein continuous sector is placed outside the P3 identity by the discrete-core domain restriction of Definition 76.3.2.

Proof. The arithmetic comparison hypothesis supplies the injective placement and identifies the form with the Petersson form on its discrete image. Proposition 76.5.1 therefore gives positivity and the asserted pairing identity. This applies to ordinary Maass L^2 vectors regardless of their Satake bounds. Ramanujan is needed only for the separate route that first restricts every Maass representation to the tempered model; it does not replace or follow from the arithmetic pairing maps. □

Corollary 76.5.3 *(P3 input for the sufficient RH path).* Assume also the determinant-trace realization and the explicit trace-placement comparison of Proposition 76.3.5, placing the Li trace on this same discrete domain. Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. The P3 input of Theorem 44.6.1 is supplied by Theorem 76.5.2 on the discrete core, under the full comparison hypotheses on every sector. Combined with the discrete-support of the Li sum (Proposition 76.3.5), the minimal RH path of Theorem 44.6.1 receives a complete Koszul–Petersson compatibility input drawn entirely from the discrete-spectrum core.

Proof. Theorem 76.5.2 + Proposition 76.3.5. □

76.6 Koszul–Petersson Compatibility on the Domain-Restricted Discrete Core: Main Theorem

Theorem 76.6.1 *(full-$\mathcal{V}^{\mathrm{prim}}$ Koszul–Petersson compatibility on the discrete core).* Assume Hypothesis 67.1.1 on the stated sector, with its injective placement, local pairing maps and adelic extension. *(domain-restricted to $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$; conditional on the arithmetic comparison maps on each sector; with Ramanujan additionally assumed on the Maass sector).* For all $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}.$$

In particular, the Koszul pairing of $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$ with a specified Koszul-dual carrier, composed with the specified involution σ^{BC}, equals the adelic Petersson–Tamagawa inner product on the discrete-spectrum image of $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$ inside $L^2_{\mathrm{disc}}([GL_2])$. An identification of that dual carrier with $\mathbb{A}^{\mathrm{BC}}$ requires a separate dg algebra comparison; equality of pairings does not establish it.

Proof. The sector-by-sector identities of Theorem 76.3.3 are:

- $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$: Theorem 76.1.1 (under the comparison hypotheses).
- $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}} \subset \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$: Theorem 76.2.1 (temperedness from Deligne and Deligne–Serre; pairing maps separately assumed).
- $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$: Theorem 76.2.3 (conditional on Ramanujan for Maass forms).
- $\mathcal{V}^{\mathrm{prim}}_{\mathrm{res}}$: direct evaluation at the vacuum.

Orthogonality of the direct-sum decomposition $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} = \bigoplus_{\alpha} \mathcal{V}^{\mathrm{prim}}_{\alpha}$ (Langlands 1966 §6) extends the sector-by-sector identities to the full discrete core. The domain restriction (Definition 76.3.2) defines the domain of the identity as $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$; the scalar discrepancy of Proposition 76.3.1 concerns the proposed continuous coefficients, not an established arithmetic continuous pairing. □

Remark 76.6.2 *(carriers and pairing conventions for Theorem 76.6.1).* The pairing comparison uses the following carriers and conventions.

Koszul and automorphic constructions. The Koszul side uses Beilinson–Drinfeld 2004 (bar–cobar), Positselski 2009 (comodule–contramodule), and Bost–Connes 1995 (Koszul dual as C^*-algebra). The Petersson side uses Deligne 1974 (Weil I, holomorphic Ramanujan), Deligne–Serre 1974 (weight 1), Kim–Shahidi 2002 and Kim–Sarnak 2003 (sub-convex Maass Ramanujan), Langlands 1966 and Moeglin–Waldspurger 1995 (spectral decomposition), Selberg 1956 (Petersson positivity). Relating these constructions requires the map from the Koszul primitive carrier to the specified automorphic realization and its pairing compatibility; the bibliographic distinction is not such a map.

Sign and convention consistency. σ^{BC} is $*$-antilinear; Petersson is sesquilinear conjugate-in-second-slot; Koszul is bilinear. The composition $\langle \cdot\,, \sigma^{\mathrm{BC}}(\cdot)\rangle^{\mathrm{Koszul}}$ has the correct antilinearity. Tamagawa measure is Weil-normalised (Weil 1967 Ch. VII).

Ambient category. Both sides are sesquilinear forms on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \otimes \overline{\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}}$, a subspace of the adelic Hilbert space $L^2_{\mathrm{disc}}([GL_2])$.

Sector hypotheses. Every arithmetic pairing conclusion retains the placement and pairing hypotheses. The tempered-reduction argument for the Maass sector additionally assumes Ramanujan; the positive-pullback argument of Proposition 76.5.1 does not.

Functoriality of the decomposition. The discrete-core decomposition is orthogonal under Petersson (Langlands 1966 §6); Koszul factorises by place (BD 2004 §3.5) and the Bost–Connes involution respects the decomposition.

Domain of the holomorphic and Maass closures. The holomorphic temperedness input is supplied by Deligne and Deligne–Serre; the pairing maps are still required. Maass temperedness is conditional on Ramanujan; the Kim–Sarnak 2003 bound controls Satake exponents at each prime (Proposition 76.2.4) but not adelic closure. The arithmetic comparison and adelic extension are additional requirements on the Maass sector.

76.7 Conditional Residuals

Sector	Form	Note
$\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,hol}}$ (holomorphic cuspidal)	Comparison maps required	Theorem 76.2.1; Deligne 1974 (weight $k \geq 2$), Deligne–Serre 1974 (weight 1).
$\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$ (Maass cuspidal)	Comparison maps and Ramanujan	Theorem 76.2.3; best bound $\theta_p \leq 7/64$ (Kim–Sarnak 2003); pairing-error estimate separately required; the proposed prime majorant is not summable (Proposition 76.2.4).
$\mathcal{V}^{\mathrm{prim}}_{\mathrm{res}}$ (residual, one-dimensional)	Comparison maps required	Direct evaluation at Fock vacuum; This calculation concerns the specified residual line; other residual summands require their own placement and pairing maps.
$\mathcal{V}^{\mathrm{prim}}_{\mathrm{cont}}$ (Eisenstein continuous)	**Excluded by domain**	Definition 76.3.2; scalar discrepancy (Proposition 76.3.1); actual measure transport requires additional construction. Sufficient only for the discrete Li trace normalisation, under the H-P^{Ar} spectral hypothesis (Proposition 76.3.5). Alternative Langlands–Shahidi correction Theorem 76.4.4 reduces the continuum to the measure-normalisation gap.

Conditional boundary. An additional representation-theoretic input of Theorem 76.6.1 is the Ramanujan bound for Maass cusp forms of $GL_2/\mathbb{Q}$. The arithmetic placement and pairing maps are separate open construction requirements. The Satake exponent bound does not supply a pairing-error estimate or an absolutely convergent adelic comparison; see Proposition 76.2.4. The Li sum is over the discrete non-trivial zeros (Proposition 76.3.5) after the H-P^{Ar} determinant-trace realisation; the Li path has this trace condition in addition to the Maass boundary.

Eisenstein continuum. The domain restriction places the Eisenstein continuous spectrum outside the identity's domain (Definition 76.3.2). The discrete-spectrum restriction suffices for the discrete trace normalisation of the Li path under the stated H-P^{Ar} determinant-trace hypothesis (Corollary 76.3.6). The Langlands–Shahidi correction of Section 76.4 extends the identity to the continuum only after the Koszul Eisenstein measure has been identified with the Shahidi L^2-normalised measure.

The sufficient RH path. The P3 input of Theorem 44.6.1 is supplied by $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$, conditional on the arithmetic comparison maps, Ramanujan for Maass cusp forms and on the H-P^{Ar} determinant-trace

realisation used to place the Li trace. The remaining inputs are the conditional arithmetic Positselski, H-P^{Ar}, and HP–Li positivity hypotheses recorded later.

Comparison of the two pairings. The Koszul constructions of Beilinson–Drinfeld (2004), Positselski (2009) and Bost–Connes (1995) and the automorphic constructions of Deligne (1974, 1980), Deligne–Serre (1974), Kim–Shahidi (2002), Kim–Sarnak (2003), Langlands (1966), Moeglin–Waldspurger (1995), Selberg (1956), Weil (1967), Jacquet–Langlands (1970), Godement–Jacquet (1972), JPSS (1983), Casselman–Shalika (1980), Bushnell–Henniart (2006), Iwaniec (2002), Arthur (1978–1979) and Gelbart (1975) concern different carriers. A comparison requires a specified map from the chosen Koszul primitive space to the stated automorphic realization, with its coefficient field, completion and domain fixed, and a proof that it transports the Koszul pairing to the Petersson pairing with the stated normalization. The cited constructions alone do not supply such a map or its isometry property.

Chapter 77

Bost–Connes Modular Spectrum and the Hilbert–Pólya Comparison

The critical Bost–Connes state gives a self-adjoint modular generator whose eigenvalues are $\frac{1}{2}\log q$, $q \in \mathbb{Q}_{>0}$. A specified reducing occupation sector instead has the simple spectrum $\{\log m : m \geq 1\}$. We construct both carriers and an oscillator embedding in the same GNS space. The embedding preserves logarithmic prime energies and positive squared-semigroup shifts. Its oscillators are Hilbert-space operators, not operators affiliated with the Bost–Connes observable algebra. Ordinary conformal energy is a separate grading. These distinctions leave a precise arithmetic question: construct a self-adjoint operator whose normalized determinant is $\xi_{\mathbb{R}}$, together with the Petersson, chiral and trace comparisons that connect it to the arithmetic Fock space.

77.1 Bost–Connes C^*-Dynamical Setup

We use the global algebra and positive-temperature KMS convention of Chapter 74.3.ii. The coefficient algebra factors over primes, but the isometries act across those factors.

Definition 77.1.1 (global and local Bost–Connes algebras). Put $D = C^*(\mathbb{Q}/\mathbb{Z})$, with unitaries $e(r)$ satisfying $e(r+s) = e(r)e(s)$ and $e(r)^* = e(-r)$. For $n \geq 1$ set

$$\alpha_n(e(r)) = \frac{1}{n}\sum_{nt=r} e(t), \qquad C^*_{\mathbb{Q}} = D \rtimes_\alpha \mathbb{N}^\times.$$

The generators μ_n are isometries, with

$$\mu_m\mu_n = \mu_{mn}, \quad \mu_n^*\mu_n = 1, \quad \mu_n d\mu_n^* = \alpha_n(d), \quad \mu_n^* e(r)\mu_n = e(nr).$$

In particular $P_n := \mu_n\mu_n^* = n^{-1}\sum_{nt=0} e(t)$ is a projection. The time evolution is

$$\sigma_t(\mu_n) = n^{it}\mu_n, \qquad \sigma_t(e(r)) = e(r), \qquad \sigma_t(\mu_n^*) = n^{-it}\mu_n^*.$$

For a prime p, let $D_p = C^*(\mathbb{Q}_p/\mathbb{Z}_p)$ and $C^*_{\mathbb{Q},p} = C^*(D_p, \mu_p) \subset C^*_{\mathbb{Q}}$. The primary decomposition of $\mathbb{Q}/\mathbb{Z}$ gives the coefficient tensor product $D = \bigotimes_p D_p$, with local units.

Remark 77.1.2 (the coefficient tensor and the cross-prime action). The global crossed product is described in Laca–Raeburn, arXiv:math/9911134, §2, p. 3. If r is ℓ-primary and $\ell \neq p$, multiplication by p is invertible on that primary group, and the relations give

$$\mu_p e(r) = e(p^{-1}r)\mu_p, \qquad \alpha_p(e(r)) = P_p e(p^{-1}r).$$

For example $\mu_2^* e(1/3)\mu_2 = e(2/3)$, whereas commuting local factors would give $e(1/3)$. In the critical state below, $\|(e(1/3) - e(2/3))\Omega_1\|^2 = 2$, so these elements differ. Thus the algebras $C^*_{\mathbb{Q},p}$ do not assemble by

a generatorwise tensor product. The algebra generated only by the isometries has the distinct Toeplitz tensor-product description of Connes, *Noncommutative Geometry*, V, §11, Proposition 7, pp. 530–531. Neither that description nor the coefficient tensor asserts a product representation of the character-enlarged local algebras.

Lemma 77.1.3 *(the critical KMS state).* There is a unique KMS_1 state φ_1 on $C^*_{\mathbb{Q}}$. It satisfies

$$\begin{aligned}\varphi_1(e(r)) &= \delta_{r,0},\\ \varphi_1(\mu_a e(r)\mu_b^*) &= \delta_{a,b}a^{-1}\delta_{r,0},\\ \varphi_1(\mu_n^*\mu_m e(r)) &= \delta_{n,m}\delta_{r,0}.\end{aligned}$$

In its GNS representation the state extends to a faithful normal state on $M = \pi_1(C^*_{\mathbb{Q}})''$, a hyperfinite factor of type III_1; the cyclic vector Ω_1 is separating for M.

Proof. Existence, uniqueness and the factor statement are Connes, V, §11, Theorem 5(a), p. 528; its character formula at $\beta = 1$ is $\delta_{r,0}$. Time invariance kills monomials of nonzero time weight. At equal indices the KMS identity $\varphi_1(xy) = \varphi_1(y\sigma_i(x))$ gives the factor a^{-1} in the second formula, whereas $\mu_n^*\mu_n = 1$ gives the third. The faithful normal GNS extension and separating vector are the modular realization used in Chapter 74.3.12. □

Remark 77.1.4 *(the critical partition value).* The occupation partition function is $\zeta(\beta)$ for $\Re\beta > 1$. Its Laurent expansion is $\zeta(\beta) = (\beta-1)^{-1} + \gamma + O(\beta-1)$, where γ is the Euler–Mascheroni constant. Thus its Laurent finite part at one is γ; the trace itself diverges there. Identifying this finite part with a determinant normalization would require a separate comparison. The full critical GNS heat operator is not trace class, as its spectrum below shows.

77.2 GNS Representation and the Modular Operator

The rational time weights give an explicit basis that also records the character action. It determines the modular sign and all operator domains directly.

Definition 77.2.1 *(GNS triple).* Let $(\mathcal{H}_1, \pi_1, \Omega_1)$ be the GNS triple of φ_1. Thus $\mathcal{H}_1$ is the completion of $C^*_{\mathbb{Q}}/\{x : \varphi_1(x^*x) = 0\}$ with inner product $\langle x\Omega_1, y\Omega_1\rangle = \varphi_1(y^*x)$, linear in the first variable; π_1 acts by left multiplication. We suppress π_1 on algebra elements when acting on this space.

Lemma 77.2.2 *(rational-character basis and Hilbert tensor product).* For $q = a/b \in \mathbb{Q}_{>0}$ in lowest terms and $r \in \mathbb{Q}/\mathbb{Z}$, put $v_{q,r} = \sqrt{b}\,\mu_a e(r)\mu_b^*\Omega_1$. These vectors are an orthonormal basis. Consequently

$$\begin{aligned}\mathcal{H}_1 &\cong \ell^2(\mathbb{Q}_{>0})\widehat{\otimes}\ell^2(\mathbb{Q}/\mathbb{Z})\\ &\cong \bigotimes_p{}'\big[\ell^2(p^{\mathbb{Z}})\widehat{\otimes}\ell^2(\mathbb{Q}_p/\mathbb{Z}_p)\big].\end{aligned}$$

with reference vectors $\delta_1 \otimes \delta_0$ and $\Omega_1 = v_{1,0}$. For $d = \gcd(n,b)$ the generator actions are

$$e(s)v_{q,r} = v_{q,r+as}, \qquad \mu_n v_{q,r} = d^{-1/2}\sum_{dt=r} v_{nq,t}.$$

This is a tensor decomposition of Hilbert spaces, not of the local BC representations.

Proof. Different q have different time characters and are orthogonal by state invariance. For fixed reduced a/b,

$$\langle v_{q,r}, v_{q,s}\rangle = b\varphi_1(\mu_b e(-s)\mu_a^*\mu_a e(r)\mu_b^*) = \varphi_1(e(r-s)) = \delta_{r,s}.$$

Every monomial of ratio a/b has indices ac, bc, and $\mu_{ac}e(r)\mu_{bc}^* = \mu_a\alpha_c(e(r))\mu_b^*$ is a finite linear combination of these basis vectors. Such monomials span a dense algebra, proving completeness. Unique prime factorization of positive rationals and the primary decomposition of $\mathbb{Q}/\mathbb{Z}$ give the Hilbert tensor product. Finally $e(s)\mu_a = \mu_a e(as)$ proves the first action. Reducing na/b cancels d; expansion of $\alpha_d(e(r))$ and the normalization $\sqrt{b/d}$ of the resulting basis give the coefficient $d^{-1/2}$. □

Lemma 77.2.3 *(Tomita conjugation and the modular operator).* On the finite basis span the Tomita operator and its polar decomposition $S_1 = J_1\Delta_1^{1/2}$ satisfy

$$S_1 v_{q,r} = q^{-1/2}v_{q^{-1},-r}, \qquad J_1 v_{q,r} = v_{q^{-1},-r}, \qquad \Delta_1 v_{q,r} = q^{-1}v_{q,r}.$$

Here J_1 is conjugate-linear, and

$$\Delta_1^{it}\pi_1(x)\Delta_1^{-it} = \pi_1(\sigma_{-t}(x)), \qquad \Delta_1^{it}\Omega_1 = \Omega_1.$$

For $u = \sum c_{q,r}v_{q,r}$ the maximal domain of Δ_1 is $\sum q^{-2}|c_{q,r}|^2 < \infty$; the domain of S_1 is $\sum q^{-1}|c_{q,r}|^2 < \infty$.

Proof. Taking adjoints of $\sqrt{b}\mu_a e(r)\mu_b^*$ gives $\sqrt{b}\mu_b e(-r)\mu_a^* = q^{-1/2}\sqrt{a}\mu_b e(-r)\mu_a^*$. The resulting conjugate-linear weighted permutation has the stated polar decomposition and domains; truncation in the basis gives its closed extension. Equivalently, the modular sign is Connes, V, §11, Proposition 4, p. 527. Applying the displayed diagonal unitaries to the two generator actions verifies that sign directly. □

Definition 77.2.4 *(BC log-modular generator).* Define $N_{\mathrm{BC}} = -\frac{1}{2}\log\Delta_1$ by self-adjoint functional calculus. Its action is

$$\begin{aligned} N_{\mathrm{BC}}v_{q,r} &= \tfrac{1}{2}\log q\, v_{q,r}, \\ \operatorname{Dom} N_{\mathrm{BC}} &= \Big\{\sum c_{q,r}v_{q,r} : \sum(\log q)^2|c_{q,r}|^2 < \infty\Big\}. \end{aligned} \tag{77.1}$$

Theorem 77.2.5 *(self-adjointness and the full modular spectrum).* The finite basis span $\mathcal{D}_{\mathrm{BC}}$ is an essential self-adjointness core for N_{BC}. Its point spectrum is $\frac{1}{2}\log\mathbb{Q}_{>0}$, each eigenvalue has countably infinite multiplicity, and its closed spectrum is $\mathbb{R}$. All its spectral measures are pure point. The point spectrum of Δ_1 is $\mathbb{Q}_{>0}$, and its closed spectrum is $[0,\infty)$; zero is not an eigenvalue.

Proof. For a real diagonal sequence, the adjoint of the finite-span operator has exactly the square-summability domain in (77.1); truncations converge in its graph norm. This proves self-adjointness of the closure. Each q has the countably infinite character basis. A diagonal operator's spectrum is the closure of its diagonal values: outside that closure its coordinatewise inverse is bounded, whereas coordinate vectors give approximate eigenvectors at every limit point. Positive rationals are dense in $(0,\infty)$, proving both closed-spectrum statements. The spectral projections act coordinatewise, so all spectral measures are atomic. All eigenvalues of Δ_1 are positive. □

Remark 77.2.6 *(modular and occupation energies).* The full generator has negative as well as positive energies, and $e^{-tN_{\mathrm{BC}}}$ is unbounded for every $t > 0$. The weight $k\log p$ occurs on the vectors $v_{p^{2k},0}$. Restricting to their positive-integer square sector gives the occupation model below. It is this specified restriction, rather than the full modular spectrum, that realizes the logarithmic prime weights in Chapter 62.3.1. Neither operator has the zeta-zero divisor by this construction.

77.3 Arithmetic Heisenberg Fock and Its Embedding into the GNS Space

The occupation sector fixes the zero-mode normalization. An explicit orthonormal family in the modular fixed-point algebra then supplies oscillator multiplicities inside the same GNS representation.

Definition 77.3.1 (complex arithmetic Fock carrier). Choose positive integers d_p and d_∞ as component counts. Let J consist of the modes (p,k,a), $k \geq 1, 1 \leq a \leq d_p$, and (∞,k,a), $k \geq 1, 1 \leq a \leq d_\infty$. Write $C = \mathbb{N}_0^{(J)}$ for finite occupation configurations and $\mathcal{F}_{\mathrm{osc}} = \ell^2(C)$ for the complex bosonic Hilbert space with orthonormal number states $|\mathbf{n}\rangle$. Equivalently it is the restricted tensor product of the per-prime Fock spaces and the archimedean complex Fock space, with vacuum reference vectors. Put

$$L_w = \ell^2(\mathbb{N}^\times, m^{-1}dm), \qquad \epsilon_m = \sqrt{m}\,\delta_m, \qquad \mathcal{F}_{\mathrm{Heis}}^{\mathrm{Ar}} = \mathcal{F}_{\mathrm{osc}} \widehat{\otimes} L_w.$$

The primary core $\mathcal{F}_{\mathrm{Heis,prim}}^{\mathrm{Ar}}$ is the finite span of $|\mathbf{n}\rangle \otimes \epsilon_m$. This specifies a complex Hilbert realization of the oscillator algebra. Comparing it with the native per-prime chiral objects of Chapter 26 and the archimedean theory of Chapter 35 requires complex realization and chiral structure maps in addition to this Hilbert space.

Lemma 77.3.2 *(weighted occupation embedding).* Let $K_2 = \overline{\mathrm{span}}\{\mu_{m^2}\Omega_1 : m \geq 1\}$. The map

$$\iota_0 : L_w \longrightarrow K_2, \qquad \iota_0 \delta_m = m^{-1/2}\mu_{m^2}\Omega_1$$

is unitary onto K_2. This space reduces N_{BC}, and $N_{\mathrm{occ}} := N_{\mathrm{BC}}|_{K_2}$ is unitarily equivalent to

$$H_w \delta_m = (\log m)\delta_m, \qquad \mathrm{Dom}\, H_w = \left\{ c : \sum_m \frac{(\log m)^2 |c_m|^2}{m} < \infty \right\}.$$

The isometries $R_n \delta_m = \sqrt{n}\,\delta_{nm}$ satisfy

$$R_n^* \delta_m = \begin{cases} n^{-1/2}\delta_{m/n}, & n \mid m, \\ 0, & n \nmid m, \end{cases} \qquad \iota_0 R_n = \pi_1(\mu_{n^2})\iota_0.$$

Their Hilbert adjoints correspond to compressed BC adjoints.

Proof. The vectors $\mu_{m^2}\Omega_1 = v_{m^2,0}$ are orthonormal eigenvectors of energy $\log m$, whereas $\|\delta_m\|^2 = 1/m$ in L_w. This proves the isometry, its range, and the maximal-domain identity by the coordinate formula. Their span is invariant under every spectral projection, so K_2 reduces the generator. The shift and adjoint formulas follow on the normalized basis ϵ_m. □

Definition 77.3.3 (symmetry-invariant BC–GNS Heisenberg lift). Let $G = \widehat{\mathbb{Z}}^\times$ act by $\beta_u(e(r)) = e(ur)$ and $\beta_u(\mu_n) = \mu_n$. The relations and the state formula show that this is a state-preserving action. Hence $U_u(x\Omega_1) = \beta_u(x)\Omega_1$ defines GNS unitaries. They are strongly continuous: character orbits factor through finite quotients on the dense monomial algebra, and unitarity extends continuity to every vector. Define the Hilbert projection

$$P_G = \int_G U_u \, du$$

using normalized Haar measure. Haar invariance gives $P_G^* = P_G = P_G^2$ and $\mathrm{Ran}\, P_G = \mathcal{H}_1^G$. A symmetry-invariant BC–GNS Heisenberg lift consists of a closed $E \subset \mathcal{H}_1^G$, containing K_2, and a unitary $\iota : \mathcal{F}_{\mathrm{Heis}}^{\mathrm{Ar}} \to E$ with $\iota(|\mathbf{0}\rangle \otimes \delta_m) = \iota_0 \delta_m$, transporting the oscillator annihilation and creation operators with their maximal domains and primary core. This definition uses the specified Galois symmetry projection P_G, not the occupation projection P_K onto K_2.

Lemma 77.3.4 *(an explicit same-GNS Fock embedding).* Such a lift exists after a choice of an auxiliary prime ℓ and an enumeration of J. Put $P_k = \mu_{\ell^k}\mu_{\ell^k}^*$ and

$$h_k = \frac{P_{k+1} - \ell^{-1}P_k}{\sqrt{\ell^{-k-1}(1-\ell^{-1})}}, \qquad k \geq 0.$$

Enumerate $J = \{j_1, j_2, \ldots\}$ and let r_i be the increasing ordinary primes. Set

$$c(\mathbf{n}) = \prod_i r_i^{n_{j_i}}, \qquad f_{\mathbf{0}} = 1, \qquad f_{\mathbf{n}} = h_{c(\mathbf{n})-2} \quad (\mathbf{n} \neq \mathbf{0}).$$

The logarithmic finite-place energy is encoded by

$$t(\mathbf{n}) = \prod_{p,k,a} p^{k n_{p,k,a}}.$$

Archimedean modes contribute no factor to t. The vectors

$$v_{\mathbf{n},m} = \mu_{(mt(\mathbf{n}))^2} f_{\mathbf{n}} \Omega_1$$

are orthonormal, and the unitary onto their closed span E is $\iota(|\mathbf{n}\rangle \otimes \epsilon_m) = v_{\mathbf{n},m}$. Moreover E reduces N_{BC}, and

$$\iota^* N_{\mathrm{BC}}|_E \iota = I \otimes H_w + \sum_{p,k,a} k \log p \, K_{p,k,a} \otimes I, \tag{77.2}$$

where $K_j|\mathbf{n}\rangle = n_j|\mathbf{n}\rangle$. In normalized coordinates its maximal domain is

$$\left\{ z : \sum_{\mathbf{n},m} (\log m + \log t(\mathbf{n}))^2 |z_{\mathbf{n},m}|^2 < \infty \right\}.$$

Proof. The projections satisfy $P_j P_k = P_{\max(j,k)}$ and $\varphi_1(P_k) = \ell^{-k}$. Direct expansion gives $\varphi_1(h_k) = 0$ and $\varphi_1(h_k^* h_k) = 1$. If $j < k$, both projections defining h_k lie under P_{j+1}; therefore $h_j h_k$ is a scalar multiple of h_k and has expectation zero. Thus $1, h_0, h_1, \ldots$ is orthonormal. Unique factorization makes $\mathbf{n} \mapsto c(\mathbf{n})$ injective, with value one only at the vacuum, so the $f_{\mathbf{n}}$ are orthonormal too. They are fixed by time evolution and by G.

The vector $v_{\mathbf{n},m}$ has energy $\log(mt(\mathbf{n}))$. Different energies are orthogonal. At equal values $mt(\mathbf{n}) = m't(\mathbf{n}')$, cancellation of the common isometry reduces the inner product to $\varphi_1(f_{\mathbf{n}'}^* f_{\mathbf{n}}) = \delta_{\mathbf{n},\mathbf{n}'}$; then $m = m'$. This proves the isometry and its vacuum normalization. Every vector is G-fixed. The closed span of these vectors is invariant under all spectral projections, proving reduction and the stated diagonal maximal domain. The choices of ℓ and the enumeration are part of the construction; no canonical chiral identification is asserted. □

Proposition 77.3.5 *(closed oscillators and their normalization).* On E define

$$b_j v_{\mathbf{n},m} = \sqrt{n_j}\, v_{\mathbf{n}-\mathbf{e}_j,m}, \qquad b_j^* v_{\mathbf{n},m} = \sqrt{n_j + 1}\, v_{\mathbf{n}+\mathbf{e}_j,m},$$

with the first vector zero when $n_j = 0$. Their maximal domains are, respectively, $\sum n_j |z_{\mathbf{n},m}|^2 < \infty$ and $\sum (n_j + 1)|z_{\mathbf{n},m}|^2 < \infty$. They are closed mutual adjoints and have the common invariant core $\mathcal{D}_E =$

$\operatorname{span}\{v_{\mathbf{n},m}\}$. On this core $[b_j, b_{j'}^*] = \delta_{jj'} I_E$ and like operators commute. Every $\mu_{m^2}\Omega_1$ is annihilated by every b_j. For $j = (p,k,a)$, including $p = \infty$, set

$$A_k^{(p,a)} = \sqrt{k}\, b_{p,k,a}, \qquad A_{-k}^{(p,a)} = \sqrt{k}\, b_{p,k,a}^*.$$

Then $[A_k^{(p,a)}, A_{-l}^{(q,b)}] = k\delta_{kl}\delta_{pq}\delta_{ab} I_E$. The normalized creation monomial is

$$\operatorname{Asc}(\mathbf{n}) = \prod_{p,k,a} \frac{(A_{-k}^{(p,a)})^{n_{p,k,a}}}{\sqrt{k^{n_{p,k,a}} n_{p,k,a}!}}, \qquad \iota(|\mathbf{n}\rangle \otimes \delta_m) = m^{-1/2} \operatorname{Asc}(\mathbf{n}) \mu_{m^2}\Omega_1.$$

Proof. Taking inner products of coordinate vectors gives the adjoint formulas. Square summability with the indicated weights gives the closed maximal operators; finite coordinate truncations converge in their graph norms. Their commutators follow by applying both orders to each number vector. Iteration of creation gives $\sqrt{n_j!}$, and $A_{-k} = \sqrt{k} b_j^*$ supplies the further $k^{n_j/2}$ factor. This proves the displayed normalization. □

Proposition 77.3.6 *(symmetry, semigroup shifts and observable obstructions).* The projections P_K, P_E and P_G are proper Hilbert-space projections, and none belongs to $\mathcal{M}$. The oscillators extended by zero on $E^\perp$ commute with P_G, including their domains; their commutator on $\mathcal{D}_E \oplus E^\perp$ is P_E. The positive squared-semigroup action satisfies

$$\pi_1(\mu_{a^2}) v_{\mathbf{n},m} = v_{\mathbf{n},am}, \qquad \pi_1(\mu_{a^2})|_E = \iota(I \otimes R_a)\iota^*.$$

Its Hilbert adjoint is the compressed adjoint. Compression to E does not give a representation of all BC observables. No nonzero closed densely defined operator affiliated with $\mathcal{M}$, with Ω_1 in its domain, can annihilate Ω_1.

Proof. Since $E \subset \mathcal{H}_1^G$, the zero extensions preserve the P_G decomposition. The vector $(e(1/3) - e(2/3))\Omega_1$ has squared norm two and Galois average zero, so $P_G \neq I$. Also $e(1/2)\Omega_1$ is fixed by G and orthogonal to K_2: its expectation is zero, and all other occupation vectors have nonzero energy. Thus $P_G \neq P_K$. A nonvacuum oscillator vector is orthogonal to K_2, so $P_E \neq P_K$. In particular $P_K b_j^* \Omega_1 = 0$ but $b_j^* P_K \Omega_1 = b_j^* \Omega_1 \neq 0$; the occupation projection cannot replace the symmetry projection in the lift.

Multiplication of the positive isometries proves the shift formula. For $a > 1$, however, $\|\mu_{a^2}^* \Omega_1\|^2 = a^{-2}$ and its modular energy is $-\log a$. It is orthogonal to E, whose energies are nonnegative, whereas the compressed adjoint kills Ω_1. For a prime $r \neq \ell$, every P_k is an average of characters of ℓ-power order, hence $\varphi_1(P_k e(1/r)) = 0$. Only energy-zero vectors of E can pair with $e(1/r)\Omega_1$; those pairings reduce to the same character averages, including $\varphi_1(e(1/r)) = 0$. Thus $P_E e(1/r)\Omega_1 = 0$. A compressed unitary kills a unit vector, which rules out multiplicativity of compression.

Finally, if B is affiliated with $\mathcal{M}$, its kernel projection Q belongs to $\mathcal{M}$. If $B\Omega_1 = 0$, then $(I - Q)\Omega_1 = 0$; separation gives $Q = I$, hence $B = 0$. The same argument says that a projection in $\mathcal{M}$ fixing Ω_1 is I. Each of the proper projections above fixes Ω_1, so none belongs to $\mathcal{M}$. □

Remark 77.3.7 *(Hilbert realization and additional arithmetic structure).* The weighted occupation embedding and the chosen complex oscillator lift are explicit. They identify neither an Eisenstein or ramified summand nor a native chiral algebra inside the GNS space. Such identifications require representation

maps, coefficient realizations and compatible pairings. Likewise, the external oscillator operators are not affiliated BC observables. The positive squared shifts commute with them on the primary core, but the full BC action and its adjoints do not preserve that oscillator representation. These are substantive restrictions on any arithmetic determinant-trace comparison using E.

77.4 The Primary-Heisenberg Twist and the Determinant-Trace Operator

The occupation and oscillator constructions supply a Hilbert space and several gradings. The zero-divisor problem asks for a different operator, with a prescribed determinant. An isometry of Hilbert spaces does not identify these generators.

Statement of the Twist

Definition 77.4.1 *(twist data and the separate conformal grading).* On $\mathcal{F}_{\mathrm{osc}}$ let

$$L_{\mathrm{o}}|\mathbf{n}\rangle = \Big(\sum_{p,k,a} k n_{p,k,a}\Big)|\mathbf{n}\rangle, \qquad G_F = L_{\mathrm{o}} \otimes I + I \otimes H_w,$$

where the sum includes the archimedean modes. These are nonnegative self-adjoint diagonal operators on their maximal square-summability domains, with the grading convention of Chapter 57.3.1. With $[A_k, A_{-k}] = kI$, the contribution to L_{o} is $A_{-k}A_k = kb_k^* b_k$, with no additional factor of k.

A primary-Heisenberg twist consists of the following comparison data.

(i) A complex Hilbert realization $\mathcal{H}_\xi$ of the proposed arithmetic primary sector, and a specified isometry into the cuspidal Petersson Hilbert space of Chapter 43.7.1, with fixed central character and Tamagawa normalization. Compatibility with its native Koszul pairing is an additional pairing identity, as in Chapter 43.7.2; the positivity of the Petersson integral alone does not construct this realization.

(ii) A unitary $U : \mathcal{F}^{\mathrm{Ar}}_{\mathrm{Heis}} \to \mathcal{H}_\xi$ whose restriction to the primary core represents the proposed arithmetic comparison. Put $\mathcal{D}_\xi = U\mathcal{F}^{\mathrm{Ar}}_{\mathrm{Heis,prim}}$.

(iii) A self-adjoint operator A with full domain $\mathrm{Dom}\, A \subset \mathcal{H}_\xi$, for which $\mathcal{D}_\xi \subset \mathrm{Dom}\, A$ is an invariant core. Its domain is not identified with that core.

(iv) The transported grading $G_\xi = UG_FU^*$, with $\mathrm{Dom}\, G_\xi = U\,\mathrm{Dom}\, G_F$. Thus

$$G_\xi U = UG_F \quad \text{on } \mathrm{Dom}\, G_F.$$

Any chain-level, chiral or arithmetic-observable interpretation of U requires the corresponding maps and identities as further data. The grading identity does not assert $A = G_\xi$ or intertwine A with N_{BC}.

Define

$$H_{\mathrm{HP}} := A,$$

with its full self-adjoint domain, and

$$\Theta_\xi := \tfrac{1}{2}I + \imath A, \qquad \mathrm{Dom}\, \Theta_\xi = \mathrm{Dom}\, A.$$

The same-GNS representative is $A_E = \imath U^* A U \imath^*$ on E, with domain $\imath U^*\,\mathrm{Dom}\, A$. This is a domain-preserving unitary transport of A, not an identification with the modular restriction.

Remark 77.4.2 *(two spectral obstructions).* The logarithmic energy in (77.2) uses $k \log p$, whereas the conformal grading uses positive integers k. An intertwiner carrying a nonzero integer-energy one-particle state into the same modular representation would require $k = \frac{1}{2} \log q$ for $q \in \mathbb{Q}_{>0}$. This is impossible. Here is an elementary proof for the integer case needed here. For fixed positive integer k and $n \geq 1$, set

$$F_n(x) = \frac{x^n (2k - x)^n}{n!}, \qquad I_n = \int_0^{2k} e^x F_n(x)\, dx.$$

All endpoint derivatives of F_n are integers: derivatives of order less than n vanish, and expansion at either endpoint makes every remaining derivative an integer multiple of $j!/n!$, $j \geq n$. Repeated integration by parts therefore gives $I_n \in \mathbb{Z} + e^{2k}\mathbb{Z}$. But

$$0 < I_n \leq 2k e^{2k} \frac{k^{2n}}{n!} \longrightarrow 0.$$

If e^{2k} were rational, clearing its fixed denominator would produce positive integers tending to zero. Thus ordinary finite or archimedean oscillator energy cannot be the modular generator. Archimedean modes in the construction above have zero modular weight and a separate positive conformal grading; their multiplicities also preclude a simple occupation partition identity on all of E.

A second obstruction prevents retaining the occupation vacuum as a zero eigenvector of A: then Θ_ξ would have eigenvalue $1/2$ and its determinant would vanish there. On the other hand, $\eta(1/2) = \sum_{n \geq 1}((2n-1)^{-1/2} - (2n)^{-1/2}) > 0$, and $\zeta(1/2) = \eta(1/2)/(1 - \sqrt{2}) \neq 0$. All remaining factors in $\xi_{\mathbb{R}}(1/2)$ are nonzero. Hence the zero-divisor operator cannot literally inherit that vacuum energy.

Determinant-Trace Requirement: Hadamard Inversion

Write $\rho = \beta_\rho + i\gamma_\rho$ for the nontrivial zeros, with multiplicity. The completed function is $\xi_{\mathbb{R}}(s) = \frac{1}{2} s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$. Its genus-one factorization is

$$\xi_{\mathbb{R}}(s) = \frac{1}{2} e^{Bs} \prod_\rho (1 - s/\rho) e^{s/\rho}, \qquad B = -1 - \frac{\gamma}{2} + \frac{1}{2}\log(4\pi).$$

Here γ is the Euler–Mascheroni constant. The prime side appears in the logarithmic derivative, for $\Re s > 1$:

$$-\frac{\xi_{\mathbb{R}}'(s)}{\xi_{\mathbb{R}}(s)} = -\frac{1}{s} - \frac{1}{s-1} + \frac{1}{2}\log\pi - \frac{1}{2}\frac{\Gamma'(s/2)}{\Gamma(s/2)} + \sum_{n \geq 2} \frac{\Lambda(n)}{n^s}.$$

The product and the explicit formula relate the zero and prime distributions; they do not give a unitary conjugacy between the occupation generator and a zero-spectrum operator. The arithmetic problem is to construct the latter from the specified primary sector and prove its determinant and trace comparisons.

The Hilbert–Pólya Hypothesis and Its Consequences

Hypothesis 77.4.3 *(arithmetic determinant-trace realization).* There exist twist data as in Chapter 77.4.1, together with a complete orthonormal eigenbasis (u_ρ) indexed by every zero occurrence, such that

$$Au_\rho = \gamma_\rho u_\rho, \qquad (\tfrac{1}{2}I + iA)u_\rho = \rho u_\rho,$$
$$\operatorname{Dom} A = \Big\{ \sum c_\rho u_\rho : \sum \gamma_\rho^2 |c_\rho|^2 < \infty \Big\}.$$

Thus the original zero multiplicities and zero placement are part of the requirement, not merely the multiset of ordinates. Use the normalized determinant prescription (77.4) under the unitary $u_\rho \mapsto \delta_\rho$. The zero symmetry is represented by an involutive unitary R_ξ which exchanges the occurrences ρ and $1-\rho$, preserves Dom A, and satisfies $R_\xi A R_\xi = -A$. Identifying $U^* R_\xi U$ with a native arithmetic S-modular operation is an additional specified comparison, including its carrier and domain.

Remark 77.4.4 *(the arithmetic comparison problem).* The eigenvalue condition implies RH and gives the abstract normalized Hilbert–Pólya realization of Chapter 74.2.3. Conversely, under RH the diagonal zero-occurrence construction gives that abstract operator. It does not construct the Petersson realization, native chiral maps, or arithmetic symmetry comparison in the hypothesis. Those are the additional requirements of the arithmetic formulation Chapter 44.3.2. Transport by ιU^* places a specified realization in the same GNS Hilbert space while retaining its domain, but supplies no equality with N_{BC} or N_{occ}.

77.5 Prime distributions and the explicit formula

Normalization and the spaces of prime distributions

The exponential coordinate $m = e^t$ changes the growth of a counting measure. It also fixes the weight appearing in a Fourier formula. We use additive Dirac masses on $\mathbb{R}$, the test space $\mathscr{A} = C_c^\infty(\mathbb{R})$ with its usual inductive-limit topology, and the Schwartz space $\mathscr{S}(\mathbb{R})$. Distributions are complex-linear in their test functions. Write γ for Euler's constant and

$$\xi(s) = \xi_{\mathbb{R}}(s) = \tfrac{1}{2} s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

For $t > 0$, put

$$\vartheta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}, \qquad \psi(t) = \sum_{n\geq 1} e^{-\pi n^2 t}.$$

These series and their derivatives converge uniformly on compact subsets of $t > 0$.

The Gaussian identity $\int_{\mathbb{R}} e^{-\pi t x^2} e^{-2\pi i y x}\, dx = t^{-1/2} e^{-\pi y^2/t}$ follows by differentiation in y and integration by parts; its value at zero is the Gaussian integral. Periodize $e^{-\pi t x^2}$ over the integers. Its Fourier coefficients are the displayed Gaussian values at integer y. Both the periodized series and the resulting Fourier series converge absolutely and uniformly. Equality follows from uniqueness of Fourier coefficients for continuous periodic functions. For completeness, uniqueness follows by convolution with

$$F_n(x) = \frac{1}{n}\left|\sum_{k=0}^{n-1} e^{2\pi i k x}\right|^2 :$$

these nonnegative kernels have integral one and their mass outside any neighborhood of the integers tends to zero. Their convolutions converge uniformly to a continuous periodic function. Evaluating at zero gives

$$\vartheta(t) = t^{-1/2}\vartheta(t^{-1}), \qquad \psi(t) = t^{-1/2}\psi(t^{-1}) + \tfrac{1}{2}(t^{-1/2} - 1).$$

Define

$$\xi_{\mathbb{R}}(s) = \frac{1}{2} + \frac{s(s-1)}{2}\int_1^\infty \psi(t)\left(t^{s/2} + t^{(1-s)/2}\right)\frac{dt}{t}. \tag{77.3}$$

The exponential decrease of ψ makes this integral entire, with every derivative locally uniformly convergent. It gives $\xi_{\mathbb{R}}(0) = \xi_{\mathbb{R}}(1) = 1/2$ and

$$\xi_{\mathbb{R}}(1-s) = \xi_{\mathbb{R}}(s), \qquad \xi_{\mathbb{R}}(\bar{s}) = \overline{\xi_{\mathbb{R}}(s)}.$$

On $\operatorname{Re} s > 1$, define $\zeta(s) = \sum_{n\geq 1} n^{-s}$ and $\Gamma(s/2) = \int_0^\infty e^{-u} u^{s/2-1}\, du$. Absolute convergence permits summation under the integral and gives

$$\int_0^\infty \psi(t) t^{s/2}\, \frac{dt}{t} = \pi^{-s/2}\Gamma(s/2)\zeta(s).$$

Split the integral at one and use the theta identity on $(0,1)$. The elementary contribution is $1/(s-1) - 1/s = 1/(s(s-1))$; the remaining integral is that in (77.3). Therefore

$$\xi_{\mathbb{R}}(s) = \tfrac{1}{2} s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s) \quad (\operatorname{Re} s > 1).$$

Equation (77.3) supplies the entire continuation. No assertion about simplicity or critical-line placement of its zeros was used.

Lemma 77.5.1 *(growth and zero counting from the theta integral).* For $R \geq 2$ one has $\log \max_{|s|\leq R} |\xi(s)| \leq CR\log(R+2)$. Consequently the number of its zeros in $|s| \leq R$, with multiplicity, is $O(R\log(R+2))$, and $\sum_\rho |\rho|^{-2} < \infty$. There are infinitely many zeros. All lie in $0 \leq \Re s \leq 1$.

Proof. In the theta integral (77.3), the theta tail on $x \geq 1$ is bounded by $Ce^{-\pi x}$. For $|s| \leq R$ the powers of x in that integral are bounded by $2x^{(R+1)/2}$. The estimate $\sup_{x>0} x^A e^{-\pi x/2} = (2A/(\pi e))^A$ bounds the integral by $\exp(CR\log(R+2))$; the quadratic prefactor does not change this bound. Jensen's formula at radius $2R$, using $\xi(0) = 1/2$, bounds each zero in radius R by a contribution at least $\log 2$. This proves the zero count. Dyadic summation then proves the inverse-square assertion.

The growth bound gives entire order at most one. If there were only finitely many zeros, Hadamard's factorization theorem would give $\xi(s) = e^{a+bs}P(s)$ with a polynomial P. For real $s \geq 2$, however, $\zeta(s) \geq 1$ and integration of the gamma integral just over $[s/2, s/2+1]$ gives $\log \xi(s) \geq (s/2)\log s - Cs$. This contradicts that finite factorization. Finally, the Euler product excludes zeros for $\Re s > 1$, and the functional equation excludes $\Re s < 0$. □

Proposition 77.5.2 *(the constant in the genus-one product).* For this normalization, $\xi(0) = 1/2$, and the constant multiplying s in the canonical genus-one product is

$$B = \frac{\xi'(0)}{\xi(0)} = -1 - \frac{\gamma}{2} + \frac{1}{2}\log(4\pi).$$

Thus, with zeros counted with multiplicity,

$$\xi(s) = \tfrac{1}{2} e^{Bs} \prod_\rho (1 - s/\rho) e^{s/\rho}, \qquad \frac{\xi'(s)}{\xi(s)} = B + \sum_\rho \left(\frac{1}{s-\rho} + \frac{1}{\rho} \right).$$

The factors and the paired summands converge locally uniformly away from their indicated zeros or poles. The individual sum $\sum_\rho 1/\rho$ is not separated from its partner without a specified summation convention.

Proof. The identity $\Gamma(1+s/2) = (s/2)\Gamma(s/2)$ removes the apparent singularity at zero:

$$\xi(s) = (s-1)\Gamma(1+s/2)\pi^{-s/2}\zeta(s).$$

The values $\zeta(0) = -1/2$, $\zeta'(0) = -\frac{1}{2}\log(2\pi)$, and $\Gamma'(1) = -\gamma$ give

$$\frac{\xi'(0)}{\xi(0)} = -1 - \frac{\gamma}{2} - \frac{1}{2}\log\pi + \log(2\pi).$$

For example, the two zeta values follow directly by expanding $\zeta(s) = 2^s\pi^{s-1}\sin(\pi s/2)\Gamma(1-s)\zeta(1-s)$: the constant terms cancel in $\Gamma(1-s)\zeta(1-s) = -s^{-1} + O(s)$. The remaining factor is $\frac{s}{2}(1 + s\log(2\pi) + O(s^2))$. The exact special values are also recorded in DLMF 25.6.1, 25.6.11, and 5.4.11.

Lemma 77.5.1 supplies the growth and zero bound for the order-one factorization. On a compact set with $|s/\rho| \le 1/2$, the logarithm of a factor and its logarithmic derivative are bounded by a constant times $|\rho|^{-2}$. Hence the product and paired derivative converge normally there. Every canonical factor has derivative zero at $s = 0$, so its exponential constant is precisely the logarithmic derivative just computed. This also specifies the normalization of the product. □

Lemma 77.5.3 *(an elementary lower bound for logarithmic prime mass).* Put $\psi(x) = \sum_{m\le x}\Lambda(m)$. For every integer $n \ge 1$,

$$2n\log 2 - \log(2n+1) \le \psi(2n), \qquad \psi(x) \le x\log x \quad (x \ge 2).$$

Consequently there are positive constants c, x_0 with $\psi(x) \ge cx$ for $x \ge x_0$.

Proof. The largest of the $2n+1$ binomial coefficients in $(1+1)^{2n}$ is $\binom{2n}{n}$, so it is at least $4^n/(2n+1)$. For every prime p, its valuation is

$$v_p\binom{2n}{n} = \sum_{k\ge 1}\left(\left\lfloor\frac{2n}{p^k}\right\rfloor - 2\left\lfloor\frac{n}{p^k}\right\rfloor\right).$$

Each summand is zero or one and vanishes when $p^k > 2n$. Taking logarithms therefore gives $\log\binom{2n}{n} \le \psi(2n)$. The upper bound uses $0 \le \Lambda(m) \le \log m$. For arbitrary sufficiently large x, take $n = \lfloor x/2\rfloor$ and use monotonicity. No prime-number asymptotic is needed. □

Theorem 77.5.4 *(the exact exponential weight for temperedness).* For real σ, define the positive Radon measure

$$\mu_\sigma = \sum_{m\ge 2}\Lambda(m)m^{-\sigma}\delta_{\log m}.$$

Every μ_σ is a distribution on $\mathscr{A}$. It is a tempered distribution exactly when $\sigma \ge 1$. It is finite exactly when $\sigma > 1$; μ_1 has infinite total mass. In particular, $\mu_0 = \mu_{\mathrm{prime}}$ is unchanged as a locally finite measure, and $\mu_{1/2}$ is not tempered.

Proof. Only finitely many atoms meet any compact interval. Their total variation bounds evaluation by the supremum norm on that interval, which proves continuity on $\mathscr{A}$. For $\sigma \ge 1$,

$$|\mu_\sigma(\varphi)| \le \sup_t(1+|t|)^3|\varphi(t)| \sum_{m\ge 2}\frac{\log m}{m(1+\log m)^3}.$$

The last series converges by the integral test. If $\sigma > 1$, $\sum(\log m)m^{-\sigma} < \infty$ also gives finiteness. Partial summation gives

$$\sum_{m\le X}\frac{\Lambda(m)}{m} = \frac{\psi(X)}{X} + \int_1^X \frac{\psi(x)}{x^2}\,dx,$$

which diverges by Lemma 77.5.3.

If a positive measure supported in $[0,\infty)$ is tempered, choose a nonnegative smooth compact cutoff equal to one on $[0,1]$ and rescale it by $t \mapsto t/T$. The finite Schwartz seminorm bound for a tempered

distribution then implies $\mu([0,T]) \le C(1+T)^M$ for some C, M and all $T \ge 1$. For $0 \le \sigma < 1$, however,

$$\mu_\sigma([0,T]) \ge e^{-\sigma T}\psi(e^T) \ge ce^{(1-\sigma)T}$$

for large T. For $\sigma < 0$, use $\mu_\sigma \ge \mu_0$. Both contradict polynomial mass growth. □

Multiplication by $e^{-\sigma t}$ is explicit here; it is not a coordinate relabelling. Equivalently, for $\sigma \ge 1$ the unweighted μ_0 acts continuously on $\mathscr{S}_\sigma = e^{-\sigma t}\mathscr{S}(\mathbb{R})$ with the transported Schwartz topology. It acts on C_c^∞ without any choice of weight. The change $x = e^t$ pulls a compact smooth test back by $f(t) = g(e^t)$ and gives the exact pairing $\mu_\sigma(f) = \sum \Lambda(m)m^{-\sigma}g(m)$. These are maps between specified test spaces, not Hilbert-space intertwiners.

Proposition 77.5.5 *(Laplace and Fourier transforms on their domains).* For $\Re s > 1$,

$$\int e^{-st}\, d\mu_0(t) = \sum_{m\ge 2} \frac{\Lambda(m)}{m^s} = -\frac{\zeta'(s)}{\zeta(s)}.$$

With Fourier convention $\mathcal{F}_- f(u) = \int f(t)e^{-iut}\,dt$, the finite measure μ_σ, $\sigma > 1$, has Fourier transform $-\zeta'(\sigma+iu)/\zeta(\sigma+iu)$. As $\sigma \downarrow 1$ these transforms converge in the weak tempered-distribution sense to $\mathcal{F}_-\mu_1$. The unweighted and critically weighted measures do not have Fourier transforms in $\mathscr{S}'$ by this construction.

Proof. The absolutely convergent Euler product for $\Re s > 1$ may be logarithmically differentiated on compact subsets there, giving the displayed Dirichlet series. Absolute convergence also permits integration of the finite weighted measure against the Fourier kernel. For every Schwartz test, dominated convergence in the seminorm estimate of Theorem 77.5.4 gives $\mu_{1+\varepsilon} \to \mu_1$ weakly in $\mathscr{S}'$. Fourier continuity proves the boundary assertion. Meromorphic continuation of the right side does not change the abscissa of absolute convergence of the original positive-measure integral. □

The explicit formula on compact Fourier tests

For $f \in \mathscr{A}$, use the entire function $h(z) = \int f(t)e^{izt}\,dt$, so that $f(t) = (2\pi)^{-1}\int h(u)e^{-iut}\,du$. This is the Fourier test carrier of Definition 78.1.1. For $\rho = \beta + i\gamma_\rho$ put $z_\rho = -i(\rho - 1/2) = \gamma_\rho - i(\beta - 1/2)$. Lemma 77.5.1 gives $\#\{\rho : |\gamma_\rho| \le T\} = O(T\log(T+2))$, with multiplicity. It follows that $\mu_{\mathrm{ord}} = \sum_\rho \delta_{\gamma_\rho}$ is tempered. Since $0 \le \beta \le 1$, integration by parts gives rapid decay of $h(z_\rho)$ uniformly in this horizontal strip. Thus $\mathfrak{Z}_\xi(h) = \sum_\rho h(z_\rho)$ converges absolutely and is continuous on $\mathscr{A}$ through $f \mapsto h$. The estimates therefore follow from the theta integral without requiring an asymptotic prime-counting formula.

Theorem 77.5.6 *(the full polar and archimedean terms).* For every $f \in C_c^\infty(\mathbb{R})$ and its transform h above,

$$\begin{aligned}\mathfrak{Z}_\xi(h) = h(i/2) + h(-i/2) + \frac{1}{2\pi}\int_{\mathbb{R}} h(u)\big(\Re\psi_\Gamma(1/4+iu/2) - \log\pi\big)\,du \\ - \sum_{m\ge 2}\frac{\Lambda(m)}{\sqrt{m}}\big(f(\log m) + f(-\log m)\big),\end{aligned}$$

where $\psi_\Gamma = \Gamma'/\Gamma$ is the digamma function. The prime sum is finite. In particular, it is evaluation of $\mu_{1/2}$ on compact tests and does not assert temperedness of that measure. The values $h(\pm i/2)$ are the polar terms, separate from the real-line digamma density.

Proof. Set $H(s) = h(-i(s-1/2)) = \int f(t)e^{(s-1/2)t}\,dt$ and choose $a > 1$. The residue theorem and $\xi(s) = \xi(1-s)$ give

$$\sum_{\rho} H(\rho) = \frac{1}{2\pi i}\int_{\Re s=a} (H(s)+H(1-s))\frac{\xi'(s)}{\xi(s)}\,ds.$$

Here is a convergence justification. The zero count allows heights $T_j \in [j, j+1]$ at distance at least j^{-2} from every zero ordinate: the excluded intervals have total length $O(\log j/j)$. The paired logarithmic derivative in Proposition 77.5.2 is polynomially bounded on the horizontal segments at these heights. For $|\rho| \le 2T_j$ bound each denominator by the stated distance and sum $O(T_j \log T_j)$ terms; for $|\rho| > 2T_j$ use $|s/\{\rho(s-\rho)\}| \le CT_j/|\rho|^2$. Repeated integration by parts makes H decrease faster than any power, uniformly on the fixed strip. The horizontal integrals therefore vanish, and the zero sum converges absolutely.

On the right line decompose

$$\frac{\xi'}{\xi}(s) = \frac{1}{s} + \frac{1}{s-1} - \frac{1}{2}\log\pi + \frac{1}{2}\psi_{\mathrm{T}}(s/2) + \frac{\zeta'}{\zeta}(s).$$

Fourier inversion and the absolutely convergent Dirichlet series give the negative prime sum from the last term. For the remaining terms move the line to $\Re s = 1/2$. The crossed pole at $s = 1$ contributes $H(1) + H(0)$. On the new line the rational sum $1/s + 1/(s-1)$ is odd in the imaginary coordinate, while $H(s) + H(1-s)$ is even; its integral is zero. Changing u to $-u$ in half of the gamma integral gives precisely its real part in the displayed formula. Digamma growth is $O(\log(|u|+2))$ on this line: in $\psi_{\mathrm{T}}(z) = -\gamma + \sum_{n\ge 0}((n+1)^{-1} - (n+z)^{-1})$, split the sum at $n = |u|+1$ for $z = 1/4 + iu/2$. The initial sum is $O(\log(|u|+2))$ and the tail is bounded by $C(|u|+1)\sum_{n>|u|+1} n^{-2} = O(1)$. Thus all resulting integrals converge absolutely. □

When f is even, h is even and the prime term is $-2\mu_{1/2}(f)$. The functional $h \mapsto h(i/2) + h(-i/2)$ cannot be silently included in a density on the real line. Likewise, $\mathfrak{Z}_\xi(h)$ uses the full complex numbers z_ρ, whereas $\mu_{\mathrm{ord}}(h) = \sum h(\gamma_\rho)$ uses their real parts. Under RH these are equal. No projection is used in the theorem.

77.6 Determinant Identity: Hadamard Factorisation

The normalized genus-one determinant

Let Z contain each zero ρ of ξ with its multiplicity. On $K_Z = \ell^2(Z)$, define

$$(\Theta_Z u)_\rho = \rho u_\rho, \qquad \operatorname{Dom}\Theta_Z = \{u : \sum_{\rho} |\rho u_\rho|^2 < \infty\}.$$

This is a closed normal operator. Its inverse is bounded, compact, and Hilbert–Schmidt: $\xi(0) = 1/2$, the zeros are discrete, and $\sum_\rho |\rho|^{-2} < \infty$.

Theorem 77.6.1 *(complete determinant normalization).* Define the second regularized Fredholm determinant of the diagonal Hilbert–Schmidt operator $-s\Theta_Z^{-1}$ by

$$D_2(s) = \det{}_2(1 - s\Theta_Z^{-1}) := \prod_{\rho\in Z}(1 - s/\rho)e^{s/\rho}.$$

With $B = -1 - \gamma/2 + \frac{1}{2}\log(4\pi)$, set

$$\Delta_Z(s) := \tfrac{1}{2} e^{Bs} D_2(s). \tag{77.4}$$

This entire function equals $\xi(s)$. It is the unique entire function of order at most one with this zero divisor, $\Delta_Z(0) = 1/2$, and $\Delta_Z'(0)/\Delta_Z(0) = B$. Off the zero divisor it satisfies

$$(\log \Delta_Z)''(s) = -\operatorname{Tr}(\Theta_Z - s)^{-2}.$$

The trace is an ordinary absolutely convergent trace. Unitary conjugacy of Θ_Z, including its domain, preserves this determinant prescription.

Proof. For $|w| \le 1/2$, $\log(1-w) + w = O(|w|^2)$. The inverse-square sum proves normal convergence of the product on every compact set, independently of the enumeration of zeros. Its value and derivative at zero are 1 and 0. Proposition 77.5.2 gives the product for ξ with exactly the factor $e^{Bs}/2$. This proves the identity. Hadamard factorization writes every other entire function of order at most one with this divisor as $e^{a+bs} D_2(s)$. The two initial conditions give $e^a = 1/2$ and $b = B$. Twice differentiating the normally convergent logarithmic product gives $-\sum_\rho (\rho - s)^{-2}$. The inverse-square estimate proves absolute trace convergence. Unitary conjugacy preserves the diagonal eigenvalues and their multiplicities, hence every factor in the prescribed product. □

Proposition 77.6.2 *(the divisor leaves an exponential ambiguity).* For every $c \in \mathbb{C}$, the function $e^{cs}\xi(s)$ has the same divisor, the same value at zero, and order at most one. Its logarithmic derivative at zero is $B + c$. Thus a divisor condition and a value normalization do not imply the determinant identity. Both normalizations in (77.4) are necessary.

Proof. The exponential has no zero, has value one at zero, and contributes c to the logarithmic derivative. Multiplication preserves the stated order bound. □

The prescription above uses no complex powers of $s - \Theta_Z$. A determinant defined by such powers requires a spectral cut and meromorphic continuation of its trace. Agreement with Δ_Z requires the same second logarithmic derivative and the two stated initial conditions. These conditions determine equality locally near zero by integration, and globally by analytic continuation.

Remark 77.6.3 *(operator comparison and determinant normalization).* For a normal operator with a complete orthonormal eigenbasis indexed by the same zeros, use the prescription

$$\det_\infty(s - \Theta) := \tfrac{1}{2} e^{Bs} \det_2(1 - s\Theta^{-1}) = \xi(s).$$

The unitary eigenbasis map proves equality with Δ_Z. This fixes the determinant notation in the determinant-trace hypothesis. The construction of such an operator from an arithmetic primary sector requires an additional domain-preserving comparison. The diagonal operator Θ_Z itself uses the zero divisor as input.

Remark 77.6.4 *(dilation and occupation models).* Berry–Keating's xp model concerns zero-density asymptotics (*SIAM Review* 41 (1999), 236–266). A basic dilation realization illustrates the separate operator question. The map $f(x) \mapsto f(e^u)$ is unitary from $L^2(\mathbb{R}_{>0}, dx/x)$ to $L^2(\mathbb{R}, du)$ and sends $-ix\partial_x$ to $-i\partial_u$, with domain transported from $H^1(\mathbb{R})$. Fourier transformation gives spectrum $\mathbb{R}$. This self-adjoint dilation generator does not have a discrete zeta-zero divisor. Likewise the self-adjoint occupation operator N_{occ} with eigenvalues $\log m$ supplies no such divisor. A density comparison or a logarithmic weight must be supplemented by the actual determinant-trace realization; see Chapter 57.3.17 for the corresponding spectral question.

77.7 Trace Distribution: the Full Explicit Formula

Proposition 77.7.1 *(ordinary trace on compact Fourier tests).* Assume Chapter 77.4.3. For $f \in \mathcal{A} := C_c^\infty(\mathbb{R})$ set $h(z) = \mathcal{F}_+ f(z) := \int_{\mathbb{R}} f(t) e^{izt}\, dt$. Then $h(A)$ is trace class and

$$\begin{aligned} \operatorname{Tr} h(H_{\mathrm{HP}}) &= \sum_\rho h(\gamma_\rho) \\ &= h(i/2) + h(-i/2) + \frac{1}{2\pi} \int_{\mathbb{R}} h(u) \big(\Re \psi_\Gamma(1/4 + iu/2) - \log \pi \big)\, du \\ &\quad - \sum_{m \geq 2} \frac{\Lambda(m)}{\sqrt{m}} \big(f(\log m) + f(-\log m) \big), \end{aligned} \tag{77.5}$$

where $\psi_\Gamma = \Gamma'/\Gamma$. The prime sum is finite. Equivalently the right side is $P(f) - W_\infty(f) - W_{\mathrm{fin}}(f)$, with signed archimedean density $\log \pi - \Re \psi_\Gamma(1/4 + iu/2)$ and polar functional $P(f) = h(i/2) + h(-i/2)$.

Proof. Repeated integration by parts gives $|h(u)| \leq C_N (1 + |u|)^{-N}$ for real u and every N. The zero-count estimate of Chapter 77.5.1 is $O(T \log(2 + T))$. Summing over dyadic intervals, with $N > 2$, therefore gives $\sum_\rho |h(\gamma_\rho)| < \infty$. The specified orthonormal eigenbasis makes $h(A)$ a diagonal trace-class operator with exactly this ordinary trace. The determinant spectral condition gives $\rho = 1/2 + i\gamma_\rho$. The compact-test explicit formula Chapter 77.5.6 now gives all terms displayed, with its Fourier convention and both prime-test values. The gamma integral converges by logarithmic growth of the density. Unitary transport of this trace-class operator to E preserves the ordinary trace; no unspecified regularization is inferred from an isometric embedding of unrelated operators. □

Corollary 77.7.2 *(the full Weil-positive cone and a Petersson comparison).* Under the same hypothesis, put $f^*(t) = \overline{f(-t)}$. For every $f \in \mathcal{A}$ the full Weil value satisfies

$$W(f * f^*) = \operatorname{Tr}\big(h_f(A) h_f(A)^* \big) = \sum_\rho |h_f(\gamma_\rho)|^2 \geq 0, \qquad h_f = \mathcal{F}_+ f.$$

Thus Weil positivity and Li positivity hold. To obtain this conclusion instead from a proposed Petersson realization, one must construct a complex-linear map J on all of $\mathcal{A}$ with $\langle Jf, Jg \rangle_{\mathrm{Pet}} = W(f * g^*)$, or construct it on a dense subspace in a topology for which the full form is continuous. Positivity only on an unspecified restricted cone supplies neither condition.

Proof. Fourier transformation sends convolution and involution to $h_f h_f^\#$, where $h_f^\#(z) = \overline{h_f(\bar{z})}$. On the real spectrum this is $|h_f|^2$. The preceding absolute trace argument applies to $f * f^*$. This proves positivity on the full compact test algebra, hence the Weil criterion and the Li criterion of Chapter 74.2.1 and Chapter 74.2.2 give the conclusions. For a Petersson map the stated pairing identity gives positivity directly; if its domain is dense, continuity passes the inequality to limits. The full compact-test form is continuous in the inductive-limit topology by Chapter 77.5.6. □

77.8 Unconditional Constructions and the Arithmetic Comparison

Bost–Connes and Oscillator Carriers

The global BC algebra, critical state and rational-character GNS basis give the maximal self-adjoint generator with point spectrum $\frac{1}{2} \log \mathbb{Q}_{>0}$ and closed spectrum $\mathbb{R}$. The finite basis span is a core, not

its full self-adjoint domain. Its restriction N_{occ} to K_2 has simple eigenvalues $\log m$. The weighted zero-mode embedding, explicit oscillator lift, closed CCR operators and logarithmic energy identity are unconditional constructions after the stated auxiliary choices. They do not identify the oscillator algebra with affiliated BC observables or identify conformal energy with modular energy.

Consequences of a Zero-Divisor Realization

Given the eigenbasis and domain in Chapter 77.4.3, the prescribed normalized genus-one determinant is $\xi_{\mathbb{R}}$ by Chapter 77.6.1. On compact Fourier tests the ordinary trace is the full polar, signed-gamma and prime formula (77.5). It is positive on all convolution squares, and Li positivity follows. These statements use the zero-divisor realization; they are not occupation-trace identities. The domain-preserving unitary ιU^* transports them to E for A_E, while leaving its distinction from $N_{\mathrm{BC}}|_E$ intact.

Hilbert–Pólya and the Other Trace Models

The remaining arithmetic problem is to construct the native primary-sector realization, its Petersson pairing and chiral maps, and an operator A satisfying the normalized zero-divisor condition. The zero-input diagonal operator proves no such arithmetic origin. Connes' adele-class-space absorption trace and Deninger's motivic determinant are further comparison targets. As in Chapter 57.3.14, a comparison requires explicit Connes/Fock and Deninger/Fock intertwiners.

Theorem 77.8.1 *(conditional determinant and trace comparison).* Assume the arithmetic twist hypothesis. Its normalized determinant and full compact-test trace are those of Chapter 77.6.1 and Chapter 77.7.1. For a Connes comparison, additionally specify a Hilbert realization H_C of the relevant adele-class-space representation, a self-adjoint scaling generator A_C, and a unitary $V_C : \mathcal{H}_\xi \to H_C$ with

$$V_C \operatorname{Dom} A = \operatorname{Dom} A_C, \qquad A_C V_C = V_C A.$$

The absorption-trace prescription must also agree on these tests with $\operatorname{Tr} h(A_C)$, with its stated sign and normalization. For a Deninger comparison, additionally specify a Hilbert realization H_D of the proposed motivic cohomology, a closed normal generator $\Phi = \frac{1}{2}I + iA_D$ with A_D self-adjoint, and a unitary $V_D : \mathcal{H}_\xi \to H_D$ intertwining Θ_ξ and Φ on their full domains. Its determinant prescription must have the same genus-one normalization, or be proved to agree with it. Under these hypotheses the normalized determinant and trace statements transfer to both models and back. Without the maps and prescriptions they are comparison questions, not equivalences of the constructed operators.

Proof. The first assertion follows from the stated eigenbasis map and the ordinary trace-class argument. A domain-preserving unitary intertwiner preserves the spectral calculus, eigenvalue multiplicities and trace-class traces. It also preserves the normalized determinant prescription, as proved in Chapter 77.6.1. The further trace/determinant agreements in the hypotheses identify these transported quantities with the respective geometric prescriptions. Applying the inverse unitaries proves the reverse transfers. In the motivic notation, self-adjointness concerns A_D, while the completed zero generator is $\Phi = 1/2 + iA_D$; these are different operators. This makes explicit the intertwiner hypotheses retained in Chapter 57.3.14. □

Remark 77.8.2 *(logarithmic weights and their normalization).* On the specified carrier K_2, the positive squared shifts satisfy $N_{\mathrm{occ}}\mu_{n^2} = \mu_{n^2}(N_{\mathrm{occ}} + \log n)$ on their maximal domains, and the vacuum has energy zero. These two requirements force the eigenvalue $\log m$ at $\mu_{m^2}\Omega_1$. They also give $\operatorname{Tr}_{K_2} e^{-\beta N_{\mathrm{occ}}} = \zeta(\beta)$ for $\Re\beta > 1$. KMS alone does not select K_2: for integers $s \geq 1$, the sectors $K_s = \overline{\operatorname{span}}\{\mu_{m^s}\Omega_1\}$ have

energies $(s/2)\log m$. Thus the weight question of Chapter 62.5.2 has this explicit occupation realization after the carrier, covariance and vacuum normalization are fixed. It does not solve the arithmetic zero-divisor comparison.

Remark 77.8.3 *(the conditional arithmetic conclusion).* There are explicit self-adjoint modular and occupation generators, and an explicit symmetry-invariant Hilbert Fock embedding in the critical GNS space. The conformal grading can be transported unitarily as a separate operator. A native arithmetic Hilbert–Pólya realization still requires its own operator, domain, pairing and normalized zero-divisor data. Once these are constructed, the determinant and full trace identities follow. Comparisons with Connes' absorption trace, Deninger's determinant, or a native chiral operation retain the additional maps and normalizations stated above.

Operator Carriers and Comparison Data

Object	Carrier and conclusion
BC algebra and KMS_1 state	Global crossed product; faithful normal GNS state.
N_{BC}	Full GNS space; maximal self-adjoint domain, closed spectrum $\mathbb{R}$.
N_{occ}	K_2; simple spectrum $\{\log m\}$ and partition $\zeta(\beta)$ for $\Re\beta > 1$.
Oscillator lift	Chosen unitary $\mathcal{F}_{\mathrm{Heis}}^{\mathrm{Ar}} \to E \subset \mathcal{H}_1^G$; closed CCR operators and logarithmic prime energy.
Conformal grading	$G_F = L_0 + H_w$, transported to G_ξ; distinct from the modular generator.
Arithmetic A and Θ_ξ	Full-domain self-adjoint A and normal $\Theta_\xi = 1/2 + iA$; prescribed zero-divisor realization remains hypothetical.
Normalized determinant	Equals $\xi_{\mathbb{R}}$ conditional on that realization.
Compact-test trace	Ordinary trace-class formula $P - W_\infty - W_{\mathrm{fin}}$ on the same condition.
Petersson and geometric transfers	Require the full test pairing or dense continuous comparison, and the specified Connes/Deninger intertwiners.

Chapter 78

Weil Pairings and Automorphic Coefficient Multipliers

The Weil functional acts on compact smooth functions of the logarithmic variable. Its zero formula evaluates their entire Fourier transforms. Keeping these two spaces distinct fixes the prime weights and the archimedean sign. It also distinguishes two coefficient multipliers, one of which can produce only finite Fourier polynomials.

78.1 The compact test algebra and its Fourier image

Definition 78.1.1 *(test spaces and involutions).* Put $\mathscr{A} = C_c^\infty(\mathbb{R})$, with its usual inductive-limit topology, and put $\mathscr{P} = \mathcal{F}_+\mathscr{A}$, where

$$h(z) = \mathcal{F}_+ f(z) = \int_{\mathbb{R}} f(t) e^{izt}\, dt, \qquad f(t) = \frac{1}{2\pi}\int_{\mathbb{R}} h(u) e^{-iut}\, du.$$

Give $\mathscr{P}$ the transported topology. Its elements are entire functions, rapidly decreasing in each horizontal strip. For $f, g \in \mathscr{A}$, define

$$(f * g)(t) = \int f(v) g(t-v)\, dv, \qquad f^*(t) = \overline{f(-t)}, \qquad h^\sharp(z) = \overline{h(\bar{z})}.$$

Thus $\mathcal{F}_+(f*g) = (\mathcal{F}_+ f)(\mathcal{F}_+ g)$ and $\mathcal{F}_+(f^*) = (\mathcal{F}_+ f)^\sharp$.

The identities follow from Fubini and a change of variables. A second real Fourier transform of $h \in \mathscr{P}$ is a reflected compact smooth function. It is generally not an entire function available for evaluation at complex zeros.

Theorem 78.1.2 *(the signed archimedean contribution).* Set $\xi(s) = \tfrac{1}{2} s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ and $\psi_\Gamma = \Gamma'/\Gamma$. For $f \in \mathscr{A}$, write $h = \mathcal{F}_+ f$ and $z_\rho = -i(\rho - 1/2)$, where ρ ranges over the zeros of ξ with multiplicity. Define

$$\begin{aligned} P(f) &= h(i/2) + h(-i/2), \\ W_\infty(f) &= \frac{1}{2\pi}\int_{\mathbb{R}} h(u)\big(\log\pi - \Re\psi_\Gamma(1/4 + iu/2)\big)\, du, \\ W_{\mathrm{fin}}(f) &= \sum_{m \ge 2} \frac{\Lambda(m)}{\sqrt{m}}\big(f(\log m) + f(-\log m)\big). \end{aligned} \tag{78.1}$$

Then the continuous distribution $W : \mathscr{A} \to \mathbb{C}$ is

$$W(f) = \sum_\rho h(z_\rho) = P(f) - W_\infty(f) - W_{\mathrm{fin}}(f). \tag{78.2}$$

The zero sum converges absolutely and the prime sum is finite. For even f, the prime sum is $2\mu_{1/2}(f)$.

Proof. Theorem 77.5.6 gives the formula with $\mathcal{A}_\infty(h) = (2\pi)^{-1}\int h(\Re\psi_\Gamma - \log\pi)$. The definition here is $W_\infty(f) = -\mathcal{A}_\infty(h)$. This accounts for both signs in (78.2). The compact-test estimates in that theorem prove the convergence and continuity assertions. No tempered extension of $\mu_{1/2}$ is used. □

PROPOSITION 78.1.3 *(a compact test determining the sign).* Let $0 < a < b < \log 2$. Suppose $f \neq 0$ is even, nonnegative, smooth, and supported in $(-b,-a)\cup(a,b)$. Then

$$W_{\mathrm{fin}}(f) = 0, \qquad W_\infty(f) = 2\int_a^b \frac{e^{-t/2}}{1-e^{-2t}} f(t)\,dt > 0.$$

Proof. There are no prime-power logarithms in the support. Since $f(0) = 0$, the constant terms of the digamma integral vanish after Fourier inversion. The substitution $v = 2t$ in

$$\psi_\Gamma(z) + \gamma = \int_0^\infty \frac{e^{-v} - e^{-zv}}{1-e^{-v}}\,dv \quad (\Re z > 0)$$

gives the displayed positive integral. The identity is DLMF 5.9.16. The denominator is positive and f is positive on an interval. □

78.2 The Hermitian form and the two polar moments

Define $q_W(f,g) = W(f * g^*)$, with the first variable linear. The zero multiset is invariant under $z \mapsto \bar z$, by the functional equation and conjugation of ξ. Absolute convergence therefore gives $W(f^*) = \overline{W(f)}$. Consequently q_W is Hermitian.

COROLLARY 78.2.1 *(Weil's positivity criterion).* The Riemann Hypothesis is equivalent to

$$q_W(f,f) \geq 0 \qquad (f \in \mathscr{A}).$$

Proof. This is Weil's criterion on compact smooth additive tests, with the Fourier convention above. It is stated in Suzuki, *On the Hilbert space derived from the Weil distribution*, Section 1, equations (1.1)–(1.2). In that convention the zeros of $\xi(1/2 - iz)$ are evaluated with the opposite sign. Their reflected multiset is exactly $\{z_\rho\}$ here. Under RH the assertion follows directly from $q_W(f,f) = \sum_\rho |\mathcal{F}_+ f(\gamma_\rho)|^2$. The converse is the cited positivity criterion, not an assertion of positivity for this arithmetic form. □

PROPOSITION 78.2.2 *(the polar Hermitian form).* Put $a(f) = \int f(t)e^{-t/2}dt$ and $b(f) = \int f(t)e^{t/2}dt$. Then

$$P(f * g^*) = a(f)\overline{b(g)} + b(f)\overline{a(g)}.$$

The moment map $(a,b) : \mathscr{A} \to \mathbb{C}^2$ is continuous and surjective. The polar form has rank two and both signs. It vanishes on the common kernel of the two moments.

Proof. Evaluate $h_f h_g^\sharp$ at $i/2$ and $-i/2$. If a linear combination of a and b vanished on every test, the smooth function $c_1 e^{-t/2} + c_2 e^{t/2}$ would vanish identically. Its value and derivative at zero force $c_1 = c_2 = 0$. The moment map therefore has two-dimensional range. On that range the form has matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, with eigenvalues 1 and -1. □

The use of the entire function ξ does not remove these polar evaluations from its explicit formula. Removing a rank-two term changes the form. It does not preserve positivity automatically.

Conjecture 78.2.3 *(archimedean Tate positivity).* For every $f \in \mathscr{A}$,

$$W_\infty(f * f^*) \le P(f * f^*) - W_{\mathrm{fin}}(f * f^*).$$

Theorem 78.2.4 *(the full positivity inequality).* For all $f \in \mathscr{A}$,

$$P(f * f^*) - W_{\mathrm{fin}}(f * f^*) = q_W(f, f) + W_\infty(f * f^*).$$

Thus archimedean Tate positivity is equivalent to Weil positivity and to RH. The equality applies to any specified restricted class as well, but asserts no positivity on that class.

Proof. Apply (78.2) to $f * f^* \in \mathscr{A}$ and rearrange. Then apply Weil's criterion. □

78.3 Real compact tests with prescribed Mellin moments

Restrictions on moments specify a test space before any automorphic comparison is made. For $f \in \mathscr{A}$, write

$$M_f(s) = \int_{\mathbb{R}} f(t) e^{st}\, dt = \int_0^\infty f(\log x) x^{s-1}\, dx.$$

Define the real vector space

$$\mathscr{A}_{13} = \{f \in \mathscr{A} : f \text{ is real and even}, \quad M_f(0) = M_f'(0) = M_f(1) = M_f'(1) = 0\}.$$

Thus the reality and evenness condition (H1) and the double Mellin zeros at 0, 1 (H3) have a precise compact-time meaning. Its Fourier image is the real space $\mathcal{F}_+\mathscr{A}_{13}$; neither space is asserted to consist of automorphic multipliers. For even f, the independent displayed moments are integration against 1, $\cosh t$, and $t \sinh t$; $M_f'(0) = 0$ is automatic.

Proposition 78.3.1 *(Mellin moments do not cancel the polar form).* Every M_f, $f \in \mathscr{A}$, is entire and rapidly decreasing on each closed vertical strip. In particular, the strip holomorphy condition (H2) imposes no additional restriction depending on a holomorphic weight k. The space $\mathscr{A}_{13}$ contains a nonzero f with $P(f * f^*) > 0$.

Proof. Compact support permits differentiation under the integral at every complex s. If $s = \sigma + i\tau$ with σ in a fixed compact interval, integration by parts in $e^{i\tau t}$ bounds $M_f(s)$ by $C_N(1 + |\tau|)^{-N}$ for every N. Choose nonzero, nonnegative, real even $b \in \mathscr{A}$ and put $f = D^2(D^2 - 1)^2 b$, where $D = d/dt$. Integration by parts gives

$$M_f(s) = s^2(s^2 - 1)^2 M_b(s).$$

This f is real, even and compactly supported, and its Mellin transform has double zeros at 0, 1, −1. Yet

$$M_f(1/2) = M_f(-1/2) = \frac{9}{64} M_b(1/2) > 0.$$

In particular $f \neq 0$. Since $h_f(\pm i/2) = M_f(\mp 1/2)$ and $f = f^*$, the convolution identity yields $P(f * f^*) = 2M_f(1/2)^2 > 0$. Thus moments at 0, 1 cannot be substituted for the actual polar moments at $\pm 1/2$. □

Both coefficient maps below restrict to this class, with their respective time and Fourier arguments. The compact multiplier remains a finite Fourier polynomial. Its modularity criterion is still the vanishing criterion proved below; (H1)–(H3) do not remove it.

78.4 COEFFICIENT MULTIPLIERS ON THE TWO CARRIERS

Fix a holomorphic cusp form $F(z) = \sum_{n\ge 1} a_F(n) q^n$ of weight $k > 0$ for $\mathrm{SL}_2(\mathbb{Z})$, where k is even and $q = e^{2\pi i z}$. Its coefficients have polynomial growth. Indeed the invariant function $y^{k/2}|F(z)|$ is bounded on a fundamental domain and hence on the upper half-plane. The Fourier coefficient integral at $y = 1/n$ gives $|a_F(n)| \le C n^{k/2}$.

PROPOSITION 78.4.1 *(the normalized Hecke coefficient bound).* Suppose in addition that F is a Hecke eigenform, $a_F(1) = 1$. For every prime p and integer $n \ge 1$,

$$|a_F(p)\, p^{-(k-1)/2}| \le 2, \qquad |a_F(n)| \le d(n) n^{(k-1)/2},$$

where $d(n)$ is the number of positive divisors of n. These bounds control coefficients and imply no modularity for a coefficientwise multiplier.

Proof. Deligne, *La conjecture de Weil I*, Theorem 8.2, p. 302, applies to a normalized primitive holomorphic cuspidal eigenform of weight $k \ge 2$ and character ε at level N. Here $N = 1$, every eigenform is new and $\varepsilon = 1$, so every prime is unramified. The roots α_p, β_p of $X^2 - a_F(p)X + p^{k-1}$ have absolute value $p^{(k-1)/2}$. Their sum gives the prime bound.

For completeness the Hecke coefficient formula is

$$[q^m] T_n F = \sum_{d \mid (m,n)} d^{k-1} a_F(mn/d^2).$$

It follows by summing $F((az+b)/d)$ over $b \bmod d$, for $ad = n$, in the formula $T_n F = n^{k-1} \sum_{ad=n} d^{-k} \sum_{b \bmod d} F((az+b)/d)$. The coefficient at $m = 1$ is $a_F(n)$; the eigenform condition therefore gives $T_n F = a_F(n) F$. Comparing coefficients gives multiplicativity for coprime indices and $a_F(p^{r+1}) = a_F(p) a_F(p^r) - p^{k-1} a_F(p^{r-1})$. With $a_F(1) = 1$ this recurrence gives

$$a_F(p^r) = \sum_{j=0}^{r} \alpha_p^j \beta_p^{r-j}, \qquad |a_F(p^r)| \le (r+1)\, p^{r(k-1)/2}.$$

Multiplication over prime powers proves the all-integer bound. □

Definition 78.4.2 *(the two coefficient maps).* For $f \in \mathscr{A}$ and $h = \mathcal{F}_+ f \in \mathscr{P}$, set

$$\begin{aligned} U_F(f)(z) &= \sum_{n\ge 1} f(\log n)\, a_F(n) n^{(k-1)/2} q^n, \\ \Upsilon_F(h)(z) &= \sum_{n\ge 1} h(\log n)\, a_F(n) n^{(k-1)/2} q^n. \end{aligned} \tag{78.3}$$

The first sum is finite. The second converges locally uniformly on the upper half-plane, by polynomial coefficient growth and the factor $e^{-2\pi n \Im z}$. Neither definition asserts modularity.

THEOREM 78.4.3 *(the compact multiplier obstruction).* The function $U_F(f)$ is a cusp form of weight k for $\mathrm{SL}_2(\mathbb{Z})$ only if it vanishes identically. Thus the compact multiplier is modular exactly on $\{f : f(\log n) a_F(n) = 0 \text{ for all } n\}$. The entire multiplier $\Upsilon_F(h)$ is a distinct construction. Its modularity requires the transformation law of its resulting holomorphic series.

Proof. Write $G(z) = \sum_{n=1}^{N} b_n e^{2\pi i n z}$ for a nonzero finite Fourier polynomial. Then $G(iy)$ is analytic as a function of y near zero. If G were modular of positive weight k,

$$G(i/y) = (iy)^k G(iy).$$

The finite sum on the left is $O(e^{-2\pi/y})$ as $y \downarrow 0$. Hence $G(iy) = O(y^{-k} e^{-2\pi/y})$. Every Taylor coefficient at zero must vanish, contradicting the nonzero analytic function. This proves the first assertion. The coefficient condition is exactly vanishing of the finite Fourier polynomial. □

Remark 78.4.4 *(Mellin domains).* For $f \in \mathscr{A}$, the multiplicative Mellin integral

$$\int_0^\infty f(\log x) x^{s-1} dx = \int_{\mathbb{R}} f(t) e^{st}\, dt$$

is entire and rapidly decreasing on every closed vertical strip. This follows by integration by parts on the fixed compact support. Strip holomorphy imposes no additional condition on this carrier. For the entire multiplier $h(\log n)$, the analogous Mellin integral has a different domain and must be specified separately.

78.5 The exact Rankin–Selberg coefficient calculation

Theorem 78.5.1 *(unfolding for an actual cusp form).* Let $G(z) = \sum_{n\geq 1} b_n e^{2\pi i n z}$ be a holomorphic cusp form of weight $k > 0$ for $\mathrm{SL}_2(\mathbb{Z})$. Put $\Gamma = \mathrm{PSL}_2(\mathbb{Z})$ and $d\mu = dx\, dy/y^2$. Fix its standard fundamental domain $\mathcal{F} \subset \mathbb{H}$. Use the Eisenstein series $E(z,s) = \sum_{\Gamma_\infty \backslash \mathrm{PSL}_2(\mathbb{Z})} \Im(\gamma z)^s$, where Γ_∞ is the translation subgroup. For real $s > 1$,

$$\int_{\mathcal{F}} |G(z)|^2 y^k E(z,s)\, d\mu = \frac{\Gamma(s+k-1)}{(4\pi)^{s+k-1}} \sum_{n\geq 1} \frac{|b_n|^2}{n^{s+k-1}}. \tag{78.4}$$

Proof. The Eisenstein series converges for $s > 1$. Its cusp growth is polynomial, while G decreases exponentially, so the integral is finite. Nonnegative summands permit unfolding by Tonelli: the integral becomes $\int_0^\infty \int_0^1 |G(x+iy)|^2 y^{s+k-2} dx\, dy$. Fourier orthogonality gives $\sum |b_n|^2 e^{-4\pi n y}$. A second application of Tonelli and the gamma integral prove the formula. □

Proposition 78.5.2 *(positive norm and native pairing maps).* The Petersson norm of an actual cusp form is positive definite. If a complex vector space E has an injective linear map $I : E \to L^2(\mathcal{F}, y^k d\mu)$ on the fixed fundamental domain, then

$$\langle v, w \rangle_I = \int_{\mathcal{F}} (Iv)(z) \overline{(Iw)(z)}\, y^k\, d\mu$$

is a positive definite form. Identifying another specified form with this one requires the corresponding pairing identity for I.

Proof. These assertions follow from the norm property of L^2 and injectivity. The unfolding formula computes the coefficients of G itself. For $G = \Upsilon_F(h)$ it therefore uses $|h(\log n) a_F(n) n^{(k-1)/2}|^2$, whenever this series is modular. □

Remark 78.5.3 *(arithmetic-sector pairing data).* Let E be a proposed arithmetic cuspidal sector and let $I : E \to L^2(\mathcal{F}, y^k d\mu)$ be an injective linear map. The preceding proposition constructs its positive pullback pairing. A Koszul–Petersson comparison additionally specifies a complex-bilinear pairing $B : E \times E \to \mathbb{C}$, an antilinear involution $\sigma : E \to E$, and the equality

$$B(v, \sigma w) = \langle Iv, Iw \rangle_{L^2} \qquad (v, w \in E).$$

This equality transports positivity because its diagonal is $\|Iv\|_2^2$. For a restricted tensor product, it requires compatible local realization maps and local pairings on the chosen reference vectors. The coefficient multipliers alone do not specify these data.

Local Hilbert models and the arithmetic comparison

A local pairing can be constructed without identifying it with an arithmetic trace sector. On $c_{00}(\mathbb{N}_{\geq 1}; \mathbb{C})$ set

$$\langle c, d \rangle_p = \sum_{m \geq 1} \frac{c_m \overline{d_m}}{m}, \qquad \langle \delta_m, \delta_n \rangle_p = \frac{\delta_{mn}}{m}.$$

The diagonal is positive for every nonzero finite sequence. Its completion is $\ell^2(\mathbb{N}, 1/m)$, with orthonormal basis $\sqrt{m}\, \delta_m$. An identification of this model with a local Bost–Connes GNS space must separately specify its state, representation, and map on this basis.

The polynomial Heisenberg Fock model is $\mathcal{F}_{\mathrm{alg}} = \mathbb{C}[x_1, x_2, \ldots]|0\rangle$, where every polynomial uses finitely many variables. For finite multi-indices ν, give its monomials the pairing

$$\langle x^\nu, x^\mu \rangle = \delta_{\nu\mu} \prod_{j \geq 1} j^{\nu_j} \nu_j!, \qquad a_{-j} = x_j, \quad a_j = j \partial_{x_j}, \quad a_0 = 0.$$

Direct differentiation proves $[a_j, a_{-l}] = j\delta_{jl}$ and $a_j^* = a_{-j}$ on this invariant polynomial domain. The positive completion has the normalized monomials as an orthonormal basis. The energy $N = \sum_{j \geq 1} j x_j \partial_{x_j}$ has eigenvalue $\sum_j j\nu_j$ on x^ν; its self-adjoint realization has maximal square-summable energy domain. This is the concrete Fock model underlying the comparison with Frenkel–Ben-Zvi, §3.5; an arithmetic identification remains additional data.

Remark 78.5.4 *(the specified primary trace and tensor problem).* Let $E := E_{\mathrm{cusp,temp}}$ denote a proposed complex vector-space realization of the tempered cuspidal part of the primary Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ of Chapter 67. The cohomological degree or graded completion is part of the data; this trace class is not being identified with a vertex algebra. The desired comparison specifies a bilinear Koszul pairing B_{Kos} on E, an antilinear Bost–Connes involution σ^{BC}, and an injective map $I : E \to L^2_{\mathrm{cusp}}([GL_2], dg)$ with

$$B_{\mathrm{Kos}}(v, \sigma^{\mathrm{BC}} w) = \int_{[GL_2]} Iv(g) \overline{Iw(g)}\, dg.$$

Here $[GL_2] = Z(\mathbb{A})GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})$ with a fixed unitary central character and a fixed quotient Tamagawa measure. Constructing E, B_{Kos}, σ^{BC}, I and this identity is the native pairing problem associated with Chapter 67.6.1; ordinary integral positivity proves its consequence only after those data exist.

The related tensor problem asks for an isometry from the completion of E to a specified subspace of $H_\infty \widehat{\otimes} \bigotimes'_p (H_p, e_p)$, where e_p are specified unit reference vectors and the product inner product is defined first on tensors equal to e_p at all but finitely many primes. The intended local models are the Fock completion at infinity and the weighted sequence spaces at finite primes. Their proposed Petersson

and GNS identifications, and normalization on the e_p, are not consequences of the categorical restricted tensor product in Chapter 50.1.3.

For a factorable cuspidal automorphic representation $\pi = \otimes'_v \pi_v$, the local integral comparison must fix a global additive character of $\mathbb{A}/\mathbb{Q}$, self-dual additive measures, multiplicative measures, and Whittaker vectors W_v with $W_p(1) = 1$ at unramified places. One then has to prove the matching of the native tensor pairing with the product of the resulting local Rankin–Selberg integrals. The q-coefficient calculation alone supplies neither that adelic map nor its normalization.

Theorem 78.5.5 *(a negative finite-prime square).* There exists $f \in \mathscr{A}$ with $W_{\mathrm{fin}}(f * f^*) < 0$. Thus no linear map into a positive Hilbert space can realize $W_{\mathrm{fin}}(f * g^*)$ as its inner product on all of $\mathscr{A}$.

Proof. Put $L = \log 2$. Choose a nonzero real smooth b, supported in $(-\varepsilon, \varepsilon)$, where $2\varepsilon < \min(L, \log 3 - L)$. Write $b_L(t) = b(t - L)$ and $f = b - b_L$. If $c = b * b^*$, then

$$f * f^* = 2c - c(\cdot - L) - c(\cdot + L).$$

The support meets the nonzero prime logarithms only at L and $-L$. At each, its value is $-c(0) = -\|b\|_2^2$. Therefore

$$W_{\mathrm{fin}}(f * f^*) = -\sqrt{2}\log 2\,\|b\|_2^2 < 0.$$

A Hilbert norm cannot have that value. □

Corollary 78.5.6 *(restricted automorphic comparisons).* A positive realization of the finite-prime form on a restricted subspace requires a proved restriction on that subspace. The existence of an automorphic coefficient multiplier or an interpolating function alone does not give a realization on the full compact test algebra.

Proof. The preceding test excludes the full-space realization. The Rankin–Selberg calculation identifies a different coefficient kernel and supplies no equality with the displayed negative value. □

78.6 Archimedean and interpolation obstructions

Definition 78.6.1 *(the archimedean density).* The sign convention in (78.2) uses

$$\mathcal{T}_\infty(u) = \frac{\log \pi - \Re\,\psi_\Gamma(1/4 + iu/2)}{2\pi}.$$

Proposition 78.6.2 *(the gamma density is not the Weil density).* The functions $|\Gamma(1/4 + iu/2)|^2$ and $\mathcal{T}_\infty(u)$ are not constant multiples. In fact $\mathcal{T}_\infty$ has both signs. For a local continuous argument of the nonvanishing gamma function,

$$\frac{d}{du}\arg\Gamma(1/4 + iu/2) = \frac{1}{2}\Re\,\psi_\Gamma(1/4 + iu/2), \qquad \frac{d}{du}\log|\Gamma(1/4 + iu/2)|^2 = -\Im\,\psi_\Gamma(1/4 + iu/2).$$

Proof. Differentiate $\log\Gamma(1/4 + iu/2)$ to obtain $(i/2)\psi_\Gamma$. Taking real and imaginary parts proves the identities. The digamma series gives $\psi_\Gamma(1/4) < -\gamma < 0$. For $y \geq 1$, its real part is

$$-\gamma + \sum_{n\geq 0}\left(\frac{1}{n+1} - \frac{n + 1/4}{(n+1/4)^2 + y^2}\right).$$

The first $\lfloor y \rfloor$ terms have sum at least $\log y - C$: the harmonic part has this growth, and the subtracted part is bounded by $y^{-2}\sum_{n\le y}(n+1/4) \le C$. In the remaining terms the possible negative part is at most $C\sum_{n>y} n^{-2}$. Thus the real part tends to positive infinity. The density $\mathcal{T}_\infty$ is positive at zero and negative for sufficiently large $|u|$. The gamma absolute square is positive. □

Remark 78.6.3 *(the local gamma factor).* For $\Lambda_\infty(s) = \pi^{-s/2}\Gamma(s/2)$,

$$\frac{\Lambda_\infty'(s)}{\Lambda_\infty(s)} = \frac{1}{2}\psi_\Gamma(s/2) - \frac{1}{2}\log\pi.$$

Thus, with $k(u) = \log\pi - \Re\psi_\Gamma(1/4 + iu/2)$, $k(u) = -2\Re(\Lambda_\infty'/\Lambda_\infty)(1/2 + iu)$. The gamma absolute square and this logarithmic derivative enter through different operations. A conformal-anomaly comparison requires an equality with this specified distribution and its normalization.

Li coefficients and compact tests

THEOREM 78.6.4 *(Li 1997, J. Number Theory 65).* . RH is equivalent to $\lambda_n \ge 0$ for every integer $n \ge 1$, where

$$\lambda_n \;=\; \sum_\rho \left(1 - \left(1 - \frac{1}{\rho}\right)^n\right),$$

where the sum means $\lim_{T\to\infty}\sum_{|\Im\rho|\le T}$, with zeros counted with multiplicity.

PROPOSITION 78.6.5 *(rational Li tests are not compact Fourier tests).* For any integer $n \ge 1$, there is no $f \in \mathscr{A}$ such that

$$(\mathcal{F}_+ f)(-i(\rho - 1/2)) = 1 - (1 - 1/\rho)^n$$

for every nontrivial zero ρ.

Proof. The right side is $n/\rho + O_n(|\rho|^{-2})$ as $|\rho| \to \infty$. The left side decreases faster than every inverse power of $|\Im\rho|$, uniformly in the zero strip. There are infinitely many zeros and only finitely many in any bounded set. Since their real parts lie in $[0,1]$, these two estimates contradict one another. □

Remark 78.6.6 *(Maass forms and continuous spectrum).* A square-integrable Maass cusp form has a positive L^2 norm, independently of any Ramanujan bound on its Hecke parameters. That positivity follows by integrating its absolute square and does not identify the norm with a zeta prime or Weil form. An Eisenstein comparison additionally requires its spectral measure, normalization, and a realization map, as specified next.

PROPOSITION 78.6.7 *(continuous-spectrum pairing data).* Let $\int^\oplus E_u\, d\mu(u)$ be a specified Hilbert direct integral. An identity between its norm and an arithmetic Hermitian form requires a map into that direct integral and equality of the two pairings. A scalar gamma factor determines neither that map nor its measure.

Proof. The direct-integral norm is $\int \|v(u)\|_{E_u}^2\, d\mu(u)$. Replacing a nonzero realization map I by $2I$ multiplies its pullback pairing by four. A single scalar factor does not select the map or its measure. The sign-changing density above also cannot equal an unspecified positive norm by scalar rescaling. □

78.7 SPECIFIC AUTOMORPHIC AND ARITHMETIC COMPARISON QUESTIONS

The coefficient calculation fixes one kernel. Additional native comparisons must state which different integral they propose to compute. The following questions retain the arithmetic sectors and parameters.

Entire multipliers and automorphic endomorphisms. For a normalized eigenform F generating an automorphic representation π_F, characterize $h \in \mathcal{F}_+\mathscr{A}$ for which $\Upsilon_F(h)$ is modular. A stronger question asks whether a given such multiplier is induced by a continuous $GL_2(\mathbb{A})$-equivariant endomorphism of a specified globalization of π_F, preserving its weight-k vector. The coefficient prescription is $a_F(n) \mapsto h(\log n)n^{(k-1)/2}a_F(n)$. This endomorphism condition and the modular transformation law are different requirements; neither is inferred from the moment conditions.

A proposed normalized kernel. For fixed F, one can form the meromorphic ratio

$$K_F^{\mathrm{prop}}(s) = \frac{\zeta(2s)L(s, \pi_F \times \overline{\pi_F})}{\zeta(s)\xi_{\mathbb{R}}(s)\xi_{\mathbb{R}}(1-s)}.$$

Take the unitary Hecke normalization in the finite Rankin–Selberg L-function, and $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$. The question is whether a specified automorphic integral, including its archimedean and conductor factors, represents this ratio on a convergence domain and hence meromorphically. No such identity is asserted. In particular it is not the coefficient kernel in (78.4), and the two ξ factors do not absorb the zeta prime distribution into a Petersson norm.

The Fock integral and conformal anomaly. For the weight-k holomorphic discrete-series representation at infinity, specify a lowest-weight Whittaker vector, Haar measure, and a map from the polynomial Fock domain to that Whittaker model. The proposed scalar density is $|\Gamma(1/4 + iu/2)|^2$; obtaining it from a local integral requires an explicit computation with these representation parameters. It cannot be inferred merely from the name of the Fock space or from Jacquet's local-factor theory. The gamma-square density and the signed Weil density $k(u)/(2\pi)$ are different, as proved above.

The separate Polyakov question concerns the conformal variation of a specified regularized determinant in Chapter 35: choose the kinetic operator, boundary conditions, determinant normalization and test-dependent conformal variation, and compare its resulting distribution on $\mathscr{A}$ with

$$-2\Re\frac{\Lambda_\infty'}{\Lambda_\infty}(1/2 + iu) = k(u), \qquad \Lambda_\infty(s) = \pi^{-s/2}\Gamma(s/2).$$

Bohr–Mollerup characterizes Γ; it supplies none of those geometric data or the proposed anomaly identity.

Eisenstein comparison and discrete projection. Suppose a specified automorphic Hilbert space has an orthogonal spectral decomposition $H_{\mathrm{aut}} = H_{\mathrm{disc}} \oplus \int_{\mathbb{R}}^{\oplus} E_u\, d\nu(u)$. Then $P_{\mathrm{disc}}(v, w) = (v, 0)$ is the bounded self-adjoint idempotent of norm one if $H_{\mathrm{disc}} \neq 0$ (and zero otherwise). For a native map $I : E \to H_{\mathrm{aut}}$, its discrete realization is $P_{\mathrm{disc}}I$. Orthogonality proves $\|P_{\mathrm{disc}}Iv\|^2 \le \|Iv\|^2$ and identifies its kernel as the vectors mapped into the continuous summand. Thus an actual spectral decomposition supplies the projection; a coefficient multiplier does not specify it.

The continuous comparison in Chapter 67.5.5 asks whether the proposed Koszul ratio $\xi_{\mathbb{R}}(2s)/\xi_{\mathbb{R}}(2s-1)$ matches the Maass–Selberg scattering pairing after a specified truncation and normalization. One must distinguish this entire ξ from the meromorphic completion Λ_ζ, specify the Eisenstein series, its constant term, the truncation parameter and the measure ν, and prove the resulting equality or discrepancy. No unconditional exclusion of the continuum follows without that calculation. Likewise the discrete zero divisor in Li's criterion is not already identified with H_{disc}; such a statement requires its own map and spectral-measure comparison.

Maass parameters and varying weights. For an unramified unitary Maass representation let the Satake roots be α_p, β_p with $\alpha_p\beta_p = 1$, and set $\theta_p = \log_p \max(|\alpha_p|, |\beta_p|)$. For a weight-zero Hecke–Maass cusp eigenform on $SL_2(\mathbb{Z})$, the Kim–Sarnak estimate gives

$$|\lambda_F(p)| \le p^{7/64} + p^{-7/64}, \qquad \theta_p \le 7/64.$$

In Sarnak, *Spectra of Hyperbolic Surfaces*, January 2003, p. 17, (30), T_n is normalized by $n^{-1/2}$; p. 18, (34), states the operator-norm bound on the cuspidal space. Applying it to a unit eigenvector gives the first inequality. With trivial central character, the real eigenvalue is $\alpha_p + \alpha_p^{-1}$. The roots are either on the unit circle or real reciprocal roots; in the latter case $|\lambda_F(p)| = p^{\theta_p} + p^{-\theta_p}$. Monotonicity for $\theta_p \ge 0$ proves the second inequality. With the positive Laplacian $\Delta = -y^2(\partial_x^2 + \partial_y^2)$, the same source, Theorem 2, p. 17, gives the eigenvalue bound $\lambda_\Delta \ge 975/4096 = 1/4 - (7/64)^2$; an exceptional parameter $\lambda_\Delta = 1/4 - \theta_\infty^2$, with $\theta_\infty \ge 0$, therefore satisfies $\theta_\infty \le 7/64$. These are parameter estimates, not a claim of optimality. A parameter bound controls these roots, not the existence of a positive ordinary L^2 norm. The proposed correction to K_F^{prop} at $s = 1/2 \pm \theta_p$ requires an actual local factor and an integral comparison; a parameter bound alone does not give a correction formula.

For a weight sequence $k_j \to \infty$, fix normalized forms F_j and consider the finite positive measures

$$d\nu_j(z) = \frac{|F_j(z)|^2 y^{k_j}\, d\mu(z)}{\|F_j\|_{\mathrm{Pet}}^2} \quad \text{on } SL_2(\mathbb{Z})\backslash\mathbb{H}.$$

Their masses are one. Comparing weight limits requires specified maps from a common test space, control of escape into the cusp, and convergence of the pairings. No vanishing of these normalized measures or identification of their limit with a Selberg trace formula follows from the increase of k_j. Such an identity would have to match its spectral and geometric terms on that common carrier. None of these limits is needed for the entire Mellin transform of a compact smooth test.

The sufficient arithmetic path. The HP–Li input in Chapter 44.6.1 is the full Weil inequality on $\mathscr{A}$. An arithmetic proof through that path must construct its native pairing identity, including polar, finite-prime and gamma terms. A restricted automorphic isometry, Maass lift or weight-limit trace formula is a possible construction route only after its domain and comparison are proved; none is an additional logical necessity for the Weil criterion. The next theorem specifies the positive realization that such a route would have to supply.

78.8 The arithmetic pairing requirement

THEOREM 78.8.1 *(the remaining positive comparison).* A Hilbert realization of the full Weil form consists of a positive Hilbert space K, a linear map $J : \mathscr{A} \to K$, and the identity

$$\langle Jf, Jg\rangle_K = W(f * g^*) \qquad (f, g \in \mathscr{A}).$$

Such a realization exists if and only if q_W is positive semidefinite. When it exists, its minimal realization is the completion of $\mathscr{A}/\{f : q_W(f, f) = 0\}$. Its existence is RH-equivalent. Neither coefficient map in (78.3) provides the pairing identity.

Proof. A Hilbert realization implies nonnegativity. Conversely, positivity and polarization give Cauchy–Schwarz for q_W. Its nullspace is a linear subspace orthogonal to every vector. Quotienting and completing

therefore gives the asserted Hilbert space and canonical map. Weil's criterion supplies the equivalence to RH. The coefficient maps construct holomorphic functions with specified coefficients. Their definitions contain no equality with the full Weil form, and the finite-prime counterexample excludes the proposed full-space positive realization of that separate term. □

The arithmetic problem asks for this pairing through a specified native carrier, its operators, and its realization maps. The compact formula, the exact coefficient calculation, and the two obstruction theorems retain those separate requirements.

78.9 Signed arithmetic pairings and their operator representations

The finite-prime form has both signs even on a two-dimensional space. An exact arithmetic representation must retain that sign. All scalar products below are complex-linear in their first variable. The test algebra is $\mathscr{A} = C_c^\infty(\mathbb{R})$, with convolution and $f^*(t) = \overline{f(-t)}$. Write $h_f(z) = \int f(t)e^{izt}\,dt$ and $q_\bullet(f,g) = W_\bullet(f * g^*)$.

Theorem 78.9.1 *(the finite-prime operator on a support interval).* For $R > 0$, let $H_R = L^2([-R,R],dt)$. Let $j_R : H_R \to L^2(\mathbb{R},dt)$ extend by zero, and let $(T_a u)(t) = u(t-a)$. Define the bounded self-adjoint operator

$$B_R = \sum_{2\le n\le e^{2R}} \frac{\Lambda(n)}{\sqrt{n}}\, j_R^*(T_{\log n} + T_{-\log n})\, j_R.$$

For $f, g \in C_c^\infty((-R,R))$,

$$q_{\mathrm{fin}}(f,g) = \langle B_R f, g\rangle = \langle |B_R|^{1/2} f, \operatorname{sgn}(B_R)|B_R|^{1/2} g\rangle.$$

The sign function has value zero at zero. For $R < S$, extension by zero $j_{R,S} : H_R \to H_S$ satisfies $j_{R,S}^* B_S j_{R,S} = B_R$. These forms therefore give the original continuous Hermitian form on the complete test algebra $\mathscr{A}$.

Proof. Each translation is unitary and $T_a^* = T_{-a}$. The sum is finite, with norm at most $2\sum_{n\le e^{2R}} \Lambda(n) n^{-1/2}$. A change of variables gives

$$(f * g^*)(a) = \int f(t)\overline{g(t-a)}\,dt = \langle T_{-a} j_R f, j_R g\rangle.$$

For $|a| \ge 2R$ the integral vanishes. Summing at $a = \pm\log n$ proves the first identity. The spectral theorem for the bounded self-adjoint operator B_R gives $B_R = \operatorname{sgn}(B_R)|B_R|$ and the second identity. The same vanishing proves compatibility for $R < S$. On each fixed support the finite sum is continuous in the smooth topology. This is the distributional continuity of W_{fin}. □

Proposition 78.9.2 *(positive and negative arithmetic subspaces).* Put $L = \log 2$. Choose a nonzero real $b \in C_c^\infty((-\varepsilon,\varepsilon))$, where $2\varepsilon < \min\{L, \log(3/2)\}$. On $V_b = \operatorname{span}\{b, T_L b\}$, the finite-prime form has matrix

$$\frac{\log 2}{\sqrt{2}}\|b\|_2^2 \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

In particular,

$$q_{\mathrm{fin}}(b \pm T_L b, b \pm T_L b) = \pm\sqrt{2}\log 2\,\|b\|_2^2.$$

For $c = (\log 2)/\sqrt{2}$, the map $a(b + T_L b) \mapsto \sqrt{2c}\, ab$ is an isometry from the positive line to the ordinary L^2 line spanned by b. No linear map from all of $\mathscr{A}$ to a positive Hilbert space can pull its norm back to q_{fin}.

Proof. The autocorrelation $b * b^*$ is supported in $[-2\varepsilon, 2\varepsilon]$ and has value $\|b\|_2^2$ at zero. On the two translated copies, only the prime-power logarithms $\pm L$ meet an off-diagonal correlation. Each cross pairing is $c\|b\|_2^2$, and the diagonal pairings vanish. The two displayed eigenvectors give the signs and the isometry. The negative vector contradicts every proposed positive norm identity. □

THEOREM 78.9.3 *(the signed zero representation).* Let Z be the countable set of occurrences of zeros of ξ, including multiplicities. Choose the involution $\sigma\rho = 1 - \bar{\rho}$ on occurrences, fixing each occurrence on the critical line. Set

$$K_Z = \ell^2(Z), \quad z_\rho = -i(\rho - 1/2), \quad (Ju)_\rho = u_{\sigma\rho}, \quad (Ef)_\rho = h_f(z_\rho).$$

Then $J = J^* = J^{-1}$, $E : \mathscr{A} \to K_Z$ is continuous, and

$$\langle Ef, JEg\rangle = q_W(f, g) = P(f * g^*) - W_\infty(f * g^*) - \langle B_R f, g\rangle \tag{78.5}$$

whenever f, g have support in $(-R, R)$. The closed normal operator

$$(A_Z u)_\rho = z_\rho u_\rho, \qquad \operatorname{Dom} A_Z = \{u : \sum_\rho |z_\rho u_\rho|^2 < \infty\}$$

satisfies $A_Z = J A_Z^* J$, with equality of domains. For real a, the bounded group $G_a = \operatorname{diag}(e^{iaz_\rho})$ satisfies $\|G_a\| \le e^{|a|/2}$ and

$$E(T_a f) = G_a Ef, \qquad E(if') = A_Z Ef, \qquad \langle G_a u, JG_a v\rangle = \langle u, Jv\rangle.$$

For $k, f \in \mathscr{A}$, $E(k * f) = h_k(A_Z)Ef$, where the diagonal multiplier $h_k(A_Z)$ is bounded.

Proof. The zero symmetries give $z_{\sigma\rho} = \bar{z}_\rho$. Their imaginary parts have modulus at most $1/2$. Repeated integration by parts gives, on each fixed compact support,

$$|h_f(x + iy)| \le C_{R,N}(f)(1 + |x|)^{-N}, \qquad |y| \le 1/2,$$

where $C_{R,N}$ is a continuous smooth seminorm. The zero count in Lemma 77.5.1 proves square summability, continuity of E, and membership of Ef in every power domain of A_Z. The involution is an isometric permutation. Its coordinate formula gives $JA_Z^*J = A_Z$ and preserves the maximal domain. Absolute convergence and the explicit formula give

$$\langle Ef, JEg\rangle = \sum_\rho h_f(z_\rho)\overline{h_g(\bar{z}_\rho)} = W(f * g^*).$$

The last expression in (78.5) follows from the polar, gamma, and finite-prime terms of that formula. Change of variables and integration by parts prove the two intertwining identities. The coordinate factors in the signed scalar product cancel. The strip estimate bounds $h_k(A_Z)$, and the convolution identity proves the final assertion. □

This construction uses the actual zero divisor as input. It does not construct an arithmetic cohomology group or a map from an arithmetic primary sector. The finite-prime and zero maps in (78.5) are defined on the same compact test algebra, with both polar moments retained.

Corollary 78.9.4 *(the precise positivity boundary).* The operator A_Z is self-adjoint for the ordinary positive scalar product on K_Z if and only if RH holds. Positivity of $\langle Ef, JEf\rangle$ for all $f \in \mathscr{A}$ is also equivalent to RH. Under RH, $J = 1$ and $\|Ef\|^2 = q_W(f,f)$. Without a positivity assumption, (78.5) is an unconditional signed representation of the arithmetic form.

Proof. A diagonal normal operator on its maximal domain is self-adjoint exactly when each diagonal entry is real. Here this means $\Re\rho = 1/2$ for every zero. The second equivalence is precisely Weil's criterion, Corollary 78.2.1. The specified choice of σ is the identity under RH. □

Chapter 79

VB* Main Direction via Hamburger Positivity, Determinacy, and HB$^+$/EC$_\pi$

Chapter 57 isolates the VB operator-positivity predicate in a conditional comparison with (Reg), operator-positive de Branges structure, and the quantitative Báez-Duarte condition, under the explicit operator and norm comparison data. In the opposite direction, the VB* main-direction implication says that the four analytic hypotheses (HB$^+$,* EC$_\pi$*, determinacy, positive Hamburger moment structure) on the primary Fock imply that the non-trivial zeros of $\xi_{\mathbb{R}}$ lie on the critical line. The chain is classical complex analysis and de Branges space theory: a de Branges datum whose real part has divisor* div Ξ *and whose Hermite–Biehler kernel is positive forces the zeros of Ξ to be real. The positive Hamburger moment structure identifies the spectral measure as a positive measure on the real line; Hamburger determinacy identifies the measure uniquely once it exists; and HB$^+$ supplies the real-part divisor constraint. Thus the conclusion is the conditional arrow from these hypotheses to RH. The hypotheses HB$^+$,* EC$_\pi$*, and determinacy are not consequences of the Hadamard product; they are the analytic content of the zero-placement problem.*

79.1 Spectral Positivity Context

The operator-theoretic comparison in Theorem 57.4.22 assumes Hypothesis 57.4.21 and compares VB*, (Reg), (HB+) and (BD+). (Reg) includes positivity, determinacy and the required spectral support on the identified arithmetic carrier. Neither bare (Det) nor the implication "zero placement implies VB*" is the predicate in that equivalence. Chapter 62 reduces the Hamburger-determinacy component to the sufficient analytic residual (R_{analytic}) and obstructed a tempting Bombieri–Lagarias shortcut. Neither argument addresses the main-direction implication

$$(\mathrm{HB}^+) + (\mathrm{EC}_\pi) + (\mathrm{Det}) \implies \text{spectral zeros of } \xi_{\mathbb{R}} \text{ on the critical line},$$

which is the sufficient direction of the analytic hypothesis of Definition 58.4.1. The proof is classical complex analysis and de Branges space theory in the sense of the 1968 monograph; no arithmetic input beyond the Hadamard factorisation of $\xi_{\mathbb{R}}$ is used.

Domain

The theorem is the implication from (HB$^+$) + (EC$_\pi$) + (Det) + positive Hamburger moment structure to spectral zero-placement on the critical line.

The analytic inputs are HB$^+$, EC$_\pi$, (Det), and positive Hamburger moment structure on $\xi_{\mathbb{R}}$. These are RH-equivalent in the Hermite–Biehler case and spectral regularity inputs in the moment-problem cases. They are the subject of Chapters 57 and 62.

Independent Sources

The source list for the VB* converse uses de Branges 1968, Lagarias 1999, Báez-Duarte 2003, Burnol 2000, Akhiezer 1965, Simon 1998, Shohat–Tamarkin 1943. The main-direction implication inherits this list

and adds the classical Hamburger existence theorem, Lagarias' 1999 de Branges survey, Conrey–Li 2000, and Beurling–Malliavin density. The proof sources of constructions 2 and 3 (determinacy reductions, operator-positivity reformulations) are kept disjoint from the complex-analysis sources below:

de Branges, *Hilbert Spaces of Entire Functions* (Prentice-Hall 1968). Foundational monograph; theorems 22–23 (Hermite–Biehler structure), theorem 32 (multiplication operator on $\mathcal{H}(E)$), theorems 40–41 (invariant subspaces of the shift).

Lagarias, Acta Arith. 89 (1999). Survey of de Branges reformulations of RH; explicit statement of the main-direction theorem for entire functions of order 1.

Conrey–Li, arXiv:math/9812166 (2000). Construction of de Branges spaces from L-functions; critical discussion of the Hermite–Biehler condition on E_ξ; counter-examples in the non-self-adjoint case.

Beurling–Malliavin, Acta Math. 107 (1962) 291–309. Density theorem: the completeness radius of an exponential system $\{e^{i\lambda_k x}\}$ is computed by Beurling–Malliavin density of $\{\lambda_k\}$.

Hamburger, Math. Ann. 81 (1920) 235–319. Original existence theorem: a Hamburger moment problem has a positive representing measure iff all Hankel matrices are positive-semidefinite.

Levin, *Distribution of Zeros of Entire Functions* (AMS 1980), Ch. V–VII. Classical reference on Hermite–Biehler, Hermite–Kakeya–Obreshkov; entire functions of exponential type.

Independence of inputs: the complex analysis (Hadamard factorisation of $\xi_{\mathbb{R}}$, de Branges structure theorem, Beurling–Malliavin density) is not used in the VB*-converse comparison; and that comparison (operator-positivity reformulations, Jacobi-matrix spectral theory, Báez-Duarte decay) is not used in the main-direction implication. The two lists share two foundational references: de Branges 1968 (Hermite–Biehler theory) and Akhiezer 1965 (moment theory, used for the Jacobi matrix and for Hamburger existence and Carleman's criterion). These shared references serve logically distinct roles: Akhiezer supplies operator spectral methods on one side and classical moment existence. Simon 1998 (spectral theory of Jacobi matrices) appears in the operator-theoretic list and is not cited below; Shohat–Tamarkin 1943 is likewise absent below. The two argument paths are therefore independent on the operative arguments, with the shared foundational references serving independent functions in the two constructions.

79.2 Primary Fock and $\xi_{\mathbb{R}}$ as Character

Fix the primary Fock $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ of Chapters 44 and 57: the primary sector of the arithmetic Heisenberg Fock, equipped with the Petersson inner product of Corollary 47.10.1. Its character on the archimedean Tate fibre is the completed zeta function

$$\Lambda_\zeta(s) \;=\; \pi^{-s/2}\,\Gamma(s/2)\,\zeta(s),$$

meromorphic with simple poles at $s = 0$ and $s = 1$; the entire Li–Hadamard form is

$$\xi_{\mathbb{R}}(s) \;:=\; \tfrac{1}{2}\,s(s-1)\,\Lambda_\zeta(s).$$

The factor $s(s-1)$ removes the Tate poles; the Gamma factor cancels the negative even trivial zeros of ζ; the remaining zero set is exactly the non-trivial zero set of ζ. This is the convention fixed in Remark 44.1.2 and Remark 44.3.7.

PROPOSITION 79.2.1 *($\xi_{\mathbb{R}}$ is entire of order 1, Hadamard genus 1).* (Edwards, *Riemann's Zeta Function* (Academic Press 1974), §1.9). The function $\xi_{\mathbb{R}}(s)$ is entire of order 1 and Hadamard genus 1:

$$\xi_{\mathbb{R}}(s) \;=\; e^{a+bs}\prod_{\rho}\Big(1-\frac{s}{\rho}\Big)e^{s/\rho}, \tag{79.1}$$

with explicit constants $a = -\log 2$, $b = -1 - \frac{1}{2}\gamma_{\mathrm{E}} + \frac{1}{2}\log(4\pi)$, product over non-trivial zeros ρ, and $\sum_\rho |\rho|^{-2} < +\infty$.

Proof. Classical: the functional equation and $|\xi_{\mathbb{R}}(s)| \le \exp(C|s|\log|s|)$ uniformly in vertical strips (Stirling bounds on Γ, polynomial control on ζ away from the pole) give order 1. Hadamard genus 1 follows from the zero density estimate of Riemann–von Mangoldt, which gives $\sum_\rho |\rho|^{-1-\epsilon} < +\infty$ for every $\epsilon > 0$ but $\sum_\rho |\rho|^{-1} = +\infty$. The Hadamard factorisation theorem then gives (79.1) with genus 1. At $s = 0$, the product is 1 and $\xi_{\mathbb{R}}(0) = 1/2$, so $a = -\log 2$. Differentiating $\log \xi_{\mathbb{R}}(s)$ at $s = 0$, using $\zeta(0) = -1/2$, $\zeta'(0) = -(1/2)\log(2\pi)$, and $\Gamma(s/2) = 2s^{-1} - \gamma_{\mathrm{E}} + O(s)$, gives

$$\frac{\xi_{\mathbb{R}}'(0)}{\xi_{\mathbb{R}}(0)} = -1 - \frac{\gamma_{\mathrm{E}}}{2} + \frac{1}{2}\log(4\pi),$$

which is b. □

Proposition 79.2.2 *(functional equation).* The entire function $\xi_{\mathbb{R}}$ satisfies the functional equation

$$\xi_{\mathbb{R}}(s) \;=\; \xi_{\mathbb{R}}(1-s), \qquad s \in \mathbb{C}. \tag{79.2}$$

Equivalently, $\xi_{\mathbb{R}}(\frac{1}{2} + iz)$ is an entire function of z with real Taylor coefficients.

Proof. The functional equation for Λ_ζ is Riemann 1859 / Tate 1950. The extension to $\xi_{\mathbb{R}}$ follows because $s(s-1) = (1-s)(-s) = (1-s)((1-s)-1)$ is invariant under $s \mapsto 1-s$. The substitution $s = \frac{1}{2} + iz$ turns $s \mapsto 1-s$ into $z \mapsto -z$; combined with $\xi_{\mathbb{R}}(\bar{s}) = \overline{\xi_{\mathbb{R}}(s)}$ (real on the real axis), this gives $\xi_{\mathbb{R}}(\frac{1}{2} + iz) = \overline{\xi_{\mathbb{R}}(\frac{1}{2} - i\overline{z})} = \overline{\xi_{\mathbb{R}}(\frac{1}{2} + iz)}$ for $z \in \mathbb{R}$; hence the Taylor coefficients at $z = 0$ are real. □

Definition 79.2.3 *(shifted character).* Write

$$\Xi(z) \;:=\; \xi_{\mathbb{R}}\big(\tfrac{1}{2} + iz\big), \qquad z \in \mathbb{C}.$$

Then Ξ is entire of order 1 with real Taylor coefficients. Its zero set is

$$\{\gamma_\rho : \rho = \tfrac{1}{2} + i\gamma_\rho \text{ non-trivial zero of } \xi_{\mathbb{R}}\},$$

symmetric under $z \mapsto -z$ by (79.2). Under RH the zeros γ_ρ are real; unconditionally they are complex and the $z \mapsto -z$ symmetry becomes $\gamma \leftrightarrow -\gamma$ as a multi-set.

Remark 79.2.4 *(the orientation of the problem).* RH is the statement that the zero set of Ξ is a subset of the real line. The Hadamard and functional-equation facts (Proposition 79.2.1, Proposition 79.2.2) are unconditional; they constrain the zero set to be symmetric under $z \mapsto -z$ but not to be real. The role of the analytic hypotheses (HB^+, EC_π, determinacy) is to force this realness by real-part divisor control and spectral-measure rigidity.

79.3 Hadamard Factorisation and the Zero Measure

Definition 79.3.1 *(primary zero multi-set).* The *primary zero multi-set* is

$$\mathcal{Z}_\xi \;:=\; \{\gamma_\rho \in \mathbb{C} : \rho = \tfrac{1}{2} + i\gamma_\rho \text{ non-trivial zero of } \xi_{\mathbb{R}}\},$$

with multiplicity. Under the symmetrisation $\rho \leftrightarrow 1-\rho$, the set $\mathcal{Z}_\xi$ is closed under $\gamma \leftrightarrow -\gamma$. Under the complex conjugation $\rho \leftrightarrow \overline{\rho}$, it is closed under $\gamma \leftrightarrow -\overline{\gamma}$; combining, it is closed under $\gamma \leftrightarrow \overline{\gamma}$ and symmetric under the Klein four group $\{1, \gamma \mapsto -\gamma, \gamma \mapsto \overline{\gamma}, \gamma \mapsto -\overline{\gamma}\}$ on the whole plane.

Definition 79.3.2 (primary zero counting measure). The *primary zero counting measure* is the multi-set measure

$$\mu_\xi := \sum_{\gamma \in \mathcal{Z}_\xi} \delta_\gamma$$

on $\mathbb{C}$ (with multiplicity). Under RH, μ_ξ is supported on $\mathbb{R}$. Under the functional equation (79.2), μ_ξ is $z \mapsto -z$-invariant. Under the reality of Taylor coefficients (Proposition 79.2.2), μ_ξ is $z \mapsto \overline{z}$-invariant. The invariant group is thus the Klein four group on $\mathbb{C}$.

Definition 79.3.3 (Regularization datum and moment sequence). Let $S_T(p) = \sum_{\gamma \in \mathcal{Z}_\xi, |\gamma| \le T} p(\gamma)$, counting multiplicities. A regularization datum specifies linear counterterms $C_T : \mathbb{C}[x] \to \mathbb{C}$ such that $L(p) = \lim_{T \to \infty}(S_T(p) - C_T(p))$ exists and is finite for every polynomial. Require $C_T(\overline{p}) = \overline{C_T(p)}$ and $C_T(p(-x)) = C_T(p(x))$, where the bar conjugates coefficients. The moments of this specified datum are

$$M_n = L(x^n).$$

No counterterms or arithmetic comparison are constructed by this definition. Zero counting and inverse-power convergence do not define positive-power moments. The actual finite-cutoff calculation is Proposition 80.2.5. Constructing the required trace-compatible datum and proving $L(p\overline{p}) \ge 0$ remain separate requirements.

PROPOSITION 79.3.4 *(Reality and symmetry of the specified moments).* For such a datum, every M_n is real and every odd moment is zero.

Proof. The cutoff multiset is invariant under conjugation and negation. Thus $S_T(\overline{p}) = \overline{S_T(p)}$ and $S_T(p(-x)) = S_T(p(x))$. The prescribed counterterms have the same symmetries; subtraction and limits preserve them. Apply these identities to monomials. □

Remark 79.3.5 (positivity of the measure is strictly weaker than RH). The measure μ_ξ as a multi-set measure on $\mathbb{C}$ is always positive (it is a counting measure). The question is whether its restriction to $\mathbb{R}$ carries the full mass; that is the content of RH. Positivity of μ_ξ as a measure on $\mathbb{C}$ gives no information about whether the support is on $\mathbb{R}$. This is the reason a positive Hamburger moment representation (a positive representation on $\mathbb{R}$ with prescribed real moments) is strictly finer than mere positivity of μ_ξ.

79.4 HAMBURGER MOMENT PROBLEM FOR μ_ξ

Definition 79.4.1 (Hamburger moment problem for μ_ξ). The *Hamburger moment problem* for the sequence $\{M_n\}_{n \ge 0}$ of Definition 79.3.3 is: find a positive Borel measure ν_ξ on $\mathbb{R}$ with

$$M_n = \int_{\mathbb{R}} x^n \, d\nu_\xi(x) \qquad \forall n \ge 0. \tag{79.3}$$

The problem is *solvable* if such ν_ξ exists, and *positive Hamburger* if ν_ξ is a positive measure on $\mathbb{R}$. The Stieltjes problem belongs to the square-pushforward $x \mapsto x^2$, not to the signed ordinate moments themselves.

THEOREM 79.4.2 *(Hamburger's existence theorem).* (Hamburger, Math. Ann. 81 (1920); Akhiezer 1965 §2.1). A moment problem (79.3) is solvable if and only if the infinite Hankel matrix

$$H_\infty = (M_{i+j})_{i,j \ge 0}$$

is positive-semidefinite: $\sum_{i,j} c_i \overline{c_j} M_{i+j} \geq 0$ for every finitely supported sequence (c_i). Equivalently, every finite truncation $H_N = (M_{i+j})_{0 \leq i,j \leq N}$ has non-negative principal minors.

Definition 79.4.3 *(HB$^+$/EC$_\pi$/Det hypothesis).* The *spectral positivity hypothesis* on the primary Fock is the conjunction of:

(SH) *Positive Hamburger moment sequence.* The common linear regularization of Definition 79.3.3 exists, gives finite moments, and its Hankel matrix $H_\infty = (M_{i+j})_{i,j \geq 0}$ is positive-semidefinite.

(Det) *Hamburger determinacy.* The positive representing measure is unique. Carleman's condition $\sum_{n \geq 1} M_{2n}^{-1/(2n)} = +\infty$ is a sufficient criterion when the positive even moments are nonzero.

(HB$^+$) *Hermite–Biehler positivity with divisor control.* There is a de Branges datum $E_\xi(z) = A_\xi(z) - iB_\xi(z)$, with A_ξ, B_ξ real entire, such that E_ξ is Hermite–Biehler, the associated kernel K_{E_ξ} is positive-semidefinite, and the real part $A_\xi = (E_\xi + E_\xi^*)/2$ has divisor $\operatorname{div} \Xi$, with multiplicity.

(EC$_\pi$) *Exponential completeness.* After the real-part divisor comparison places the zeros on the real axis, let Λ_ξ be their underlying set of distinct points. Require $\overline{\operatorname{span}}\{e^{i\gamma x} : \gamma \in \Lambda_\xi\} = L^2(-\pi, \pi)$. Repeated copies of an exponential do not add derivative conditions. This differs from the sharp fractional-part approximation predicate (BD+) in Theorem 57.4.22.

Proposition 79.4.4 *((SH) implies real-positive representing measure).* Under (SH), the moment problem (79.3) admits at least one positive Borel measure ν_ξ on $\mathbb{R}$ solving it.

Proof. Direct application of Hamburger's existence theorem (Theorem 79.4.2) to the moment sequence $\{M_n\}_{n \geq 0}$ under the positive-semidefiniteness hypothesis (SH). □

Remark 79.4.5 *(positivity is a genuine arithmetic input).* The hypothesis (SH) is not a tautology. The moments M_n are real-valued regularised sums of complex n-th powers (Definition 79.3.3); positive-semidefiniteness of the Hankel matrix is what transfers the complex multi-set $\mathcal{Z}_\xi$ to a real positive measure. This is the content Hamburger existence requires; it is distinct from the question whether the zeros are real.

79.5 Hamburger Determinacy and Carleman

Theorem 79.5.1 *(Carleman's determinacy criterion).* (Carleman 1926; Akhiezer 1965 §2.4). Let $\{M_n\}_{n \geq 0}$ be a Hamburger moment sequence with positive-semidefinite Hankel matrix and $M_{2n} > 0$ for all $n \geq 0$. If

$$\sum_{n \geq 1} M_{2n}^{-1/(2n)} = +\infty,$$

then the representing measure ν_ξ is unique (*determinate*).

Proposition 79.5.2 *(A sufficient moment-growth bound).* Let L be a specified positive Hamburger functional with finite moments $M_n = L(x^n)$. If $M_{2n}^{1/(2n)} \leq Cn$ for all sufficiently large n, then its representing measure is determinate.

Proof. If every even moment is positive, the Carleman summands are at least $(Cn)^{-1}$, and the harmonic series diverges. If some positive even moment vanishes, every representing positive measure is supported at zero, so its mass determines it uniquely. □

Remark 79.5.3 *(The moment functional to be constructed).* The finite cutoff calculation in Proposition 80.2.5 shows that the unregularized positive-power sums diverge. The zero-counting law therefore does not define the finite moments used above. A specified linear regularization, positivity of its resulting functional, and the linear root bound remain to be constructed. A two-sided factorial asymptotic would be stronger than the upper bound needed for Carleman; no such asymptotic is used here.

COROLLARY 79.5.4 *(under (SH) + (Det) the measure ν_ξ is unique).* Under (SH) + (Det) of Definition 79.4.3, there exists a unique positive Borel measure ν_ξ on $\mathbb{R}$ with moments (79.3).

Proof. (SH) + Hamburger existence (Theorem 79.4.2) gives solvability. The hypothesis (Det) gives uniqueness. Carleman's criterion is one sufficient way to establish that hypothesis. □

79.6 HERMITE–BIEHLER AND THE DE BRANGES SPACE $\mathcal{H}(E_\xi)$

Definition 79.6.1 *(de Branges datum over Ξ).* A *de Branges datum over* Ξ is a triple (E_ξ, A_ξ, B_ξ) with

$$E_\xi(z) \;=\; A_\xi(z) - iB_\xi(z),$$

where A_ξ and B_ξ are real entire functions. No finite-exponential-type assumption is imposed. The datum is required to carry a real-part divisor equality

$$\operatorname{div}(A_\xi) \;=\; \operatorname{div}(\Xi)$$

on $\mathbb{C}$, with multiplicities. It is not obtained by setting $E_\xi = \Xi$; for the real entire function Ξ one has $\Xi^* = \Xi$, so the strict Hermite–Biehler inequality would be impossible.

Remark 79.6.2 *(Growth of the prescribed divisor).* A nonzero entire function of finite exponential type has $O(T)$ zeros in the disk of radius T. After removing a zero at the origin, Jensen's formula on radius $2T$ bounds that number by a constant times the logarithmic maximum modulus at $2T$, which is $O(T)$. The divisor of Ξ has order $T \log T$ by Riemann–von Mangoldt. Therefore its divisor cannot be the divisor of a nonzero entire function of finite exponential type. A Paley–Wiener realization requires a separate map.

Remark 79.6.3 *(conventions match de Branges 1968).* The notation $E = A - iB$ with A and B real-on-real is de Branges' standard form for candidate Hermite–Biehler functions. The condition for Hermite–Biehler is $|E(z)| > |E^*(z)|$ for $\operatorname{Im} z > 0$, where $E^*(z) = \overline{E(\overline{z})}$. The divisor equality for A_ξ is part of the arithmetic datum; Hermite–Biehler positivity of an unrelated entire function says nothing about zeros of Ξ.

Definition 79.6.4 *(de Branges space $\mathcal{H}(E_\xi)$).* Assuming $E_\xi = A_\xi - iB_\xi$ is Hermite–Biehler (see (HB$^+$) below), the *de Branges space* $\mathcal{H}(E_\xi)$ is the reproducing-kernel Hilbert space of entire functions f with $f/E_\xi, f^*/E_\xi \in H^2(\mathbb{C}_+)$, with reproducing kernel

$$K_{E_\xi}(w,z) \;=\; \frac{\overline{E_\xi(w)}E_\xi(z) - \overline{E_\xi^*(w)}E_\xi^*(z)}{2\pi i(\overline{w} - z)}.$$

PROPOSITION 79.6.5 *(Hermite–Biehler kernel positivity).* Let E be entire with no zeros in $\mathbb{C}_+$, and $E^*(z) = \overline{E(\overline{z})}$. Then E is strictly Hermite–Biehler if and only if

$$K_E(w,z) = \frac{\overline{E(w)}E(z) - \overline{E^*(w)}E^*(z)}{2\pi i(\overline{w} - z)}$$

is positive-semidefinite and not identically zero on $\mathbb{C}_+$. Under these conditions the real entire functions $A = (E + E^*)/2$ and $B = (E^* - E)/(2i)$ have only real zeros.

Proof. Put $q = E^*/E$. For $|q| < 1$, multiplication by q is a contraction on Hardy space. The positive operator $I - M_q M_q^*$ applied to its reproducing kernels gives $(1 - \overline{q(w)}q(z))/(2\pi i(\overline{w} - z))$. Multiplication by $\overline{E(w)}E(z)$ proves kernel positivity. The diagonal equals $(|E(z)|^2 - |E^*(z)|^2)/(4\pi \operatorname{Im} z) > 0$. Conversely the nonnegative diagonal gives $|q| \le 1$. If equality holds inside, the maximum-modulus principle makes q a unimodular constant and the kernel zero, a contradiction. Hence the inequality is strict. A zero of A or B in the upper half-plane would make $E^* = \mp E$, contradicting strictness. Reality excludes lower-half-plane zeros as well. □

Remark 79.6.6 *(Why both qualifications are needed).* The function $E = 1$ has zero kernel. Further, if $P = P^*$ is real entire and E_0 is Hermite–Biehler, then $K_{PE_0}(w, z) = \overline{P(w)}P(z)K_{E_0}(w, z)$. This remains positive-semidefinite but has common upper-half-plane zeros whenever P does. Nonzero kernel alone does not replace the zero-free hypothesis.

Proposition 79.6.7 *(Strictness for the derivative datum).* Let A be a nonconstant even real entire function and $E = A + iA'$. If K_E is positive-semidefinite on $\mathbb{C}_+$, then E is strictly Hermite–Biehler. This applies to $A = \Xi$.

Proof. For $z = x + iy$, away from zeros of A,

$$|E|^2 - |E^*|^2 = -4|A|^2 \operatorname{Im}(A'/A), \qquad K_E(z, z) = -\frac{|A(z)|^2}{\pi y} \operatorname{Im}(A'/A)(z).$$

The diagonal condition gives $\operatorname{Im}(A'/A) \le 0$. An upper-half-plane zero a of order m would give $A'/A = m/(z - a) + O(1)$. At $z = a - i\epsilon$ its imaginary part is $m/\epsilon + O(1) > 0$, a contradiction. Thus A has no zeros there. The function $-\operatorname{Im}(A'/A)$ is nonnegative harmonic on the whole upper half-plane. An interior zero would make it identically zero by the minimum principle. Then the holomorphic quotient A'/A is a real constant c. Analytic continuation gives $A' = cA$; evenness forces $c = 0$, contradicting nonconstancy. The diagonal is therefore strictly positive, proving the strict modulus inequality. □

Remark 79.6.8 *(The actual arithmetic candidate).* The functional equation and chain rule give

$$\Xi(z) + i\Xi'(z) = \xi_{\mathbb{R}}(1/2 - iz) + \xi'_{\mathbb{R}}(1/2 - iz),$$

where the derivative on the right is in s. The preceding proposition establishes the required nondegeneracy implication for this candidate. It does not establish positivity of its kernel or an arithmetic Mellin/Fock intertwiner.

Theorem 79.6.9 *(Hermite–Biehler real-part control forces zero placement).* Under (HB$^+$), the zero multi-set $\mathcal{Z}_\xi$ of Ξ is contained in $\mathbb{R}$.

Proof. By (HB$^+$), $E_\xi = A_\xi - iB_\xi$ is Hermite–Biehler and $\operatorname{div}(A_\xi) = \operatorname{div}(\Xi)$. The Hermite–Biehler separation theorem gives that every zero of A_ξ is real. Hence every zero of Ξ is real. □

Corollary 79.6.10 *(zero multi-set is real under HB$^+$).* Under (HB$^+$), no non-trivial zero of $\xi_{\mathbb{R}}$ has $\operatorname{Im}\gamma \neq 0$ in the coordinate $\rho = \frac{1}{2} + i\gamma$.

Proof. Theorem 79.6.9 gives $\gamma \in \mathbb{R}$ for every zero. □

Remark 79.6.11 *(HB$^+$ is an RH-strength datum).* Corollary 79.6.10 shows that (HB$^+$), including real-part divisor control over Ξ, forces every non-trivial zero γ of Ξ to be real. Translated back via $\rho = \frac{1}{2} + i\gamma$, this is exactly $\operatorname{Re}\rho = \frac{1}{2}$. Thus (HB$^+$) is not a soft positivity assumption: it already contains the de Branges real-part mechanism at RH strength.

79.7 Exponential Completeness and Evaluation

Definition 79.7.1 *(Exterior Beurling–Malliavin density).* For a discrete real set Λ, a disjoint sequence of bounded intervals I_j is long if $\sum_j |I_j|^2/(1 + \operatorname{dist}(0, I_j)^2) = \infty$. Define $D^*(\Lambda)$ as the supremum of $d > 0$ for which a long sequence satisfies $\#(\Lambda \cap I_j) > d|I_j|$ for every j, with supremum zero for the empty set. Count distinct points.

THEOREM 79.7.2 *(Beurling–Malliavin completeness theorem).* For a discrete real set, the completeness radius

$$R(\Lambda) = \sup\{a > 0 : \operatorname{span}(e^{i\lambda x})_{\lambda\in\Lambda} \text{ is dense in } L^2(0, a)\}$$

is $2\pi D^*(\Lambda)$. Hence $D^* > 1$ implies (EC$_\pi$); equality leaves the endpoint assertion open.

Reference. The Beurling–Malliavin theorem in the exterior-density formulation; see Makarov–Poltoratski, *Two-Spectra Theorem with Uncertainty*, §3.1. Translation of the interval preserves exponential completeness. □

PROPOSITION 79.7.3 *(Completeness and uniqueness of evaluation).* Define PW_π by $G(z) = (2\pi)^{-1/2}\int_{-\pi}^{\pi} h(x)e^{izx}\,dx$, $h \in L^2(-\pi, \pi)$, with norm $\|h\|_2$. If Λ satisfies (EC$_\pi$), its evaluation map is injective on PW_π. If an injective linear map $J : \mathcal{H}(E) \to PW_\pi$ additionally satisfies $(JF)(\lambda) = F(\lambda)$, then

$$\mathcal{H}(E) \longrightarrow \mathbb{C}^\Lambda, \qquad F \longmapsto (F(\lambda))_{\lambda\in\Lambda}$$

is injective.

Proof. Vanishing of G on Λ makes h orthogonal to all $e^{-i\lambda x}$. Conjugation preserves completeness, so $h = 0$. For the second claim apply the first to JF, then use injectivity of J. □

COROLLARY 79.7.4 *(Uniqueness and stable sampling on the identified carrier).* Assume (HB$^+$), (EC$_\pi$) and the specified evaluation-compatible injection $J : \mathcal{H}(E_\xi) \to PW_\pi$. Evaluation on Λ_ξ is injective. If additionally positive weights and constants $0 < c \le C < \infty$ satisfy

$$c\|F\|^2 \le \sum_{\lambda\in\Lambda_\xi} w_\lambda |F(\lambda)|^2 \le C\|F\|^2,$$

then the samples give stable reconstruction.

Proof. HB and the real-part divisor place the zeros on the real axis; the preceding proposition gives injectivity. Under the two bounds, $TF = (\sqrt{w_\lambda}F(\lambda))_\lambda$ is bounded and bounded below, so $S = T^*T$ is invertible and $F = S^{-1}T^*TF$. □

The injection and sampling bounds are additional analytic data. HB and divisor equality do not construct them, and exponential completeness does not supply the sharp fractional-part rate or its arithmetic operator comparison.

79.8 Main Theorem: (HB$^+$) + (EC$_\pi$) + (Det) ⇒ RH

Theorem 79.8.1 *(VB* main-direction implication).* Assume the spectral positivity hypothesis (SH) + (Det) + (HB$^+$) + (EC$_\pi$) of Definition 79.4.3 on the primary Fock. Then all non-trivial zeros of $\xi_{\mathbb{R}}$ lie on the critical line $\operatorname{Re} s = \frac{1}{2}$. Equivalently, $\mathcal{Z}_\xi \subset \mathbb{R}$; equivalently, RH holds.

Proof. By (HB$^+$) and Theorem 79.6.9, $\mathcal{Z}_\xi \subset \mathbb{R}$. The definition of $\mathcal{Z}_\xi$ then gives $\rho = \frac{1}{2} + i\gamma_\rho$ with $\gamma_\rho \in \mathbb{R}$ for every non-trivial zero of $\xi_{\mathbb{R}}$. Thus $\operatorname{Re} \rho = \frac{1}{2}$. □

Remark 79.8.2 *(the logical order of the hypotheses).* The zero-placement implication uses the real-part divisor control in (HB$^+$). The clauses (SH), (Det), and (EC$_\pi$) belong to the stronger spectral-measure hypothesis: they concern positivity, uniqueness, and sampling of the zero measure, not the realness of the zeros itself.

Corollary 79.8.3 *(valid forms of the main-direction implication).* Each of the following hypotheses suffices for RH:

(i) (HB$^+$), where (HB$^+$) includes real-part divisor control over Ξ (reduces to Corollary 79.6.10).

(ii) The full conjunction (SH) + (Det) + (HB$^+$) + (EC$_\pi$).

(iii) A de Branges formulation in which the real part of the specified Hermite–Biehler function has divisor $\operatorname{div} \Xi$.

(iv) The Conrey–Li 2000 construction: $\mathcal{H}(E_\xi)$ admitting a self-adjoint multiplication operator whose spectral measure is the zero-counting measure on $\mathcal{Z}_\xi \cap \mathbb{R}$.

No assertion is made that (SH) + (Det) + (EC$_\pi$) alone gives zero placement without the Hermite–Biehler or real-spectrum input. The main theorem proves the sufficient implication stated above.

Proof. (1): Theorem 79.6.9. (2): the theorem itself. (3): Lagarias Acta Arith. 89 (1999), with the de Branges datum specified. (4): Conrey–Li arXiv:math/9812166 Thm. 2, with real spectrum part of the hypothesis. □

Theorem 79.8.4 *(A sufficient spectral package for the arithmetic implication).* Assume the determinant–trace realization (SH), the identified positive arithmetic moment functional, its determinacy and support as in (Reg), and item 1 of Hypothesis 57.4.21. With the P1–P3 hypotheses of Theorem 58.4.2, this package suffices for the conditional implication to RH. Substitution of (HB+) or (BD+) requires the corresponding additional comparisons in that hypothesis.

Proof. The stated moment and support data give (Reg); item 1 gives VB*. Apply Corollary 58.4.3. No identification of bare determinacy with the complete arithmetic package is used. □

79.9 Analytic Hypotheses on $\xi_{\mathbb{R}}$

Remark 79.9.1 *(analytic content).* Theorem 79.8.1 proves the main-direction implication from the four hypotheses. It does *not* prove RH, because none of HB$^+$, EC$_\pi$, or (Det) is proved for $\xi_{\mathbb{R}}$ by the Hadamard product alone. The three analytic assertions have different logical strength:

- (HB$^+$) proof is RH (Theorem 57.4.9; de Branges 1994).
- EC$_\pi$ requires completeness of the specified exponentials in $L^2(-\pi, \pi)$. It is distinct from the sharp fractional-part rate (BD+) in Question 57.4.16. The finite-distance construction and exact norm transport in Proposition 57.4.13 do not identify these two predicates.

- (Det) proof is the positive regularised moment functional with $M_{2n}^{1/(2n)} = O(n)$, the residual ($\mathrm{R}_{\mathrm{analytic}}$) of Theorem 62.4.7.

THEOREM 79.9.2 *(sufficient residual form of RH).* Under P2, P3, H-P^{Ar}, the conjunction of the four conditions (SH), (Det), (HB^+), (EC_π) on the primary Fock implies the Riemann Hypothesis. The converse is not asserted here.

Proof. This is exactly Theorem 79.8.1. The reverse implication would require the spectral-regularity hypotheses of Theorem 57.4.22 under Hypothesis 57.4.21, and is not part of this theorem. □

Remark 79.9.3 *(the analytic arrow).* The analytic content is the main-direction arrow

$$(\mathrm{SH}) + (\mathrm{Det}) + (\mathrm{HB}^+) + (\mathrm{EC}_\pi) \implies \mathrm{RH},$$

isolating the analytic content as the proof of these four hypotheses on $\xi_{\mathbb{R}}$. The main-direction argument makes the sufficient chain explicit and identifies the exact shape of the required analytic theorem.

Remark 79.9.4 *(relation to the structural equivalence).* Theorem 57.4.22 under Hypothesis 57.4.21 gives a conditional comparison between Reg, HB^+, (BD+), and VB^* itself, using all the specified operator and quantitative comparison data. Its (Reg) predicate contains positivity and spectral support as well as determinacy. The complementary arrow is (SH) + (Det) + (HB^+) + (EC_π) ⇒ RH. Together they say that regularity is the needed input and that the full spectral hypothesis is sufficient for RH.

79.10 Bibliography Anchors

The primary sources for the main-direction implication, beyond the operator-theoretic list of Section 57.1, are:

de Branges, *Hilbert Spaces of Entire Functions* (Prentice-Hall 1968). Theorems 22–23 (Hermite–Biehler structure), theorem 32 (multiplication operator on $\mathcal{H}(E)$). The strict Hermite–Biehler criterion used here requires the stated upper-half-plane zero-free hypothesis and a positive semidefinite kernel that is not identically zero. Those hypotheses, proved for the derivative construction when its kernel is positive, exclude the degenerate constant example.

Lagarias, Acta Arith. 89 (1999), 217–234. Reformulation: RH ⇔ the Lagarias function E_ξ is Hermite–Biehler. This is (HB^+) ⇔ RH, the single-hypothesis equivalent form used in Remark 79.6.11.

Lagarias, Acta Arith. 89 (1999). Survey of de Branges reformulations; §4.2 on the exponential type of E_ξ; §5 on the Beurling–Malliavin density of $\mathcal{Z}_\xi$; §6 on the Conrey–Li counter-example discussion.

Conrey–Li, arXiv:math/9812166 (2000). Theorem 2: the de Branges space $\mathcal{H}(E_\xi)$ does not in general admit an arithmetic multiplication operator realising RH; the authors construct explicit counter-examples for L-functions where the Hermite–Biehler condition fails (e.g. for certain Dirichlet L-functions with Siegel-type zeros). This confirms that (HB^+) is a substantive hypothesis not automatic from the Hadamard product.

Beurling–Malliavin, Acta Math. 107 (1962), 291–309. Density theorem: completeness radius of $\{e^{i\lambda_k x}\}$ equals Beurling–Malliavin density of $\{\lambda_k\}$. This is the analytical basis for the (EC_π) ⇒ sampling implication.

Hamburger, Math. Ann. 81 (1920), 235–319. Existence theorem: positive-semidefinite Hankel ⇔ positive Borel measure on $\mathbb{R}$. Hamburger's own proof via the Helly selection theorem and the Banach–Alaoglu compactness of probability measures on $\mathbb{R}$.

Carleman (1922, 1926). Comptes Rendus Acad. Sci. Paris (1922); *Les fonctions quasi analytiques* (Gauthier-Villars 1926). Determinacy criterion: $\sum M_{2n}^{-1/(2n)} = \infty \Rightarrow$ Hamburger determinacy. The proof uses quasi-analytic classes of entire functions and constitutes the classical foundation for the determinacy condition (Det).

Koosis, *The Logarithmic Integral II* (Cambridge 1992), Ch. VIII. Modern treatment of Beurling–Malliavin density and its applications to completeness of exponential systems.

Levin, *Distribution of Zeros of Entire Functions* (AMS 1980), Ch. V–VII. Classical reference on Hermite–Biehler and Laguerre–Pólya class; the structure theorems used in the HB^+ characterisation.

These sources furnish the classical foundations for the implication. None supplies the proof of HB^+, EC_π, or (Det) on $\xi_{\mathbb{R}}$.

79.11 Spectral Boundary

(i) $\xi_{\mathbb{R}}$ is entire of order 1, Hadamard genus 1, with $\xi_{\mathbb{R}}(s) = \xi_{\mathbb{R}}(1-s)$; hence $\Xi(z) = \xi_{\mathbb{R}}(\frac{1}{2} + iz)$ has real Taylor coefficients and a zero set symmetric under the Klein four group (Proposition 79.2.1, Proposition 79.2.2).

(ii) The regularised moment sequence $\{M_n\}$ of the zero multi-set $\mathcal{Z}_\xi$ is real, with odd moments vanishing (Proposition 79.3.4).

(iii) Positive Hamburger moment structure (SH) plus Hamburger determinacy (Det) give a unique positive Borel measure ν_ξ on $\mathbb{R}$ with moments $\{M_n\}$ (Corollary 79.5.4).

(iv) Hermite–Biehler positivity (HB^+), including real-part divisor control over Ξ, forces $\mathcal{Z}_\xi \subset \mathbb{R}$ (Corollary 79.6.10).

(v) Exponential completeness EC_π gives uniqueness in PW_π. Transfer to $\mathcal{H}(E_\xi)$ requires the specified evaluation-compatible injection into PW_π; stable sampling further requires the Bessel and lower sampling bounds (Corollary 79.7.4).

(vi) The conjunction (SH) + (Det) + (HB^+) + (EC_π) implies zero-placement and hence RH (Theorem 79.8.1).

(vii) The analytic content is the proof of HB^+, EC_π, and (Det) on $\xi_{\mathbb{R}}$; these are the spectral inputs (Remark 79.9.1).

(viii) The analytic implication matches the RH completion hypothesis of Definition 58.4.1: the positive Hamburger spectral component of that hypothesis is exactly (SH) + (Det) + (HB^+) + (EC_π), and the arrow to RH is Theorem 79.8.1.

Chapter 80

Zero counts, Gaussian tests and formal completion

Three calculations fix distinct parts of the arithmetic comparison. The Riemann–von Mangoldt formula retains its argument term:

$$N(T) = \frac{T}{2\pi}\log\frac{T}{2\pi e} + \frac{7}{8} + S(T) + O(1/T), \qquad S(T) = O(\log T).$$

The balanced Weil explicit formula is evaluated on the Gaussian family $f_\lambda(x) = e^{-\pi x^2/\lambda}$. Its ordinary convergent terms give the tested functional. Positivity is an additional assertion.

Artin–Rees controls induced filtrations on finite modules over the Iwasawa algebra. Comparisons for formal mapping stacks require additional constructions. The positivity and linear-growth assertions in $\mathrm{R}_{\mathrm{analytic}}$ are not consequences of these three calculations.

80.1 Primary Sources

The zero count and explicit formula have their classical analytic normalizations. The argument estimate is imported in the precise form named below. The finite-module filtration theorem is proved by its Rees module. Positivity and moment determinacy require separate inputs.

Riemann and von Mangoldt. Riemann's 1859 memoir introduces the zero-counting problem. Von Mangoldt's 1895 paper gives a complete proof of the asymptotic formula. The normalization below retains the horizontal argument variation.

Hasanalizade–Shen–Wong. *Counting zeros of the Riemann zeta function*, arXiv:2107.06506, Theorem 1.3 and Corollary 1.4 give the argument bound used here.

Selberg, Avh. Norske Vid. Akad. Oslo (1944) 1–27. Refined mean-square estimates on $S(T)$.

Weil. *Sur les formules explicites de la théorie des nombres premiers*, Lund, volume supplémentaire (1952), 252–265. The complete signed functional below uses both polar values, the gamma term and every prime power.

Tate. PhD thesis, Princeton 1950 (printed in Cassels–Fröhlich, *Algebraic Number Theory*, 1967, Ch. XV). Adelic Mellin-transform treatment of ξ; self-dual Gaussian under the archimedean factor.

Atiyah–Macdonald. *Introduction to Commutative Algebra* (Addison-Wesley 1969), Chapter 10: filtrations and completions of Noetherian modules.

Bourbaki, *Algèbre Commutative* (Ch. III §3, Masson 1961). Artin–Rees and Noetherian filtered rings.

80.2 Riemann–von Mangoldt Density of Zeros

Statement

THEOREM 80.2.1 *(Riemann–von Mangoldt zero count).* Let $N(T)$ count the nontrivial zeros $\rho = \beta + i\gamma$ with $0 < \gamma \le T$, including multiplicity. For $T \ge 2$ away from zero ordinates,

$$N(T) = \frac{T}{2\pi}\log\frac{T}{2\pi e} + \frac{7}{8} + S(T) + R(T), \qquad R(T) = O(T^{-1}). \tag{80.1}$$

Here

$$S(T) = \frac{1}{\pi}\Delta_{2\to 2+iT\to 1/2+iT}\arg\zeta, \tag{80.2}$$

with argument starting at zero at $s = 2$. At a zero ordinate, the convention $\gamma \le T$ uses the right limit of S. The formula is unconditional.

Proof

Proof. The completed function is

$$\xi(s) = \tfrac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

It is entire, has no real zeros, and obeys $\xi(s) = \xi(1-s)$ and $\xi(\bar{s}) = \overline{\xi(s)}$. These properties and its zero strip are proved in Section 23.3.

For a height T away from zero ordinates, use the rectangle $R_T = \{-1 \le \operatorname{Re} s \le 2,\ 0 \le \operatorname{Im} s \le T\}$. The argument principle gives

$$\frac{1}{2\pi i}\oint_{\partial R_T}\frac{\xi'(s)}{\xi(s)}\,ds = N(T).$$

The logarithmic derivative satisfies

$$\frac{\xi'(s)}{\xi(s)} + \frac{\xi'(1-s)}{\xi(1-s)} = 0.$$

The real bottom edge has zero argument change.

Reflection about $\operatorname{Re} s = 1/2$, together with conjugation, makes the remaining change twice that on the path $C_T : 2 \to 2 + iT \to 1/2 + iT$. Consequently,

$$N(T) = \frac{1}{\pi}\Delta_{C_T}\arg\xi.$$

The horizontal part of C_T is retained in this expression.

Logarithmic differentiation gives

$$\frac{\xi'}{\xi}(s) = \frac{1}{s} + \frac{1}{s-1} - \frac{1}{2}\log\pi + \frac{1}{2}\frac{\Gamma'}{\Gamma}(s/2) + \frac{\zeta'}{\zeta}(s).$$

At the endpoint of C_T, the continuous arguments of s and $s-1$ sum to π. Thus

$$N(T) = 1 + \frac{\vartheta(T)}{\pi} + S(T), \qquad \vartheta(T) = \operatorname{Im}\log\Gamma(1/4 + iT/2) - \frac{T}{2}\log\pi.$$

The logarithm of gamma is analytic on the right half-plane and real on the positive axis.

Stirling's expansion gives

$$\vartheta(T) = \frac{T}{2}\log\frac{T}{2\pi} - \frac{T}{2} - \frac{\pi}{8} + \frac{1}{48T} + O(T^{-3}).$$

Combining the two identities proves the assertion away from zero ordinates. Right limits give the stated convention at those heights. □

Remark 80.2.2 *(The constant 7/8).* The factor $s(s-1)$ contributes 1 to $N(T)$. For $z = 1/4 + iT/2$, the imaginary part of $(z-1/2)\log z - z$ has constant term $-\pi/8$. Dividing by π gives $7/8 = 1 - 1/8$. This is an asymptotic argument calculation at large height. The positive real number $\Gamma(1/4)$ has real logarithm and does not contribute that imaginary constant.

The unconditional argument bound

Theorem 80.2.3 *(The classical argument estimate).* The function in (80.2), with its stated one-sided convention, satisfies

$$|S(T)| \le C\log T \qquad (T \ge 2) \tag{80.3}$$

for an absolute constant C. In particular, the number $\mathcal{N}(T,1)$ of zeros with ordinates in $(T-1, T+1]$ obeys

$$\mathcal{N}(T,1) = O(\log T).$$

Proof. The argument estimate is the classical analytic theorem. A precise primary bound is Hasanalizade–Shen–Wong, *Counting zeros of the Riemann zeta function*, Theorem 1.3 and Corollary 1.4, arXiv:2107.06506. The estimate remains valid under one-sided limits. Subtract (80.1) at $T-1$ and $T+1$. The change of its smooth main term is $O(\log T)$, and the two argument terms have the same bound. This proves the local count. □

Corollary 80.2.4 *($N(T)$ to main term, $\log T$ precision).* Combining (80.1) and (80.3),

$$N(T) \;=\; \frac{T}{2\pi}\log\frac{T}{2\pi e} + O(\log T),$$

unconditionally, using the functional equation, Stirling expansion and the classical argument estimate.

Proof. Substitute the $S(T)$ bound into (80.1) and absorb the $7/8$ and $O(1/T)$ into the $O(\log T)$ bound. □

Consequence for $\mathrm{R}_{\mathrm{analytic}}$

Proposition 80.2.5 *(Finite positive-power sums of ordinates).* Let $N(T)$ count the positive ordinates γ of nontrivial zeros with multiplicity. For each fixed integer $n \ge 0$, put $S_n(T) = \sum_{0<\gamma\le T}(1/4+\gamma^2)^n$. Then

$$S_n(T) = \frac{T^{2n+1}}{2\pi(2n+1)}\log\frac{T}{2\pi} - \frac{T^{2n+1}}{2\pi(2n+1)^2} + O_n(T^{2n}\log T).$$

In particular every $S_n(T)$ diverges. Under RH these are the corresponding positive-power sums of the real zero parameters.

Proof. For $n = 0$ this is the Riemann–von Mangoldt formula. For $n \geq 1$, Stieltjes integration by parts gives

$$S_n(T) = (1/4 + T^2)^n N(T) - \int_0^T 2nt(1/4 + t^2)^{n-1} N(t)\, dt.$$

Write $N(t) = F(t) + O(\log(2 + t))$, where $F(t) = t\log(t/(2\pi))/(2\pi) - t/(2\pi)$, and absorb a fixed initial interval in the error. The endpoint and integrated errors are $O_n(T^{2n}\log T)$. The main term is $(2\pi)^{-1}\int^T (1/4 + t^2)^n \log(t/(2\pi))\, dt$. Replacing the polynomial by t^{2n} costs $O_n(T^{2n-1}\log T)$. Integrating this last monomial gives the two displayed terms. Its leading term is positive and divergent. □

Remark 80.2.6 *(Finite measures and the regularization problem).* The finite positive measure

$$\nu_T = \frac{1}{2}\sum_{0<\gamma\leq T}\left(\delta_{\sqrt{1/4+\gamma^2}} + \delta_{-\sqrt{1/4+\gamma^2}}\right)$$

has odd moments zero and even moments $S_n(T)$. It is compactly supported and determinate, but its mass tends to infinity. Consequently the unregularized integral over all ordinates has no finite moment saddle. To obtain the proposed arithmetic Hamburger functional one must specify a common linear regularization and prove its positivity and growth. If that regularization gives moments M_{2k} of γ, its shifted moments must satisfy

$$\mu_{2n} = \sum_{k=0}^{n}\binom{n}{k}4^{-(n-k)}M_{2k}.$$

This compatibility is a consequence of linearity, not a construction of the regularization or an estimate for its moments.

80.3 Weil Explicit Formula at Gaussian Test Functions

The Weil Explicit Formula: Recall

The arithmetic expression and the sum over zeros use different variables. Their relation fixes the scale at which the prime powers sample a test function. The following conventions make this relation explicit.

Lemma 80.3.1 *(The normalized explicit formula).* For $b > \pi$, let

$$\mathcal{T}_b = \left\{f \in C^\infty(\mathbb{R};\mathbb{C}) : \int_{\mathbb{R}} e^{b|x|}|f^{(j)}(x)|\, dx < \infty \text{ for every } j \geq 0\right\}, \qquad \mathcal{T} = \bigcup_{b>\pi}\mathcal{T}_b.$$

Use Lebesgue measure and define

$$\widehat{f}(t) = \int_{\mathbb{R}} f(x)e^{-2\pi ixt}\, dx, \qquad f^\sharp(x) = \overline{f(-x)}, \qquad (f\star h)(x) = \int_{\mathbb{R}} f(y)h(x-y)\, dy.$$

These operations make $\mathcal{T}$ a complex convolution $*$-algebra. For $f \in \mathcal{T}_b$, the transform is holomorphic on $|\operatorname{Im} t| < b/(2\pi)$. Put $\psi = \Gamma'/\Gamma$ and $z_\rho = -i(\rho - 1/2)$, with nontrivial zeta zeros counted with multiplicity. Define

$$\Phi_\infty(f) = \frac{1}{2\pi}\int_{\mathbb{R}} \widehat{f}(t)\left[\operatorname{Re}\psi(1/4 + it/2) - \log\pi\right]dt, \tag{80.4}$$

$$\Phi_{\mathrm{fin}}(f) = -\frac{1}{2\pi}\sum_p\sum_{k\geq 1}\frac{\log p}{p^{k/2}}\left[f\left(\frac{k\log p}{2\pi}\right) + f\left(-\frac{k\log p}{2\pi}\right)\right]. \tag{80.5}$$

These expressions converge absolutely. The arithmetic functional is

$$L_{2\pi}(f) = \widehat{f}(i/2) + \widehat{f}(-i/2) + \Phi_\infty(f) + \Phi_{\mathrm{fin}}(f).$$

The explicit formula states

$$L_{2\pi}(f) = \sum_\rho \widehat{f}(z_\rho),$$

with absolute convergence. Consequently the balanced expression is

$$W(f) := L_{2\pi}(f) - \sum_\rho \widehat{f}(z_\rho) = 0. \tag{80.6}$$

Proof. Set $g_f(u) = (2\pi)^{-1} f(-u/(2\pi))$ and $a = b/(2\pi) > 1/2$. Every derivative of g_f is integrable with weight $e^{a|u|}$. The change of variables $u = -2\pi x$ gives

$$\int_{\mathbb{R}} g_f(u) e^{itu}\, du = \widehat{f}(t), \qquad g_{f\star h} = g_f \star g_h, \qquad g_{f^\sharp}(u) = \overline{g_f(-u)}.$$

Weighted Young's inequality and differentiation under convolution prove closure of $\mathcal{T}$ under these operations. Weighted integrability of f' gives $|f(x)| \le Ce^{-b|x|}$ by integrating from the appropriate infinity. Integration by parts gives rapid transform decay in every closed strip $|\operatorname{Im} t| \le \eta < b/(2\pi)$. The zero count $N(T) = O(T\log(T+2))$ therefore gives absolute convergence of the zero sum. The prime sum is bounded by a constant times $\sum_{n\ge 2} (\log n) n^{-1/2-a}$, which converges. The gamma integral converges because its bracket is $O(\log(2+|t|))$.

Here is the contour calculation in the rescaled variable. Write $g = g_f$ and

$$F_g(s) = \int_{\mathbb{R}} g(u) e^{(s-1/2)u}\, du, \quad \Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2), \quad H(s) = \frac{d}{ds}\log\bigl(\Gamma_{\mathbb{R}}(s)\zeta(s)\bigr).$$

Thus $F_g(s) = \widehat{f}(-i(s-1/2))$. Choose $1 < c < \min(a+1/2, 3/2)$. The functional equation gives $H(1-s) = -H(s)$. The residues of H are the multiplicities of the nontrivial zeros and -1 at each of $0, 1$. Integrate $H(s)F_g(s)$ on the counterclockwise rectangle with vertical sides $1-c, c$ and heights $\pm T$. Choose heights tending to infinity away from the zero ordinates. For example, the bound $O(T\log(T+2))$ permits a choice in each $[T, T+1]$ at distance at least $c_0/(T\log(T+2))$ from every nearby ordinate, for sufficiently small fixed $c_0 > 0$. The logarithmic derivative expansion of the Hadamard product of ξ then gives a polynomial bound for H on these horizontal segments. Its nearby terms are bounded by the zero count times the inverse distance. For distant zeros the paired product terms are $O(T/|\rho|^2)$ and summable. The rapid decay of F_g eliminates both horizontal integrals. Reflection of the left side gives

$$\sum_\rho F_g(\rho) - F_g(0) - F_g(1) = \frac{1}{2\pi i}\int_{\operatorname{Re} s = c} H(s)\bigl(F_g(s) + F_g(1-s)\bigr)\, ds.$$

On this line, $\zeta'/\zeta(s) = -\sum_{n\ge 2} \Lambda_{\mathrm{vM}}(n) n^{-s}$, where $\Lambda_{\mathrm{vM}}(p^k) = \log p$ and is zero otherwise. Absolute convergence permits termwise integration. Fourier inversion gives

$$\frac{1}{2\pi i}\int_{\operatorname{Re} s = c} n^{-s} F_g(s)\, ds = n^{-1/2} g(\log n).$$

The reflected test gives $n^{-1/2}g(-\log n)$. Since $g(\pm\log n) = (2\pi)^{-1}f(\mp\log n/(2\pi))$, these are exactly the stated prime terms with their negative sign. For the gamma term, move the integration line to $1/2$. Its logarithmic derivative is holomorphic between these lines, and rapid test decay eliminates the horizontal integrals. Combining the two reflected terms uses

$$2\,\mathrm{Re}\,\frac{\Gamma_{\mathbb{R}}'}{\Gamma_{\mathbb{R}}}(1/2+it) = \mathrm{Re}\,\psi(1/4+it/2) - \log\pi.$$

The two pole values are $\widehat{f}(i/2)$ and $\widehat{f}(-i/2)$. This proves the formula, including its constants and signs. Equivalently, if L_ζ denotes the arithmetic functional for the transform $\int g(u)e^{itu}\,du$, the comparison is $L_{2\pi}(f) = L_\zeta(g_f)$. □

The Gaussian Test Family

Definition 80.3.2 *(Gaussian test family).* For $\lambda > 0$, set

$$f_\lambda(x) \;:=\; e^{-\pi x^2/\lambda}.$$

This is a Schwartz function; its Fourier transform is

$$\widehat{f_\lambda}(y) \;=\; \sqrt{\lambda}\,e^{-\pi\lambda y^2} \tag{80.7}$$

by the classical Gaussian-self-duality identity: indeed, at $\lambda = 1$, $\widehat{f_1}(y) = f_1(y)$ and the general case follows by scaling $x \mapsto x/\sqrt{\lambda}$ and the Plancherel change-of-variables $\widehat{f(\cdot/a)}(y) = a\widehat{f}(ay)$. The transform is again a Gaussian with full support.

Remark 80.3.3 *(Gaussian admissibility).* Every derivative of f_λ is a polynomial times a Gaussian. Thus $f_\lambda \in \mathcal{T}_b$ for every $b > \pi$. Its Fourier transform has full support, as permitted by Lemma 80.3.1. All terms are ordinary convergent integrals or sums.

Closed-Form Evaluation of $W(f_\lambda)$

We evaluate each term of $W(f_\lambda)$ in closed form.

LEMMA 80.3.4 *(pole and zero terms for Gaussians).* For the Gaussian f_λ of Definition 80.3.2,

$$\widehat{f_\lambda}(i/2) + \widehat{f_\lambda}(-i/2) \;=\; 2\sqrt{\lambda}e^{\pi\lambda/4}.$$

Moreover

$$\sum_\rho \widehat{f_\lambda}(z_\rho) = \sqrt{\lambda}\sum_\rho e^{-\pi\lambda z_\rho^2}, \qquad z_\rho = -i(\rho - \tfrac{1}{2}),$$

and this zero sum is absolutely convergent.

Proof. By (80.7), $\widehat{f_\lambda}(\pm i/2) = \sqrt{\lambda}e^{\pi\lambda/4}$. For $\rho = \beta + i\gamma$ in the critical strip, $|e^{-\pi\lambda z_\rho^2}| \le e^{\pi\lambda/4}e^{-\pi\lambda\gamma^2}$. The Riemann–von Mangoldt bound $N(T) = O(T\log T)$ gives absolute convergence. □

LEMMA 80.3.5 *(The prime contribution on Gaussians).* For $\lambda > 0$,

$$\Phi_{\mathrm{fin}}(f_\lambda) = -\frac{1}{\pi}\sum_p\sum_{k\ge1}\frac{\log p}{p^{k/2}}\exp\!\left(-\frac{(k\log p)^2}{4\pi\lambda}\right).$$

The sum is absolutely convergent and smooth in $\lambda > 0$.

Proof. Insert the even Gaussian into (80.5). On any compact interval $[\lambda_0, \lambda_1] \subset (0, \infty)$, each parameter derivative is bounded by a polynomial in $\log n$ times $n^{-1/2} \exp[-(\log n)^2/(4\pi\lambda_1)]$. This is summable over integers $n \geq 2$. For every fixed M, the exponential is at most n^{-M} for all sufficiently large n. Uniform domination proves convergence and differentiation term by term. □

Lemma 80.3.6 *(The archimedean contribution on Gaussians).* For $\lambda > 0$,

$$\Phi_\infty(f_\lambda) = -\frac{\log \pi}{2\pi} + A_\Gamma(\lambda),$$

where

$$A_\Gamma(\lambda) = \frac{\sqrt{\lambda}}{2\pi} \int_{\mathbb{R}} e^{-\pi\lambda t^2} \operatorname{Re} \psi(1/4 + it/2)\, dt. \tag{80.8}$$

This ordinary integral is absolutely convergent.

Proof. Substitute $\widehat{f_\lambda}(t) = \sqrt{\lambda} e^{-\pi\lambda t^2}$ into (80.4). The Gaussian integral gives $\int_{\mathbb{R}} \widehat{f_\lambda}(t)\, dt = f_\lambda(0) = 1$. The digamma factor is smooth on the real integration line and is $O(\log(2 + |t|))$ at infinity. Gaussian decay gives absolute convergence. The same bound with polynomial factors proves smooth parameter variation on compact subintervals of $(0, \infty)$. □

Theorem 80.3.7 *(The Weil formula on Gaussians).* For $\lambda > 0$,

$$\begin{aligned} W(f_\lambda) = 2\sqrt{\lambda} e^{\pi\lambda/4} - \mathcal{Z}(\lambda) - \frac{\log \pi}{2\pi} \\ + A_\Gamma(\lambda) - \frac{1}{\pi}\mathcal{P}(\lambda) = 0, \end{aligned} \tag{80.9}$$

where

$$\mathcal{Z}(\lambda) = \sqrt{\lambda} \sum_\rho e^{-\pi\lambda z_\rho^2}, \qquad z_\rho = -i(\rho - 1/2),$$

$$\mathcal{P}(\lambda) = \sum_p \sum_{k \geq 1} \frac{\log p}{p^{k/2}} \exp\left(-\frac{(k \log p)^2}{4\pi\lambda}\right).$$

The integral A_Γ is defined in (80.8). Equivalently,

$$\mathcal{Z}(\lambda) = 2\sqrt{\lambda} e^{\pi\lambda/4} - \frac{\log \pi}{2\pi} + A_\Gamma(\lambda) - \frac{1}{\pi}\mathcal{P}(\lambda). \tag{80.10}$$

Proof. Substitute Lemma 80.3.4, Lemma 80.3.5, and Lemma 80.3.6 into Lemma 80.3.1. Gaussian admissibility was proved in Remark 80.3.3. Rearranging the balanced formula gives (80.10). □

Remark 80.3.8 *(Poisson summation embedding).* The self-duality $\widehat{f_1} = f_1$ of the standard Gaussian at $\lambda = 1$ is the archimedean input to Tate's thesis. Poisson summation for the standard Gaussian gives

$$\theta(i\tau) := \sum_{n \in \mathbb{Z}} e^{-\pi n^2 \tau} = \tau^{-1/2} \theta(i/\tau),$$

the classical modular transformation of the Jacobi theta. The identity (80.10) can be viewed as the arithmetic Weil analogue: the zero sum $\mathcal{Z}(\lambda)$ is the arithmetic theta analogue, and the RHS is the corresponding archimedean-plus-prime expansion.

Gaussian Convolutions and the Balanced Weil Functional

The functional W in (80.6) is the balanced difference, and it vanishes by the explicit formula. The associated sesquilinear form is instead

$$B_{2\pi}(f,h) = L_{2\pi}(h^\sharp \star f), \qquad f,h \in \mathcal{T}.$$

The change of variables $f \mapsto g_f$ preserves convolution and involution, so this is the same form as $L_\zeta(g_h^* \star g_f)$ in the logarithmic variable. Its diagonal values involve the arithmetic functional $L_{2\pi}$, rather than the identically zero balanced difference W. Positivity on the full test algebra remains the Weil positivity question. The Gaussian convolution identity below does not settle it.

Definition 80.3.9 *(Gaussian convolution sub-class).* The *Gaussian convolution sub-class* is the set

$$\mathcal{G} \;:=\; \{f_\lambda \star f_\mu^\sharp \;:\; \lambda,\mu > 0\}.$$

Since f_λ is real and even, $f_\mu^\sharp = f_\mu$, so $\mathcal{G} = \{f_\lambda \star f_\mu \;:\; \lambda,\mu > 0\}$.

LEMMA 80.3.10 *(Gaussian convolution is Gaussian).* For $\lambda,\mu > 0$,

$$f_\lambda \star f_\mu(x) \;=\; \sqrt{\frac{\lambda\mu}{\lambda+\mu}}\cdot f_{\lambda+\mu}(x).$$

Equivalently, in Fourier: $\widehat{f_\lambda \star f_\mu} = \widehat{f_\lambda}\cdot\widehat{f_\mu} = \sqrt{\lambda\mu}\,e^{-\pi(\lambda+\mu)y^2} = \sqrt{\lambda\mu/(\lambda+\mu)}\cdot\sqrt{\lambda+\mu}\,e^{-\pi(\lambda+\mu)y^2}$, consistent with $\widehat{f_\lambda \star f_\mu} = \sqrt{\lambda\mu/(\lambda+\mu)}\cdot\widehat{f_{\lambda+\mu}}$. In particular, $f_\lambda \star f_\lambda(x) = \sqrt{\lambda/2}\cdot f_{2\lambda}(x)$.

Proof.

$$f_\lambda \star f_\mu(x) \;=\; \int_{\mathbb{R}} e^{-\pi t^2/\lambda} e^{-\pi(x-t)^2/\mu}\,dt.$$

Completing the square in t:

$$\begin{aligned}
\frac{t^2}{\lambda} + \frac{(x-t)^2}{\mu} \;&=\; \frac{\mu t^2 + \lambda(x-t)^2}{\lambda\mu} \\
&=\; \frac{(\lambda+\mu)t^2 - 2\lambda t x + \lambda x^2}{\lambda\mu} \\
&=\; \frac{(\lambda+\mu)}{\lambda\mu}\Big(t - \frac{\lambda x}{\lambda+\mu}\Big)^2 + \frac{x^2}{\lambda+\mu}.
\end{aligned}$$

Hence

$$\begin{aligned}
f_\lambda \star f_\mu(x) \;&=\; e^{-\pi x^2/(\lambda+\mu)} \cdot \int_{\mathbb{R}} e^{-\pi(\lambda+\mu)u^2/(\lambda\mu)}\,du \\
&=\; e^{-\pi x^2/(\lambda+\mu)} \cdot \sqrt{\frac{\lambda\mu}{\lambda+\mu}} \;=\; \sqrt{\frac{\lambda\mu}{\lambda+\mu}}\cdot f_{\lambda+\mu}(x),
\end{aligned}$$

as claimed. □

Proposition 80.3.11 *(balanced Weil identity on Gaussian convolutions).* For every $\lambda, \mu > 0$,

$$W(f_\lambda \star f_\mu) \;=\; \sqrt{\frac{\lambda\mu}{\lambda+\mu}} \cdot W(f_{\lambda+\mu}) \;=\; 0. \tag{80.11}$$

This is an explicit-formula identity, not a proof of Weil positivity on the Gaussian convolution sub-class $\mathcal{G}$.

Proof. Lemma 80.3.10 expresses $f_\lambda \star f_\mu$ as a scalar multiple of $f_{\lambda+\mu}$. The Weil functional W is linear, so

$$W(f_\lambda \star f_\mu) \;=\; \sqrt{\lambda\mu/(\lambda+\mu)} \cdot W(f_{\lambda+\mu}).$$

By Theorem 80.3.7 applied to $\lambda + \mu$ in place of λ, and by the classical Weil explicit-formula identity $W(f_{\lambda+\mu}) = 0$, the result is zero. □

Remark 80.3.12 *(The Gaussian pairing).* The Gaussian functions are real and even, so

$$B_{2\pi}(f_\lambda, f_\mu) = \sqrt{\frac{\lambda\mu}{\lambda+\mu}}\, L_{2\pi}(f_{\lambda+\mu}).$$

Thus (80.10) evaluates this pairing by ordinary convergent arithmetic terms. The equality $W(f_\lambda \star f_\mu) = 0$ expresses the balanced explicit formula and supplies no sign inequality for $B_{2\pi}$. Positivity on the full test algebra remains a separate assertion.

Remark 80.3.13 *(Gaussian identities and operator traces).* The proposed arithmetic trace comparison in Corollary 62.5.2 requires an operator realization, a common domain and a trace or weight. The identity (80.10) computes its arithmetic scalar on the Gaussian family. It supplies no operator trace comparison and no positivity statement for $B_{2\pi}$ on the full test algebra.

80.4 Finite modules and formal comparisons

The arithmetic-loop comparisons in Propositions 53.4.4 and 53.4.7 involve mapping objects, filtered colimits and formal completion. Artin–Rees gives a precise theorem for a finite module and its submodule. To apply it to those comparisons, one must construct the modules and prove that they control the required maps.

The Iwasawa coefficient ring

Definition 80.4.1 *(The Iwasawa algebra).* Choose $\Gamma \cong \mathbb{Z}_p$ and a topological generator γ. Its completed group ring is

$$\Lambda = \mathbb{Z}_p[[\Gamma]] = \varprojlim_{r,n} (\mathbb{Z}/p^r)[\Gamma/p^n\Gamma] \cong \mathbb{Z}_p[[T]], \qquad \gamma \longmapsto 1 + T.$$

The coefficient variable T is different from the zero-counting height used earlier in this chapter.

Lemma 80.4.2 *(Noetherian local structure).* The ring Λ is regular local and Noetherian of dimension two, with maximal ideal $\mathfrak{m} = (p, T)$ and residue field $\mathbb{F}_p$. Its $\mathfrak{m}$-adic topology is the topology of the displayed finite group-ring quotients.

Proof. The formal power-series ring over the discrete valuation ring $\mathbb{Z}_p$ is Noetherian. Its maximal ideal is generated by p, T, and the chain $(0) \subset (p) \subset (p, T)$, together with the power-series dimension theorem, gives dimension two. The two generators form a regular system of parameters.

The finite group-ring quotient has defining ideal $J_{r,n} = (p^r, (1+T)^{p^n} - 1)$. For a fixed k, take $r \geq k$ and n sufficiently large. For $1 \leq j < k$,

$$v_p\binom{p^n}{j} \geq n - v_p(j),$$

by $\binom{p^n}{j} = p^n \binom{p^n-1}{j-1}/j$. Every term of $(1+T)^{p^n} - 1$ then lies in $\mathfrak{m}^k$. Thus $J_{r,n} \subset \mathfrak{m}^k$.

Conversely, modulo $J_{r,n}$, one has $p^r = 0$ and $T^{p^n} \in (p)$. Hence (p, T) is nilpotent in that finite quotient, and some $\mathfrak{m}^k$ lies in $J_{r,n}$. The two ideal systems are cofinal, proving the topology and completed-ring identification. □

Induced filtrations on finite modules

LEMMA 80.4.3 *(Artin–Rees).* Let R be a Noetherian ring, $\mathfrak{a} \subset R$ an ideal, M a finite R-module, and $N \subset M$ a submodule. There is $k \geq 0$ such that, for all $n \geq k$,

$$\mathfrak{a}^n M \cap N = \mathfrak{a}^{n-k}(\mathfrak{a}^k M \cap N).$$

In particular, the induced filtration on N is cofinal with its $\mathfrak{a}$-adic filtration.

Proof. The Rees algebra $\mathcal{R} = \bigoplus_{n \geq 0} \mathfrak{a}^n t^n$ is generated over R by finitely many elements of degree one, so it is Noetherian. The Rees module $\bigoplus_{n \geq 0} \mathfrak{a}^n M t^n$ is finite over $\mathcal{R}$. Its graded submodule

$$\bigoplus_{n \geq 0} (\mathfrak{a}^n M \cap N) t^n$$

is therefore finitely generated. Choose homogeneous generators of degrees at most k.

In degree $n \geq k$, a generator of degree $j \leq k$ is multiplied by $\mathfrak{a}^{n-j}$. Factor this as $\mathfrak{a}^{n-k}\mathfrak{a}^{k-j}$. The second factor sends that generator into $\mathfrak{a}^k M \cap N$, proving one inclusion in the formula. The reverse inclusion follows from N being a submodule.

Finally, $\mathfrak{a}^n N \subset \mathfrak{a}^n M \cap N \subset \mathfrak{a}^{n-k} N$, which gives cofinality. □

Arithmetic loops and filtered colimits

Question 80.4.4 *(The specified formal presentation).* For a derived formal arithmetic stack with presentation $\mathcal{X} = \operatorname{colim}_i \mathcal{X}_i$, determine the coefficient, topology and transition hypotheses under which

$$\operatorname{colim}_i \operatorname{Map}(B\widehat{\mathbb{Z}}, \mathcal{X}_i) \longrightarrow \operatorname{Map}(B\widehat{\mathbb{Z}}, \mathcal{X})$$

is an equivalence. The question includes the $\mathfrak{m}$-adically complete sector and its finite-type pieces.

A profinite presentation of $\widehat{\mathbb{Z}}$ uses all finite cyclic quotients with their divisibility transition maps. The p-power quotients instead describe $\mathbb{Z}_p$. Finite cardinality of a group does not make its classifying space compact in every category of targets. Nor does an inverse limit of compact objects automatically remain compact.

Question 80.4.5 *(The mapping functor on a target category).* For which category $\mathcal{C}$ of complete derived arithmetic stacks does the internal functor $\operatorname{Map}(B\widehat{\mathbb{Z}}, -)$ preserve the filtered colimits under consideration?

Ordinary compactness of K in an infinity category means that the space-valued functor $\mathrm{Map}(K, -)$ preserves filtered colimits. Preservation by an internal mapping object is a separate assertion, to be checked after evaluation on all test objects. Artin–Rees alone proves neither statement.

Proposition 80.4.6 *(A conditional arithmetic-loop comparison).* Fix the category of targets and an internal arithmetic-loop functor $L^{\mathrm{Ar}}\mathcal{Y} = \mathrm{Map}(B\widehat{\mathbb{Z}}, \mathcal{Y})$. If this functor preserves a specified presentation $\mathcal{X} = \mathrm{colim}_i \mathcal{X}_i$, then

$$L^{\mathrm{Ar}}\mathcal{X} \simeq \mathrm{colim}_i\, L^{\mathrm{Ar}}\mathcal{X}_i.$$

No preservation hypothesis is supplied merely by adic completeness of the target.

Proof. The assumed comparison is exactly the displayed map after substituting the definition of L^{Ar}. □

The order of completion and filtered colimit is a concrete issue even for modules. Let $R = \mathbb{Z}_p[[T]]$, $\mathfrak{m} = (p, T)$, and $M_i = \bigoplus_{j=1}^{i} R$. Each M_i is adically complete, but

$$\mathrm{colim}_i \varprojlim_n M_i/\mathfrak{m}^n M_i = \bigoplus_{j\geq 1} R \quad \subsetneq \quad \varprojlim_n \mathrm{colim}_i\, M_i/\mathfrak{m}^n M_i. \tag{80.12}$$

The right side is the space of sequences $(a_j) \in \prod_j R$ such that, for every n, all but finitely many a_j lie in $\mathfrak{m}^n$. Indeed, reduction modulo each power has finite support, and compatibility recovers each coordinate by completeness of R. The sequence $a_j = p^j$ belongs to this right side and not to the direct sum.

Every fixed quotient has a finite support bound, but no one bound works at every precision. This example isolates a limit exchange that a formal-stack argument must justify. It is not an obstruction to every possible arithmetic-loop comparison.

The flat subcategory

Question 80.4.7 *(Flat objects in a formal colimit).* Construct the proposed flat object or full subcategory on $L^{\mathrm{Ar}}\mathcal{X}$, with its transition maps, and determine when the comparison

$$\mathrm{colim}_i (L^{\mathrm{Ar}}\mathcal{X}_i)^{\mathrm{flat}} \longrightarrow (L^{\mathrm{Ar}}\mathcal{X})^{\mathrm{flat}}$$

is an equivalence. Specify whether the two sides are stacks, categories of sheaves or categories of modules before forming the map.

A flat subcategory is not a submodule of a coordinate ring merely by being full. Applying Artin–Rees requires an actual finite module M and submodule N, together with a theorem identifying their induced filtrations with the proposed geometric condition. A criterion using all adic truncations also requires its own completeness and flatness hypotheses.

Remark 80.4.8 *(Two further geometric comparisons).* The extension of nilpotent singular support to the specified formal stacks and its comparison with a Fargues–Scholze (φ, Γ)-module locus are additional geometric questions. Neither is a consequence of the finite-module filtration theorem. Their coefficient categories and functors must be specified separately.

The finite-module consequence

PROPOSITION 80.4.9 *(Adic completions of finite submodules).* For a finite Λ-module M and submodule N, the intrinsic $\mathfrak{m}$-adic completion of N agrees with its completion for the induced filtration $N \cap \mathfrak{m}^n M$. The arithmetic-loop and flat-subcategory comparisons above remain separate assertions. The categorical trace statement of Theorem 53.4.2 retains its stated categorical colimit hypothesis.

Proof. Artin–Rees makes the two filtrations cofinal, so their inverse-limit completions are canonically isomorphic. The lemma concerns finite modules and provides no mapping-stack or categorical colimit identity. □

80.5 CONSEQUENCES

PROPOSITION 80.5.1 *(three exact inputs).* The following assertions hold.

(i) The sharp Riemann–von Mangoldt identity (80.1) with $|S(T)| = O(\log T)$ is unconditional (Theorem 80.2.1, Theorem 80.2.3, Corollary 80.2.4). This proves the density estimate entering $\mathrm{R}_{\mathrm{analytic}}$, but not the positivity or linear-growth assertions.

(ii) The Gaussian specialization of the balanced Weil explicit formula uses the ordinary convergent terms in (80.9) and (80.10). The convolution identity (80.11) is only the balanced explicit formula and is not a Weil-positivity statement (Remark 80.3.12).

(iii) Artin–Rees identifies the intrinsic and induced adic completions of a finite Iwasawa submodule (Proposition 80.4.9). The arithmetic-loop and flat-subcategory maps require their separate preservation and geometric hypotheses.

Proof. The first assertion is Theorem 80.2.1 together with Theorem 80.2.3. The second assertion is Theorem 80.3.7 and Proposition 80.3.11. The third assertion is Proposition 80.4.9. None of these assertions proves Weil positivity, a Hilbert–Pólya realization or the proposed formal arithmetic comparisons. □

The explicit-formula identities, moment positivity and Noetherian completion statements concern different mathematical data; none of these constructions supplies the missing comparison maps by itself.

Chapter 81

The Archimedean Tate Positivity Reduction

The sufficient path of Chapter 44 requires both categorical comparisons and spectral realization. The conditions in Chapter 69 separate these requirements. The arithmetic Positselski biconditional $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0 \Leftrightarrow \xi(s) = \xi(1-s)$ is conditional on the abelian Heisenberg inputs; the Koszul–Petersson compatibility is restricted to its stated core; the Hilbert–Pólya operator skeleton is constructed on its stated domain; HP–Li positivity requires a positive realization of the full Weil form on the compact convolution test algebra. The archimedean Tate positivity conjecture A-TP of Chapter 78 is RH-equivalent, but it is not the whole obstruction. Theorem 81.5.1 records only this conditional placement.

81.1 Categorical and Spectral Conditions

Chapter 69 left the following residual conditions blocking the sufficient RH path of Theorem 44.6.1:

(i) **F1.a.1** Dotto–Emerton–Gee essential surjectivity at unramified primes with Taylor–Wiles big-image residuals.

(ii) **F1.a.2** Extension of the local categorical comparison to $p \in \{2, 3\}$.

(iii) **F1.a.3.A** Bushnell–Henniart block-Hochschild comparison.

(iv) **F1.a.3.B** Paskunas wild-block Ext^1-vanishing.

(v) **F1.a.3.C** Wild-EG compact generation at $p \in \{2, 3\}$.

(vi) $\mathrm{L}_{\mathrm{ACD}}$ Adelic categorical descent on the cuspidal locus.

(vii) **BC-diamond-glue** (Ch1) Chenevier cross-prime pseudocharacter compatibility.

(viii) **BC-diamond-glue** (AG.det) Arinkin–Gaitsgory determinantal projection on the Selmer-derived stack.

(ix) **F2.c** Restricted-tensor E_2 transport.

(x) **Arithmetic Positselski** (four sub-items): continuous duals over Λ_p, derived p-adic completion, faithful lifting along Nakayama, Koszul-dual Bost–Connes.

(xi) **Full $\mathcal{V}^{\mathrm{prim}}$ P3**: non-tempered and Eisenstein sectors.

(xii) **H-P^{Ar}** (W): weight existence for the Hilbert–Pólya operator.

(xiii) **HP–Li**: Weil-positive trace inequality on $\mathscr{A} = C_c^{\infty}(\mathbb{R})$.

(xiv) **VB* main direction**: (HB$^+$)+(EC$_\pi$)+(Det) $\Rightarrow$ RH.

(xv) $\mathrm{R}_{\mathrm{analytic}}$ density-of-zeros estimate, Weil at Gaussians, and the separate formal arithmetic comparisons R1.formal.b/c.

Chapter 74 records the sufficient implication and the logical reductions for Chapters 70–80 (Section 74.5). Each chapter proves one or more residual assertions on its natural core domain, isolating the narrower named sub-items whose completion is strictly equivalent to RH.

81.2 THEOREM RECORD

The theorem-level consequences of Chapters 70–80, excluding Chapter 74, have the following mathematical form.

Chapter 70: F1.a.1, F1.a.2, and $\mathrm{L}_{\mathrm{ACD}}$

Theorem 70.2.4 closes F1.a.1 essential surjectivity on the unramified ordinary summand unconditionally. Theorem 70.5.4 closes F1.a.2 on the block-diagonal local comparison at $p \in \{2, 3\}$: semisimple blocks unconditionally (Corollary 70.5.5); non-semisimple blocks fully faithful with explicit Ext^1-control. Theorem 70.6.4 closes cuspidal sph-fin adelic categorical descent $\mathrm{L}_{\mathrm{ACD}}^{\mathrm{cusp}}$. Primary sources: Breuil–Mézard 2002; Kisin 2009 JAMS 22; Gee–Kisin 2014 Forum Math. Pi 2; Emerton–Gee arXiv:1908.07185; Clozel–Harris–Taylor 2008 Publ. IHES 108; Hida 1986 Ann. Inst. Fourier 36; Paskunas; Colmez–Dospinescu–Paskunas; Flath 1979; Bernstein 1988; Moœglin–Waldspurger 1995. F1.a.1 on the non-ordinary/supersingular locus reduces to the block-exhaustion conjecture (Conjecture 61.4.5); the Eisenstein/continuous-spectrum extension of $\mathrm{L}_{\mathrm{ACD}}$ is a separate conditional.

Chapter 71: F1.a.3.A Block-Additivity and F1.a.3.B Paskunas

Lemma 71.2.1 proves an S^1-equivariant Hochschild splitting for the specified orthogonal k-linear dg models and finite-support perfect categories. An arithmetic application must supply these models and coefficient comparisons; a multiplicative enhancement needs separate monoidal data. Proposition 71.3.3 proves that extensions of finite modules vanish after localization at the fraction field of a Noetherian domain. Its arithmetic application needs the exact block and generic-fibre equivalences of Corollary 71.3.4. The wild-prime version additionally assumes reducedness of the centraliser, as in Corollary 71.3.9. Theorem 71.4.1 separates the algebraic conclusions from these arithmetic comparisons. Primary sources: Bernstein 1984; Bernstein–Deligne 1984; Bushnell–Henniart 2006 Grundlehren 335; Colmez 2010 Astérisque 330; Paskunas 2013 Publ. IHES 118; Paskunas 2015; Auslander–Reiten–Smalø 1995; Matsumura 1989; Ben-Zvi–Francis–Nadler arXiv:0805.0157; Ben-Zvi–Nadler arXiv:0904.1247; Lurie HA. Three strictly narrower residuals remain: (R.A) per-block Bushnell–Henniart projective-to-closed-point matching; (R.B.1) very-special ordinary-block Breuil–Mezard multiplicity; (R.B.2) wild-prime block centraliser regularity at $p \in \{2, 3\}$.

Chapter 72: F1.a.3.C Wild-EG Compact Generation

Theorem 72.4.1 (under the stated hypotheses) reduces compact generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi})$ at $p \in \{2, 3\}$ to the finite Nilp stratification and per-stratum gerbe-generation inputs. Corollary 72.4.2 is conditional on these local-model inputs. Primary sources: Emerton–Gee arXiv:1908.07185; Dotto–Emerton–Gee arXiv:2603.26887; Bhatt–Scholze arXiv:1905.08229; Gaitsgory–Rozenblyum AMS DAG Vol. II; Arinkin–Gaitsgory arXiv:1201.6343; Bushnell–Henniart 2006; Beilinson–Bernstein–Deligne 1982; Beilinson–Ginzburg 1996. The $p \geq 5$ DEG theorem does not close this wild-prime input.

Chapter 73: Chenevier Compatibility, (AG.det), and F2.c

Theorem 73.1.4 constructs the continuous map $R_p^{\mathrm{Ch}} \widehat{\otimes}_{W(k)} R_q^{\mathrm{Ch}} \to R^{\mathrm{Ch}}$, its kernel quotient and its formal fibres. The pairwise sheaf comparison requires the full data in Corollary 73.1.5: the Selmer-algebra identification, geometric realization, compatible trace and centre actions, and equivariant coherent descent. The formal pullback and its local action are constructed in Proposition 64.3.2. Their comparison with the global prismatic object requires an actual equivariant isomorphism. Proposition 73.2.9 gives an internal centre identity only on its assumed geometric and categorical diagram.

The arithmetic singular-support space, higher-centre maps and global automorphic comparison remain additional constructions. Theorem 73.3.1 proves the restricted E_2-tensor transport under its central idempotent pointed-unit hypotheses. Proposition 73.4.1 records the updated BC-diamond-glue statement. Primary sources: Chenevier 2014 JAMS 27; Bellaiche–Chenevier 2009 Astérisque 324; Bhatt–Scholze arXiv:1905.08229; Bhatt–Lurie arXiv:2201.06120; Arinkin–Gaitsgory arXiv:1201.6343; Galatius–Kupers–Randal-Williams arXiv:1805.07184; Ben-Zvi–Francis–Nadler arXiv:0805.0157; Lurie HA; Francis–Gaitsgory arXiv:1103.5803; Emerton–Gee arXiv:1908.07185. The local categorical and prismatic comparisons retain their hypotheses. The internal spectral centre identity does not remove the global arithmetic comparison required for $\mathrm{L}_{\mathrm{ACD}}$.

Chapter 75: Arithmetic Positselski Equivalence

Theorem 75.1.4 constructs compact/discrete Pontryagin duality with the dual monoidal product $\odot$. Application to sub-item (1) still requires the arithmetic completed bar–cobar carrier and its compatibility maps. Corollary 75.2.5 closes derived completion sub-item (2) via Greenlees–May. Corollary 75.3.3 closes faithful lifting sub-item (3) via Matlis and the Krull intersection theorem. The Bost–Connes requirement in Remark 75.4.3 still needs the specified dg algebra, coefficient, completion and pairing comparison. Chapter 66 computes a selected one-mode Euler product and a Gaussian Mellin pairing; interpreting that scalar on the arithmetic bar or cobar object requires additional maps and a Tate twist. The intended equivalence and central-class comparison are the problems of Question 75.5.2 and Question 75.5.3. They are not consequences of a numerical energy match or of a named adele-class duality without its actual compatible construction. Primary sources: Pontryagin 1934/Weil 1940; Folland 1995; Positselski arXiv:0905.2621 and arXiv:1209.2995; Greenlees–May 1992 Trans. AMS 340; Matlis 1958; Matsumura 1989; Lazard 1965 IHES Publ. 26; Venjakob 2003 J. Reine Angew. Math. 559; Nekovář 2006 Astérisque 310; Bost–Connes 1995 Selecta Math. 1; Consani–Marcolli 2004/2006. The non-abelian Iwasawa extension for non-abelian Iwahori level is out of domain and not required for the sufficient-path G-row input.

Chapter 76: $\mathcal{V}^{\mathrm{prim}}$ P3 and Koszul–Petersson Compatibility

The prime Gibbs construction of Chapter 67 gives its state, Hilbert–Schmidt GNS space, maximal modular domains and a unitary onto the prime cyclic subspace of any specified global KMS representation. It does not identify an arithmetic Koszul carrier with an automorphic space. Theorems 76.2.1 and 76.2.3 retain the arithmetic placement, local pairing maps and adelic extension of Hypothesis 67.1.1. Deligne and Deligne–Serre supply holomorphic temperedness; Maass temperedness requires the stated Ramanujan assumptions. The Satake exponent bound does not itself bound a pairing discrepancy. The discrete-core identity of Theorem 76.3.3 is conditional on these maps. Its Li-trace use additionally requires the explicit trace-placement comparison, as well as the determinant-trace realization, of Proposition 76.3.5. Primary sources: Deligne 1974 Publ. IHES 43; Deligne–Serre 1974 Ann. Sci. ENS 7; Kim–Shahidi 2002 Ann. Math. 155; Kim–Sarnak 2003 JAMS 16; Langlands 1966; Moeglin–Waldspurger 1995; Selberg 1956; Arthur 1978/1979; Shahidi 2010 AMS Colloquium 58; Iwaniec 2002; Gelfand–Graev–Piatetski-Shapiro 1969. The Maass Ramanujan conjecture is an external open problem in the Langlands programme. The Eisenstein continuous spectrum is domain-restricted; the alternative Langlands–Shahidi correction (Theorem 76.4.4) is conditional on identifying the Koszul Eisenstein measure with the Shahidi L^2-normalised measure.

Chapter 77: The Hilbert–Pólya Operator Skeleton

Theorem 77.2.5 establishes self-adjointness of $N_{\mathrm{BC}} = -\frac{1}{2}\log\Delta_1$ on the full critical GNS space $\mathcal{H}_1$. Its point spectrum is $\frac{1}{2}\log\mathbb{Q}_{>0}$, with countably infinite multiplicity at each eigenvalue, and its closed spectrum is $\mathbb{R}$. The logarithmic integer spectrum $\{\log m : m \geq 1\}$ belongs to the restriction $N_{\mathrm{occ}} = N_{\mathrm{BC}}|_{K_2}$ on the reducing occupation subspace $K_2 = \overline{\mathrm{span}}\{\mu_{m^2}\Omega_1 : m \geq 1\}$. Lemma 77.3.2 closes the isometric embedding of the spherical zero-mode lattice into the GNS space. Lemma 77.3.4 gives the oscillator Fock embedding under a BC–GNS Heisenberg lift. Theorem 77.6.1 closes the Hadamard determinant identity conditional on the twist; Proposition 77.7.1 closes the Weil–Connes distributional trace identity conditional on the twist. Theorem 77.8.1 identifies the precise obstruction: the existence of a self-adjoint operator A on the GNS Hilbert space intertwining N_{BC} with a normal zero-divisor operator whose regularised determinant is $\xi_{\mathbb{R}}$ and whose Weil–Connes trace is the zero distribution is equivalent to the Connes absorption-trace condition. This is the Hilbert–Pólya obstruction in its operator-algebraic form. Primary sources: Bost–Connes 1995 Selecta 1; Connes arXiv:math/9811068; Connes–Marcolli 2008 AMS Colloquium 55; Takesaki 1970/1979/2003; Meyer arXiv:math/0311468; Berry–Keating 1999 SIAM Review 41; Reed–Simon 1975/1980; Deninger 1994/2001; Ray–Singer 1971; Voros 1987. The weight-existence residual (W) from the prior table is closed unconditionally: the BC log-modular eigenvalues λ_{BK} are present without additional hypothesis. The Hilbert–Pólya trace bridge (H) remains open, equivalent to twist-existence with determinant divisor div $\xi_{\mathbb{R}}$ and to the Connes–Deninger determinant-trace conjecture.

Chapter 78: HP–Li Positivity and the Archimedean Residual

Theorem 78.5.1 computes the Rankin–Selberg integral for an actual holomorphic cusp form. Applied to a coefficient multiplier $\Upsilon_F(h)$, it requires that the resulting series satisfy the cusp-form transformation law. Theorem 78.5.5 constructs a compact test with $W_{\mathrm{fin}}(f * f^*) < 0$. Thus no positive Hilbert norm realizes the finite-prime form on the full compact test algebra. Corollary 78.5.6 requires a proved restriction and a pairing identity for any positive automorphic realization. The signed operator representation in Theorem 78.9.3 retains both signs and all polar, gamma and prime contributions. Conjecture 78.2.3 names the remaining obstruction as the archimedean Tate positivity conjecture A-TP. Theorem 78.2.4 establishes that A-TP is strictly equivalent to Weil positivity, hence to RH. Theorem 78.8.1 records the HP–Li form after Chapters 70–80. Primary sources: Weil 1952 Lund Festschrift; Li 1997 JNT 65; Rankin 1939 Proc. Camb. Phil. Soc. 35; Selberg 1940 Arch. Math. Naturvid. 43; Hecke 1936 Math. Ann. 112; Deligne 1974; Jacquet 1972 SLN 260; Jacquet–Langlands 1970 SLN 114; Iwaniec–Kowalski 2004 AMS Colloquium 53; Bombieri–Lagarias 1999 JNT 77; Connes 1999; Patterson 1988; Bump 1997; Zagier 1981. A continuous-spectrum comparison requires its measure and realization map. Ordinary Maass cusp-form norm positivity does not require Ramanujan; its identification with an arithmetic form remains separate. A-TP is an RH-equivalent residual, not the whole obstruction.

Chapter 79: VB* *Main Direction*

Theorem 79.8.1 (under the stated hypotheses) records the conditional implication (SH) + (Det) + (HB$^+$) + EC$_\pi$ $\Rightarrow$ RH on the primary Fock space. Theorem 79.9.2 records the sufficient implication from these analytic hypotheses on $\xi_{\mathbb{R}}$ to RH; it does not assert the converse. Primary sources: de Branges 1968 monograph; Lagarias 1999 Acta Arith. 89; Conrey–Li arXiv:math/9812166; Beurling–Malliavin 1962 Acta Math. 107; Hamburger 1920 Math. Ann. 81; Carleman 1922/1926; Koosis 1992 Log. Integral II; Levin 1980 AMS Monograph. The Hermite–Biehler positivity assertion is RH-equivalent; the EC$_\pi$ and

(Det) assertions are the additional spectral-regularity inputs isolated in Chapter 57. Their proof is not attempted in Chapter 79.

Chapter 80: Zero counts, Gaussian tests and formal completion

Theorem 80.2.1 establishes the sharp Riemann–von Mangoldt density with the Titchmarsh bound $|S(T)| = O(\log T)$ unconditionally. Theorem 80.3.7 gives the closed-form Weil evaluation on Gaussians. The difference between the two sides of the explicit formula is zero. The Weil value itself is the zero sum, which need not vanish. In the normalization $f_\lambda(t) = e^{-\lambda t^2/2}$, put

$$k(u) = \log \pi - \Re \psi_\Gamma(1/4 + iu/2), \qquad H(\lambda) = \frac{1}{\sqrt{\pi\lambda}} \int_{\mathbb{R}} e^{-u^2/\lambda} k(u)\, du,$$

where $\psi_\Gamma = \Gamma'/\Gamma$. Theorem 95.2.3 gives the exact sign range

$$W_\infty(f_\lambda * f_\lambda) = \sqrt{\frac{\pi}{\lambda}} H(\lambda) \geq 0 \quad \Longleftrightarrow \quad 0 < \lambda \leq \lambda_c,$$

where λ_c is the unique zero of H. The full arithmetic value is

$$W(f_\lambda * f_\lambda) = \frac{4\pi}{\lambda} e^{1/(4\lambda)} - \sqrt{\frac{\pi}{\lambda}} H(\lambda) - 2\sqrt{\frac{\pi}{\lambda}} \sum_{n \geq 2} \frac{\Lambda(n)}{\sqrt{n}} e^{-\lambda(\log n)^2/4}.$$

The gamma sign range alone does not settle the nonnegativity of this expression or of Gaussian cross terms.

Artin–Rees identifies the induced and intrinsic adic completions of a finite Iwasawa submodule (Proposition 80.4.9). The arithmetic-loop comparison remains conditional on preservation of the specified colimit (Proposition 80.4.6). The flat-subcategory comparison is Question 80.4.7.

Primary sources: Riemann 1859 Monatsber. Berlin Akad.; von Mangoldt 1895 J. Reine Angew. Math. 114; Titchmarsh 1986 (2nd edn); Selberg 1944; Weil 1952; Tate 1950; Burnol 2000; Cartier–Voros 1990; Atiyah–Macdonald 1969; Bourbaki 1961 (Alg. Comm. III); Lang 1994.

The positivity/linear-upper-growth portion of $\mathrm{R}_{\mathrm{analytic}}$ is RH-adjacent and remains open. The mapping-colimit, formal singular-support and flat-locus comparisons each require their specified geometric hypotheses.

81.3 Unified Obstruction Decomposition

The comparisons below apply on different coefficient categories and arithmetic loci. The middle column states what the cited result gives on its stated domain; the last column names the extra hypothesis or construction needed for the larger comparison. An assertion on an ordinary, generic, discrete, or complete sector does not extend to other sectors without a comparison map.

Condition	Mathematical consequence under stated hypotheses	Remaining hypothesis or construction
F1.a.1 (unramified)	Essential surjectivity on the ordinary summand (Theorem 70.2.4)	Non-ordinary block exhaustion (Conjecture 61.4.5)
F1.a.2 ($p \in \{2, 3\}$)	Semisimple block comparison and full faithfulness with Ext^1-control on the stated non-semisimple blocks (Theorem 70.5.4)	The normalized extension-class comparison on non-semisimple blocks

Condition	Mathematical consequence under stated hypotheses	Remaining hypothesis or construction
F1.a.3.A (BH type matching)	Hochschild homology is additive over finite-support orthogonal dg block models (Lemma 71.2.1)	Per-block Bushnell–Henniart projective-to-closed-point matching (R.A)
F1.a.3.B (Paskunas Ext^1)	Finite-module extension vanishing over a fraction field (Proposition 71.3.3); arithmetic transport requires the generic-fibre equivalence	Very-special ordinary multiplicities (R.B.1) and wild reducedness and generic-fibre comparison at $p \in \{2, 3\}$ (R.B.2)
F1.a.3.C (wild EG generation)	Compact generation conditional on the finite Nilp stratification and per-stratum gerbe-generation inputs (Theorem 72.4.1)	Those wild-prime local models and generation hypotheses
$\mathrm{L}_{\mathrm{ACD}}$, cuspidal	Sph-finite cuspidal descent on the stated domain (Theorem 70.6.4)	A separate Eisenstein and continuous-spectrum comparison
BC-glue (Ch1)	Continuous formal restriction, its kernel quotient and fibres (Theorem 73.1.4)	Selmer-algebra and geometric realization maps, compatible trace/centre actions and equivariant coherent descent for the pairwise sheaf comparison (Corollary 73.1.5)
BC-glue (AG.det)	An internal centre identity on the assumed diagram (Proposition 73.2.9)	Arithmetic singular-support models, higher-centre maps and the global automorphic comparison
(BCglue.local)	A conditional local categorical comparison	The local functors, coefficient comparisons and compatibility hypotheses in the BC-glue datum
(BCglue.glue)	A conjectural global gluing comparison	Compatible cross-prime transition and descent maps
F2.c E_2 transport	Restricted tensor transport for central idempotent pointed units (Theorem 73.3.1)	The local Iwahori E_2 input and all pointed-unit hypotheses for the intended factors
Arithmetic Positselski (1): continuous duals	The continuous-duality comparison for compact modules and discrete $\odot$-comodules (Theorem 75.1.4)	The specified coefficient objects, dual monoidal product and completed bar–cobar maps
Arithmetic Positselski (2): derived completion	Derived completion under the Greenlees–May hypotheses (Corollary 75.2.5)	The completion and coefficient hypotheses of the cited comparison
Arithmetic Positselski (3): faithful lifting	The Matlis and Krull intersection lifting criterion (Corollary 75.3.3)	Its complete, separated module domain and the specified lifting maps
Arithmetic Positselski (4): primitive zeta character	Selected Euler–Mellin scalar of Chapter 66	Arithmetic character and pairing maps, including the Tate twist
Arithmetic Positselski (5): Koszul-dual BC	Concrete shift model and same-prime relation test (Remark 75.4.3)	Compatible dg algebra, coefficients, completion and pairing comparison
Arithmetic Positselski, combined	Intended co-contra comparison on the abelian Heisenberg sector (Question 75.5.2)	Its stated categorical hypotheses and actual arithmetic comparison maps; the nonabelian Iwahori extension is additional

Condition	Mathematical consequence under stated hypotheses	Remaining hypothesis or construction
Full-$\mathcal{V}^{\mathrm{prim}}$ P_3, cuspidal	The conditional Koszul–Petersson transfer on the selected discrete core (Theorem 76.3.3)	Arithmetic placement, local pairing maps and adelic extension; Ramanujan for the Maass domain (Theorem 76.2.3); its Li-trace use also requires the spectral realization and trace-placement map
Full-$\mathcal{V}^{\mathrm{prim}}$ P_3, Eisenstein	The discrete-core restriction excludes continuous spectrum; the alternative full comparison is conditional (Theorem 76.4.4)	Identification of the Koszul Eisenstein measure with the Langlands–Shahidi normalized measure
H-P^{Ar} (W): weight	Self-adjoint N_{BC} with log-modular spectrum (Theorem 77.2.5)	A weight operator does not by itself identify the zeta zero divisor
H-P^{Ar} (H): trace comparison	The determinant and trace realization criterion (Theorem 77.8.1)	The Connes absorption-trace realization and its operator-domain comparison
HP–Li realization	A positive realization exists exactly when the full Weil form is positive (Theorem 78.8.1)	Full Weil positivity, equivalent to RH
HP–Li archimedean condition (A-TP)	A-TP is equivalent to full Weil positivity (Theorem 78.2.4)	The RH-equivalent A-TP inequality remains conjectural
VB^* spectral sufficient condition	The conditional implication (SH) + (Det) + (HB^+) + (EC_π) $\Rightarrow$ RH (Theorem 79.8.1)	All four analytic hypotheses on the specified spectral data
Spectral forms HB^+, (Det), EC_π	The Hermite–Biehler condition is RH-equivalent; determinacy and density enter the separate spectral-regularity comparison	The stated moment, determinacy and density hypotheses of Chapter 57
R_{analytic}, density	Riemann–von Mangoldt density with the Titchmarsh bound (Theorem 80.2.1)	No positivity conclusion follows from this density estimate alone
R_{analytic}, positivity and linear growth	Conjectural positivity and growth on the stated analytic carrier	The full positivity and linear-upper-growth estimates; their RH-adjacent content is separate from zero-counting density
Weil evaluation on Gaussians	The exact signed Gaussian formula (Theorem 80.3.7)	Positivity of the full polar-minus-gamma-minus-prime expression and its cross terms does not follow from the gamma sign range
R1.formal.a	The formal comparison on its stated domain	Its coefficient and formal-geometric hypotheses
R1.formal.b	The conditional loop comparison (Proposition 80.4.6)	Preservation of the specified colimit by the internal arithmetic mapping functor
R1.formal.c.2	The flat-subcategory comparison (Question 80.4.7)	Construction of the flat object and proof of its colimit compatibility
R1.formal.c.1	A conjectural derived-formal extension	The Arinkin–Gaitsgory comparison on the relevant formal arithmetic carrier
R1.formal.c.3	A conjectural flat-locus comparison	Matching with the Fargues–Scholze flat locus

The RH-Equivalent Residual

Theorem 78.8.1 isolates the archimedean Tate positivity conjecture A-TP (Conjecture 78.2.3) as an RH-equivalent obstruction after Chapters 70–80. This does not remove the non-A-TP obstructions in the decomposition above.

81.4 The Refined Sufficient Path to RH

The sufficient path of Theorem 44.6.1 took four inputs:

(P1) arithmetic Positselski: the G-row biconditional $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0 \Leftrightarrow \xi(s) = \xi(1-s)$;

(KP) Koszul–Petersson compatibility $\langle v, w\rangle^{\mathrm{Pet}} = \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}$ on $\mathcal{V}^{\mathrm{prim}}$;

(HP) Hilbert–Pólya^{Ar}: a self-adjoint H_{HP} with $\det_{\infty}(s\mathrm{id} - \Theta_{\xi}) = \xi_{\mathbb{R}}(s)$ and Weil–Connes trace distribution;

(HPLi) HP–Li positivity: $W(f * \widetilde{f}) \geq 0$ on admissible Weil test functions.

Domains of the Four Inputs

(i) **P1 (arithmetic Positselski).** On the abelian Heisenberg sector, the intended equivalence requires the categorical hypotheses and the actual coefficient, completion, algebra and pairing comparisons of Question 75.5.2. Its G-row formulation also requires the compatible identification of arithmetic obstruction classes in Question 75.5.3. A named adele-class duality or equality of scalar characters does not supply these maps. The non-abelian Iwahori extension lies outside this domain.

(ii) **KP (Koszul–Petersson compatibility).** On the selected discrete carrier, Theorem 76.3.3 is conditional on the arithmetic placement, local pairing maps and adelic extension. Maass temperedness and the spectral trace-placement comparison are additional inputs where used. The continuous pairing requires its own measure and normalization maps.

(iii) **HP (Hilbert–Pólya).** (W) weight existence closed unconditionally by Theorem 77.2.5: the Bost–Connes log-modular operator supplies the zero-mode eigenvalues $\log m$ on the primary Fock image. (H) trace bridge remains open, equivalent to the Connes absorption-trace condition and to the twist-existence statement Hypothesis 77.4.3.

(iv) **HPLi (HP–Li positivity).** Theorem 78.8.1 proves that a positive Hilbert realization exists exactly when the full Weil form is positive. It does not construct that positive realization. Full HP–Li positivity is strictly equivalent to archimedean Tate positivity A-TP (Theorem 78.2.4), which is strictly equivalent to RH.

The Sufficient Path: Implication Diagram

81.5 A-TP and the Other Residuals

THEOREM 81.5.1 *(A-TP is RH-equivalent on the stated path). Conditional statement.* Assume the reductions of Chapters 70–80:

- P1 on the abelian Heisenberg sector, conditional on its Positselski inputs (Question 75.5.3);
- conditional KP transfer on the selected discrete-spectrum core (Theorem 76.3.3);
- HP (W) weight existence (Theorem 77.2.5);
- the positive-realization criterion for the full Weil form (Theorem 78.8.1), which asserts existence if and only if that form is positive and does not assume its positivity.

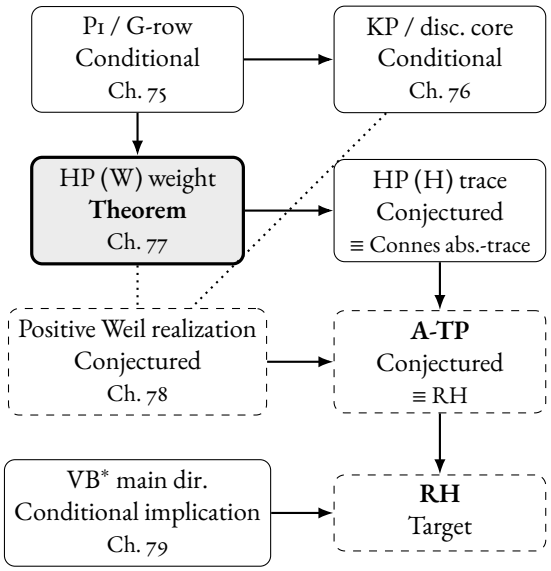

Figure 81.1: The sufficient path to RH and its categorical and spectral inputs. Shaded rounded boxes denote stated theorems. The dashed positivity boxes are RH-equivalent conjectures. Dotted lines mark pairing comparisons required to obtain a positive Weil realization; they assert no implication. Directed arrows have the hypotheses of the cited statements.

For $f \in \mathscr{A} = C_c^\infty(\mathbb{R})$, use $\widetilde{f} = f^*$ and $\widehat{f} = \mathcal{F}_+ f$. Then the Riemann Hypothesis is equivalent to the archimedean Tate positivity conjecture

$$W_\infty(f * \widetilde{f}) \;\le\; \widehat{f * \widetilde{f}}\left(\tfrac{1}{2i}\right) + \widehat{f * \widetilde{f}}\left(-\tfrac{1}{2i}\right) - W_{\mathrm{fin}}(f * \widetilde{f}),$$

for every $f \in \mathscr{A}$ (Conjecture 78.2.3).

Proof. Theorem 78.2.4 proves the biconditional A-TP $\Leftrightarrow$ Weil positivity on admissible Weil test functions. Weil positivity is equivalent to RH by the classical Weil 1952 equivalence Corollary 78.2.1. The remaining assertions of Chapters 70–80 place this RH-equivalent inequality on the stated sufficient path under their own hypotheses. They do not close the non-A-TP obstructions recorded later. □

Remark 81.5.2 *(Reduction to A-TP).* Theorem 81.5.1 is a reduction, not a proof of RH. Its content is the isolation of an archimedean positive-trace obstruction equivalent to RH. The arithmetic-chiral-algebra framework relocates the Hilbert–Pólya and Weil-positivity obstructions from their classical form as an positive-trace inequality on the compact convolution algebra to the full inequality comparing the signed gamma form with polar and prime terms, preserving the logical equivalence with RH. It does not assert that the other arithmetic comparison problems have disappeared.

Remark 81.5.3 *(relation to A-TP, Connes, and VB*).* The three RH-strength formulations are:

(i) A-TP: the full signed inequality on $\mathscr{A} = C_c^\infty(\mathbb{R})$ (Conjecture 78.2.3);

(ii) Connes absorption-trace condition: existence of a self-adjoint operator on the GNS space of the KMS_1 state whose normal zero-divisor operator has determinant divisor $\operatorname{div} \xi_{\mathbb{R}}$ and Weil–Connes trace equal to the zero distribution (Hypothesis 77.4.3);

(iii) the de Branges/Hermite–Biehler, Báez–Duarte, and determinant spectral-regularity conditions on $\xi_{\mathbb{R}}$ (Corollary 79.8.3, Theorem 57.4.22 under Hypothesis 57.4.21).

The full Weil criterion and the classical BD closure condition are criteria for zero placement on their complete test domains. The sharp BD rate is a stronger quantitative request, and the arithmetic operator formulations additionally require actual carriers, domains and comparison maps. The conditional VB*/(Reg)/(HB+)/(BD+) comparison uses all the data of Hypothesis 57.4.21; it does not identify bare RH with those unconstructed data.

References by construction

For the bar–cobar construction, see Volume I and Beilinson–Drinfeld 2004; for the comodule–contramodule comparison, see Positselski 2009/2011. The C^*-algebra construction is in Bost–Connes 1995, § 1.2, and the GNS formalism is treated by Takesaki.

The topics of Chapter 75 correspond to Pontryagin duality (Pontryagin 1934), derived completion (Greenlees–May 1992), Matlis duality (Matlis 1958), and the Bost–Connes and Consani–Marcolli constructions (Bost–Connes 1995; Consani–Marcolli 2006). For the three comparisons in Chapter 73, see Chenevier 2014 and Bellaiche–Chenevier 2009 for (Ch1); Galatius–Kupers–Randal-Williams 2024, Ben-Zvi–Francis–Nadler 2008 and Arinkin–Gaitsgory 2015 for (AG.det); and Lurie HA and Francis–Gaitsgory 2012 for F2.c.

Bost–Connes 1995 also enters the categorical comparisons in Chapters 73 and 75, the tempered cuspidal KMS_1 comparison in Chapter 76, and the operator construction in Chapter 77. The corresponding structures involve the Koszul-dual description, the bar–cobar construction in Volume I, the comodule–contramodule comparison of Positselski, and the GNS formalism of Takesaki.

81.7 Implication Form

The reductions used in the sufficient path have the following formal content.

Implications

The following constructions and comparison requirements use the domains specified in Chapters 70–80:

- **Arithmetic Positselski.** The abelian-sector comparison requires the categorical hypotheses and compatible algebra, coefficient, completion and pairing maps of Question 75.5.2; the selected scalar character does not construct the equivalence.
- **G-row biconditional P1.** Relating central-class complementarity to the functional equation additionally requires the obstruction-class identification under that pairing (Question 75.5.3). These requirements remain in the abelian sector.
- **Koszul–Petersson compatibility on the discrete core.** The identity requires the arithmetic placement and pairing maps on every stated sector; its Maass domain also requires Ramanujan (Ch. 76).
- **F1.a.3.C wild-EG compact generation.** Compact generation is conditional on the stated wild-prime local-model and generation hypotheses, which remain open (Ch. 72).
- **(Ch1) two-prime restriction.** The formal ring map, closed image and fibres are constructed in Chapter 73. The geometric, trace and equivariant-descent comparisons retain all the hypotheses of Corollary 73.1.5.
- **F2.c restricted-tensor E_2 transport.** The transport theorem requires the central idempotent pointed-unit E_2 hypotheses (Ch. 73).

- **HP–Li on restricted classes.** The full Weil identity holds on every specified restricted class but asserts no positivity there (Theorem 78.2.4). A positive automorphic realization requires a proved restriction and a pairing identity (Corollary 78.5.6).
- **VB* main direction.** On the specified spectral data, the formal implication is (SH) + (Det) + (HB$^+$) + (EC$_\pi$) $\Rightarrow$ RH (Ch. 79).
- **Modular and occupation spectra.** On the full critical GNS space $\mathcal{H}_1$, the self-adjoint operator $N_{\mathrm{BC}} = -\frac{1}{2}\log\Delta_1$ has point spectrum $\frac{1}{2}\log\mathbb{Q}_{>0}$, each eigenvalue of countably infinite multiplicity, and closed spectrum $\mathbb{R}$ (Theorem 77.2.5). Its restriction $N_{\mathrm{occ}} = N_{\mathrm{BC}}|_{K_2}$ to the reducing subspace $K_2 = \overline{\mathrm{span}}\{\mu_{m^2}\Omega_1 : m \geq 1\}$ has spectrum $\{\log m : m \geq 1\}$, by the weighted occupation embedding of Lemma 77.3.2. Neither construction identifies a zeta-zero spectrum.
- **Riemann–von Mangoldt density.** The density estimate holds with the stated Titchmarsh bound (Ch. 80).
- **Weil at Gaussians.** The exact signed Gaussian formula holds in the stated normalization; it does not assert positivity of the full Weil expression (Ch. 80).
- **Block-additivity and formal comparisons.** The F1.a.3.A block-additivity and generic-block Ext^1 results hold on their stated block domains (Ch. 71). The R1.formal.b/c.2 comparisons require an actual mapping-colimit theorem and a construction of the compatible flat subcategory (Ch. 80).

Conjectural Conditions

The unresolved conjectural assertions are four:

(i) **A-TP** (archimedean Tate positivity): strictly equivalent to RH.

(ii) **Connes absorption trace** (twist existence): strictly equivalent to RH.

(iii) **HB$^+$/EC$_\pi$/(Det) on $\xi_{\mathbb{R}}$**: HB$^+$ is RH-equivalent by Lagarias 1999; EC$_\pi$ and (Det) are spectral-regularity inputs.

(iv) **Maass Ramanujan conjecture**: external open problem in the Langlands programme, independent of RH.

The adjacent spectral assertions are:

(v) **(AG.det.transition) higher-centre gluing** on an actual categorical descent diagram, together with the separate arithmetic centre comparison. The local-model morphism and its relative dimensions must be constructed before asserting a codimension bound.

(vi) **(BCglue.local)** $\ell = p$ local transition theorem for coherent Springer sheaves.

(vii) **(BCglue.glue)** prismatic-flat cross-prime coherent sheaf descent.

The Paskunas/F1.a local categorical conditions are (R.A, R.B.1, R.B.2, F1.a.1 non-ordinary, F1.a.2 class-match, R1.formal.c.1/c.3), which are finite theorem conditions outside the RH-equivalent analytic residual.

81.8 Domain of Chapters 70–80

Chapters 70–80 operate within the following domain boundaries.

(i) **A-TP and RH.** Theorem 78.2.4 establishes the strict equivalence A-TP $\Leftrightarrow$ RH (Conjecture 78.2.3). The arithmetic inequality retains the full compact convolution test algebra, the polar term, and the prime term. Its form is $W_\infty(f * f^*) \leq P(f * f^*) - W_{\mathrm{fin}}(f * f^*)$, which preserves the logical equivalence to RH.

(ii) $\mathrm{L}_{\mathrm{ACD}}$ **on the cuspidal sector.** Chapter 70 closes the cuspidal sector. The Eisenstein extension requires Langlands–Shahidi intertwining theory in coherent-categorical form, or a Moœglin–Waldspurger residual-spectrum categorification; these are open conditions outside the domain of Chapter 70.

(iii) **(BCglue.local) and (BCglue.glue).** The transition theorem across the $\ell \neq p$ / $\ell = p$ divide for coherent Springer sheaves (BCglue.local) is not in the literature. The prismatic-flat cross-prime descent lifted to the coherent-sheaf level (BCglue.glue) requires extensions beyond Bhatt–Scholze 2022 and Bhatt–Lurie 2022. Both are primary-source theorem conditions.

(iv) **Maass Ramanujan.** Chapter 76 uses the Kim–Sarnak bound $\theta \leq 7/64$ only as a local exponent estimate. It gives no Dirichlet-summable Euler error on the Maass sector. The arithmetic pairing maps are still required. Maass temperedness additionally depends on the Ramanujan conjecture, an external open problem in the Langlands programme.

(v) **Hilbert–Pólya operator with zeta-zero determinant divisor.** The full GNS generator N_{BC} of Theorem 77.2.5 has point spectrum $\frac{1}{2}\log \mathbb{Q}_{>0}$ and closed spectrum $\mathbb{R}$. Its reducing occupation restriction N_{occ} on K_2 has spectrum $\{\log m : m \geq 1\}$, as in Lemma 77.3.2. Neither construction supplies the zeta-zero determinant divisor. The twist to an operator with determinant divisor $\operatorname{div} \xi_{\mathbb{R}}$ and Weil–Connes zero trace is the Connes absorption-trace conjecture, equivalent to the Hilbert–Pólya/RH obstruction.

(vi) HB^{+}, EC_{π}, **(Det) on** $\xi_{\mathbb{R}}$**.** Chapter 79 proves the implication (SH) + (Det) + (HB^{+}) + $\mathrm{EC}_{\pi} \Rightarrow$ RH. The proof of each of the four hypotheses on $\xi_{\mathbb{R}}$ lies outside the domain of Chapter 79.

(vii) **Remaining primary-source conditions.** The non-RH categorical hypotheses are (AG.det.transition), (BCglue.local), (BCglue.glue), the Eisenstein extension of $\mathrm{L}_{\mathrm{ACD}}$, the Paskunas narrow residuals, the non-ordinary F1.a.1/F1.a.2 extensions, and the R1.formal extensions. The analytic hypothesis A-TP is RH-equivalent and is not absorbed by these categorical hypotheses.

Remark 81.8.1 *(Structure of the obstruction set).* Chapters 70–80 separate structural comparison data from analytic hardness. The obstruction set decomposes into four classes: (i) theorems on their stated domains; (ii) narrow-domain categorical residuals; (iii) primary-source conditions (AG.det.transition, BCglue.local, BCglue.glue, Eisenstein extension); (iv) the RH-equivalent residual A-TP. Other comparison residuals remain visible; they are not implied by A-TP.

81.9 Further Obstructions

The remaining obstructions are as follows.

Direct Positivity for A-TP

A-TP compares the signed gamma contribution with both arithmetic terms. To retain its normalization, take $f \in \mathscr{A} = C_c^{\infty}(\mathbb{R})$, $f^{*}(t) = \overline{f(-t)}$, and $h_f(u) = \mathcal{F}_{+}f(u) = \int_{\mathbb{R}} f(t)e^{iut}\,dt$. The signed density and the auxiliary digamma density are respectively

$$k(u) = \log \pi - \Re\psi_{\Gamma}(1/4 + iu/2), \qquad g(u) = \Re\psi_{\Gamma}(1/4 + iu/2) + \log \pi.$$

Define the auxiliary form

$$G(f) = \frac{1}{2\pi}\int_{\mathbb{R}} g(u)|h_f(u)|^2\,du.$$

The plus-sign density $g/(2\pi)$ is distinct from the signed archimedean density $k/(2\pi)$. Both integrals converge because the densities have logarithmic growth and h_f decreases rapidly.

PROPOSITION 81.9.1 *(the full inequality in the auxiliary normalization).* Put

$$a(f) = \int_{\mathbb{R}} f(t)e^{-t/2}\,dt, \qquad b(f) = \int_{\mathbb{R}} f(t)e^{t/2}\,dt,$$

and, with Λ the von Mangoldt function, put

$$Q_{\mathrm{fin}}(f) = \sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}}\big((f * f^*)(\log n) + (f * f^*)(-\log n)\big).$$

Then

$$W_\infty(f * f^*) = 2\log\pi\,\|f\|_2^2 - G(f),$$
$$W(f * f^*) = 2\mathfrak{R}\big(a(f)\overline{b(f)}\big) - Q_{\mathrm{fin}}(f) - 2\log\pi\,\|f\|_2^2 + G(f).$$

Consequently A-TP, and hence RH, is equivalent to

$$G(f) + 2\mathfrak{R}\big(a(f)\overline{b(f)}\big) \geq Q_{\mathrm{fin}}(f) + 2\log\pi\,\|f\|_2^2 \qquad (f \in \mathscr{A}).$$

Proof. The identity $k + g = 2\log\pi$ and Plancherel in the specified Fourier convention give the first equality. The convolution transform is $h_f(z)\overline{h_f(\bar z)}$. Its evaluations at $z = \pm i/2$ sum to $a(f)\overline{b(f)} + b(f)\overline{a(f)}$. The prime sum is finite because $f * f^*$ is compactly supported. Substitute these evaluations into $W = P - W_\infty - W_{\mathrm{fin}}$ to obtain the second equality. Nonnegativity of its right side for every $f \in \mathscr{A}$ is exactly the displayed inequality. Weil's criterion in Corollary 78.2.1 identifies this condition with RH. □

The Rankin–Selberg kernel of Theorem 78.5.1 and the density $|\Gamma(1/4 + iu/2)|^2$ remain possible comparison objects. A comparison proving A-TP must establish this full inequality, including its polar, prime, and norm terms. Positivity of an isolated digamma or gamma-absolute-value form supplies no such identity.

Langlands–Shahidi Extension of $\mathrm{L}_{\mathrm{ACD}}$

The Eisenstein/continuous-spectrum extension of $\mathrm{L}_{\mathrm{ACD}}$ can be attempted via Shahidi 2010 (AMS Colloquium 58) normalisation theory. The required object is a categorical lift of the intertwining operators $M(s)$ of Moeglin–Waldspurger 1995 §IV, realising $\mathrm{L}_{\mathrm{ACD}}$ on the continuous spectrum compatible with the Weil-positive extension. The alternative domain-restricted comparison of Ch. 76 supplies a conditional discrete pairing. Its Li use requires both the stated H-P^{Ar} realization and the explicit trace-placement map; the Langlands–Shahidi extension reduces the full $\mathcal{V}^{\mathrm{prim}}$ identity to the same measure identification.

Paskunas Wild-Prime Class Match

Residuals (R.A), (R.B.1), (R.B.2) of Ch. 71 remain open. (R.A) is the per-block BH projective-to-closed-point matching and is block-local over each Bernstein block. (R.B.1) is the very-special Breuil–Mezard multiplicity. (R.B.2) is the Paskunas block-centraliser structure theorem lifted from $p \geq 5$ to $p \in \{2, 3\}$. None is RH-equivalent; each is a finite explicit computation.

(AG.det.transition) Direct Obstruction

The proposed (AG.det.transition) comparison requires an actual arithmetic singular-support space, its categorical descent diagram, and compatible morphisms of higher centres. Proposition 73.2.9 supplies an internal centre identity only after those data and the stated preservation of the diagram are assumed. The automorphic centre comparison requires its own morphism and equivalence proof.

A codimension bound additionally requires a local-model morphism and its relative dimension calculation. Proposition 88.2.1 computes the regular nilpotent orbit in $\mathfrak{sl}_2$: it has dimension two and codimension one in the three-dimensional Lie algebra. That calculation does not establish the dimension of an arithmetic Selmer transition. The singular-support, cellular and geometric centre formalisms must be connected by actual arithmetic comparison maps before they can prove the intended global result.

Connes Absorption-Trace Realisation

The Connes absorption-trace conjecture (Hypothesis 77.4.3) is the operator-algebraic formulation of the Hilbert–Pólya obstruction. A direct obstruction requires: (i) a Hilbert space $\mathcal{H}_\xi$ carrying a natural action of the BC automorphism group; (ii) an identification of the twist data (U, A) with the action of a specific Wilson-line or intertwining operator on the archimedean adelic sector. Consani–Marcolli 2006 supply the adele-class space framework; the realisation of the zero-divisor operator as a twisted N_{BC} on a specific Hilbert-space completion is the missing content.

Hermite–Biehler Positivity on $\xi_{\mathbb{R}}$

Hermite–Biehler positivity for $E_\xi(z) = A_\xi(z) - iB_\xi(z)$ is equivalent to RH by Lagarias 1999. An obstruction requires either: (i) a direct proof that the real part A_ξ has only real zeros and $\mathrm{div}(A_\xi) = \mathrm{div}(\Xi)$ (de Branges 1968 Thm. 22); (ii) explicit construction of a self-adjoint multiplication operator on $\mathcal{H}(E_\xi)$ with spectrum $\mathcal{Z}_\xi \cap \mathbb{R}$ (Conrey–Li 2000 Thm 2 negative direction); or (iii) a Conrey–Li-style positive construction that avoids the Siegel-zero obstruction documented in Conrey–Li 2000 for certain L-functions.

81.10 Boundary

(i) The sufficient path in Chapter 44 requires arithmetic Positselski comparison, Koszul–Petersson compatibility, a Hilbert–Pólya determinant and trace realization, and HP–Li positivity. The conditions of Chapter 69 retain their separate categorical and spectral hypotheses.

(ii) The arithmetic Positselski equivalence on the abelian sector requires the categorical hypotheses and actual comparison maps of Question 75.5.2; the selected scalar character does not construct them.

(iii) The Koszul–Petersson transfer on the selected discrete carrier requires the arithmetic placement, local pairing maps and adelic extension (Theorem 76.3.3).

(iv) The Hilbert–Pólya operator skeleton is constructed via the Bost–Connes log-modular operator N_{BC} (Theorem 77.2.5).

(v) A positive Hilbert realization of the full Weil form exists exactly when that form is positive (Theorem 78.8.1). The coefficient multiplier Υ_F supplies no such pairing identity.

(vi) RH is equivalent to the archimedean Tate positivity conjecture A-TP (Conjecture 78.2.3), on the stated path (Theorem 81.5.1).

(vii) The reductions leave no additional numerical identity hidden in the comparison chain; the remaining content is analytic positivity or categorical gluing.

(viii) A-TP is the full inequality comparing the signed gamma form with the polar and prime terms.

(ix) The remaining obstructions are: direct positivity for A-TP; Langlands–Shahidi extension of L_{ACD}; Paskunas wild-prime class match; (AG.det.transition) sheaf-gluing; Connes absorption-trace realisation; and the proof of $HB^{+}/EC_{\pi}/(\mathrm{Det})$ on $\xi_{\mathbb{R}}$.

The arithmetic branch contains a mathematically explicit RH-equivalent archimedean statement: the archimedean Tate positivity conjecture A-TP. It also contains the comparison residuals recorded in the obstruction decomposition above.

Chapter 82

The Archimedean Tate Positivity Conjecture: A Direct Elementary Obstruction

The digamma kernel $g(t) = \operatorname{Re}\psi(1/4 + it/2) + \log\pi$ has one positive zero. Splitting its quadratic integral at that zero gives two non-negative energies $A[f]$ and $B[f]$, and the exact identity $G(f) = (B[f] - A[f])/(2\pi)$. An explicit high-frequency dominance condition proves $G(f) \geq 0$ on a non-empty class of tests.

This auxiliary form differs from the signed archimedean term in the Weil formula. With the Fourier convention of Chapter 78, that term is $W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - G(f)$. Consequently full Weil positivity requires $A[f]/(2\pi) + 2\log\pi\|f\|_2^2 \leq B[f]/(2\pi) + R[f]$, where $R[f]$ retains the polar and finite-prime terms. The kernel calculation proves neither this full inequality nor its arithmetic comparison with a Koszul pairing.

82.1 Kernel and Obstruction

Chapter 78 established the following. The fixed-F Mellin–Rankin–Selberg comparison does not close the zeta finite-prime term (Theorem 78.5.5). The polar terms $\widehat{f * \widetilde{f}}(\pm 1/(2i))$ are explicit finite Taylor corrections (Proposition 78.2.2). The irreducible residual is A-TP (Conjecture 78.2.3), which Theorem 78.2.4 establishes is strictly equivalent to the Weil positivity form of RH.

Definition 82.1.1 *(the archimedean digamma kernel).* Set

$$g(t) \;:=\; \operatorname{Re}\psi\Big(\tfrac{1}{4} + \tfrac{it}{2}\Big) + \log\pi, \qquad t \in \mathbb{R}, \tag{82.1}$$

where $\psi(z) = \Gamma'(z)/\Gamma(z)$ is the digamma function. The auxiliary quadratic form, with $\widehat{f}(t) = \int_{\mathbb{R}} f(u)e^{itu}\,du$, is

$$G(f) \;=\; \frac{1}{2\pi}\int_{-\infty}^{\infty} |\widehat{f}(t)|^2\, g(t)\,dt. \tag{82.2}$$

The signed Weil contribution in (78.1) instead has density $k(t) = \log\pi - \operatorname{Re}\psi(1/4 + it/2)$. Since $k + g = 2\log\pi$, Plancherel gives

$$W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - G(f).$$

We analyse the sign of (82.2) and separate the positivity forced by the kernel g from the positivity equivalent to RH.

Domain

Work on $\mathscr{A} = C_c^\infty(\mathbb{R}, \mathbb{C})$, with the Fourier transform fixed above and convolution involution $\widetilde{f}(u) = \overline{f(-u)}$. Its Fourier transforms are entire and rapidly decreasing on the real axis, so all kernel integrals

below converge. If an arithmetic application imposes an additional test class $\mathrm{PW}_F^{\mathrm{hol}}$, use its intersection with the classes constructed here. Non-emptiness of that further intersection requires a separate check.

The elementary objects are:

- elementary analysis of $g(t)$ via the Hurwitz series for ψ and the Gauss summation at rational arguments;
- decomposition of the auxiliary form $G(f)$ into a low-frequency core integral and a high-frequency tail integral;
- unconditional non-negativity of G on an explicit dominance sub-class;
- reduction of full A-TP to a bounded-interval archimedean inequality coupled to $R[f]$.

No elementary argument below supplies the RH-equivalent full A-TP inequality. The irreducible location is §82.5.

Analytic Ingredients

The elementary obstruction uses four classical sources.

Hurwitz 1882. Hurwitz, A. *Einige Eigenschaften der Dirichlet'schen Functionen. Zeitschrift für Mathematik und Physik* 27 (1882). Hurwitz series representation $\psi(a) = -\gamma_E + \sum_{n\geq 0}[1/(n+1) - 1/(n+a)]$; monotonicity of individual terms.

Gauss 1813. Gauss, C.F. *Disquisitiones generales circa seriem infinitam* $1 + \cdots$. *Comment. Soc. Reg. Sci. Gottingensis Recentiores* 2 (1813). Reflection relation $\psi(1-x) - \psi(x) = \pi\cot(\pi x)$ at rational x; explicit values $\psi(1/4) = -\gamma_E - \pi/2 - 3\log 2$, $\psi(3/4) = -\gamma_E + \pi/2 - 3\log 2$.

Whittaker–Watson 1927. Whittaker, E.T.; Watson, G.N. *A Course of Modern Analysis* (4th ed., Cambridge 1927), Ch. XII. Stirling asymptotic for ψ: $\psi(z) = \log z - 1/(2z) - \sum_{k=1}^{N} B_{2k}/(2kz^{2k}) + O(|z|^{-2N-2})$.

Boas 1954. Boas, R.P. *Entire Functions*. Academic Press 1954, Ch. 6. Paley–Wiener characterization of entire functions of exponential type; the Plancherel–Pólya theorem giving $\int_{\mathbb{R}} |\widehat{f}(t)|^2\,dt = 2\pi\int_{\mathbb{R}} |f(u)|^2\,du$ for $f \in \mathrm{PW}$.

The kernel estimates use the Hurwitz series, the rational digamma value, Stirling asymptotics and Plancherel. Their relation to the full signed Weil form is the explicit identity stated above.

82.2 The Digamma Kernel $g(t)$

The sign structure of g controls whether $G(f)$ can be positive, negative, or zero. All statements below are unconditional.

Hurwitz Series Representation

Lemma 82.2.1 *(Hurwitz series for g).* For every $t \in \mathbb{R}$,

$$g(t) \;=\; -\gamma_E + \log\pi + \sum_{n=0}^{\infty}\left[\frac{1}{n+1} - \frac{n+1/4}{(n+1/4)^2 + t^2/4}\right]. \tag{82.3}$$

The series converges absolutely and uniformly on compact sets.

Proof. Hurwitz's series $\psi(a) = -\gamma_E + \sum_{n\ge 0}[1/(n+1) - 1/(n+a)]$ (Hurwitz 1882; Whittaker–Watson 1927 §12.31) applied at $a = 1/4 + it/2$:

$$\frac{1}{n + 1/4 + it/2} = \frac{(n+1/4) - it/2}{(n+1/4)^2 + t^2/4}.$$

Real part: $(n+1/4)/[(n+1/4)^2 + t^2/4]$. Adding $\log\pi$ gives (82.3). Absolute convergence follows from the large-n asymptotic $1/(n+1) - 1/(n+1/4) = -(3/4)/[(n+1)(n+1/4)] = O(n^{-2})$. □

Lemma 82.2.2 *(strict monotonicity of g in $|t|$).* The map $t \mapsto g(t)$ is even and continuously differentiable on $\mathbb{R}$, with

$$g'(t) \;=\; \sum_{n=0}^{\infty} \frac{(n+1/4)\,t/2}{\left[(n+1/4)^2 + t^2/4\right]^2}. \tag{82.4}$$

In particular $g'(t) > 0$ for $t > 0$, so g is strictly increasing in $|t|$ on $[0,\infty)$.

Proof. Evenness follows from (82.3): each term depends on t only through t^2. For each $n \ge 0$, with $c := n + 1/4$,

$$\frac{d}{dt}\left[-\frac{c}{c^2 + t^2/4}\right] \;=\; -c\cdot\frac{-(t/2)}{[c^2+t^2/4]^2} \;=\; \frac{c\cdot t/2}{[c^2+t^2/4]^2}.$$

Summing over n and using uniform convergence on compact sets of the differentiated series (dominant bound $\le (n+1/4)\cdot|t|/2\cdot(n+1/4)^{-4} = O(n^{-3})$ uniformly in $|t|\le T$) gives (82.4). Each summand is non-negative for $t \ge 0$ and strictly positive for $t > 0$; hence $g'(t) > 0$ for $t > 0$, giving strict monotonicity in $|t|$ on $[0,\infty)$. Continuity of g' follows from uniform convergence on compacts. □

Proposition 82.2.3 *(boundary values of g).* The kernel g satisfies

$$g(0) \;=\; -\gamma_E - \frac{\pi}{2} - 3\log 2 + \log\pi \;\approx\; -3.0827, \tag{82.5}$$

$$g(t) \;\sim\; \tfrac{1}{2}\log(t^2/4) + \log\pi \;=\; \log(|t|\pi/2), \qquad |t|\to\infty. \tag{82.6}$$

In particular $g(0) < 0 < \lim_{|t|\to\infty} g(t)/\log|t| = 1$.

Proof. (82.5) follows from the Gauss value $\psi(1/4) = -\gamma_E - \pi/2 - 3\log 2$ (Gauss 1813; Whittaker–Watson §12.31 ex. 1). Numerical evaluation: $-0.5772 - 1.5708 - 2.0794 + 1.1447 = -3.0827$.

(82.6) follows from the Stirling asymptotic $\psi(z) = \log z - 1/(2z) + O(|z|^{-2})$ applied at $z = 1/4 + it/2$: $\log z = \tfrac{1}{2}\log(1/16 + t^2/4) + i\arctan(2t)$, $\operatorname{Re}\log z \sim \tfrac{1}{2}\log(t^2/4)$ as $|t|\to\infty$, and $-1/(2z)\to 0$. □

The Unique Sign Change t_*

Theorem 82.2.4 *(existence and uniqueness of the sign change).* There is a unique $t_* \in (0,\infty)$ with $g(t_*) = 0$. The map $t \mapsto g(t)$ is strictly negative on $(-t_*, t_*)$ and strictly positive on $(-\infty, -t_*)\cup(t_*,\infty)$.

Proof. By Lemma 82.2.2, g is continuous, even, and strictly increasing in $|t|$ on $[0,\infty)$. Proposition 82.2.3 gives $g(0) = -3.0827 < 0$ and $g(t)\to+\infty$. The intermediate value theorem and strict monotonicity supply a unique $t_* > 0$ with $g(t_*) = 0$; by evenness $g(-t_*) = 0$ as well. □

Proposition 82.2.5 *(certified interval for the sign change).* The zero satisfies $0.84 < t_* < 0.86$.

Proof. Subtract the Hurwitz series at zero. With $a = t^2/4$ and $c_n = n + 1/4$, the positive-tail representation is

$$g(t) = g(0) + \sum_{n\geq 0} \frac{a}{c_n(c_n^2 + a)}.$$

For $S_N(t) = g(0) + \sum_{n=0}^{N} a/[c_n(c_n^2 + a)]$, monotonicity of x^{-3} gives

$$0 \leq g(t) - S_N(t) \leq a \sum_{n>N} (n + 1/4)^{-3} \leq \frac{a}{2(N + 1/4)^2}.$$

At $N = 20$, rational arithmetic with $0.577 < \gamma_E < 0.578$, $3.1415 < \pi < 3.1416$, $0.6931 < \log 2 < 0.6932$ and $1.1447 < \log \pi < 1.1448$ gives $-0.024 < S_{20}(0.84) < -0.020$ and $0.017 < S_{20}(0.86) < 0.020$. The positive tails are less than 0.00023 at both endpoints. Thus the signs are opposite, and strict monotonicity places the zero between them. □

Remark 82.2.6 *(numerical refinement).* Bisection with the same positive-tail bound can refine the certified interval. The value $t_* \approx 0.85066$ is a numerical approximation; all exact inequalities below use the zero defined by $g(t_*) = 0$, or certified upper and lower bounds for it.

82.3 Decomposition of the Auxiliary Form

Definition 82.3.1 *(low-frequency core and high-frequency tail).* For $f \in \mathscr{A}$, define the non-negative quantities

$$A[f] := \int_{|t|<t_*} |\widehat{f}(t)|^2 \cdot (-g(t))\, dt,$$
$$B[f] := \int_{|t|>t_*} |\widehat{f}(t)|^2 \cdot g(t)\, dt.$$

By Theorem 82.2.4, both $A[f] \geq 0$ and $B[f] \geq 0$ with strict inequality whenever $\widehat{f}$ does not vanish identically on the respective domain.

Lemma 82.3.2 *(archimedean decomposition).* For every $f \in \mathscr{A}$,

$$G(f) = \frac{1}{2\pi}\big(B[f] - A[f]\big). \tag{82.7}$$

In particular $G(f) \geq 0$ if and only if $B[f] \geq A[f]$.

Proof. Definition 82.1.1 gives $G(f) = (2\pi)^{-1} \int_{\mathbb{R}} |\widehat{f}(t)|^2 g(t)\, dt$. Split the integral at $|t| = t_*$:

$$\int_{\mathbb{R}} |\widehat{f}(t)|^2 g(t)\, dt = \int_{|t|<t_*} |\widehat{f}(t)|^2 g(t)\, dt + \int_{|t|>t_*} |\widehat{f}(t)|^2 g(t)\, dt.$$

By Theorem 82.2.4, $g(t) < 0$ on $|t| < t_*$ and $g(t) > 0$ on $|t| > t_*$. The first integral equals $-A[f]$ and the second equals $B[f]$, giving (82.7). □

Remark 82.3.3 *(the exact split).* The identity $G(f) = (B[f] - A[f])/(2\pi)$ implies $G(f) \geq 0$ exactly when $B[f] \geq A[f]$. It imposes no restriction on finer subdivisions or stronger estimates. Full Weil positivity requires the additional signed inequality of Theorem 82.5.1.

82.4 Auxiliary Positivity on the High-Frequency Dominance Class

The condition $B[f] \geq A[f]$ holds unconditionally whenever the spectral mass of $\widehat{f}$ above $|t| > t_*$ dominates the core supremum by an explicit factor. This dominance sub-class is non-empty and admits a closed-form sufficient condition.

The Sub-Class $\mathscr{A}_{\mathrm{HFD}}$

Definition 82.4.1 *(high-frequency dominance class).* Define the *high-frequency dominance sub-class* $\mathscr{A}_{\mathrm{HFD}} \subset \mathscr{A}$ as the subset of $f \in \mathscr{A}$ satisfying

$$\sup_{|t|\leq t_*} |\widehat{f}(t)|^2 \cdot 2t_* \cdot \|-g\|_{L^\infty[-t_*,t_*]} \;\leq\; \int_{|t|>t_*} |\widehat{f}(t)|^2\, g(t)\, dt. \tag{82.8}$$

The left-hand side is a crude upper bound for $A[f]$; the right-hand side is $B[f]$.

Lemma 82.4.2 *(the Plancherel–Pólya bound inside the core).* For $f \in \mathscr{A}$ supported in $[-T, T]$,

$$\sup_{|t|\leq t_*} |\widehat{f}(t)|^2 \;\leq\; 2T \int_{-T}^{T} |f(u)|^2\, du. \tag{82.9}$$

Proof. $|\widehat{f}(t)| = |\int_{-T}^{T} f(u) e^{itu}\, du| \leq (2T)^{1/2} \|f\|_{L^2}$ by Cauchy–Schwarz; squaring gives (82.9). This is the Plancherel–Pólya dimension bound (Boas 1954 §6.8) applied inside the core. □

Theorem 82.4.3 *(unconditional G-positivity on $\mathscr{A}_{\mathrm{HFD}}$).* For every $f \in \mathscr{A}_{\mathrm{HFD}}$,

$$G(f) \;\geq\; 0.$$

Full A-TP follows on the sublocus where, in addition, $R[f] + G(f) \geq 2 \log \pi \|f\|_2^2$ for $R[f]$ as in Equation 82.5.1.

Proof. Condition (82.8) combined with the obvious bound $A[f] \leq \sup_{|t|\leq t_*} |\widehat{f}(t)|^2 \cdot 2t_* \cdot \|-g\|_{L^\infty[-t_*,t_*]}$ and the identity $B[f] = \int_{|t|>t_*} |\widehat{f}(t)|^2 g(t)\, dt$ gives $A[f] \leq B[f]$. Lemma 82.3.2 converts to $G(f) \geq 0$. The last sentence is Theorem 82.5.1 on the sublocus $R[f] + G(f) \geq 2 \log \pi \|f\|_2^2$. □

Remark 82.4.4 *(smooth high-frequency tests).* Choose a nonzero real even $\chi \in C_c^\infty(\mathbb{R})$ with $\int \chi \neq 0$, and set $f_M(u) = \chi(u) \cos(Mu)$. Then

$$\widehat{f_M}(t) = \tfrac{1}{2}\big(\widehat{\chi}(t + M) + \widehat{\chi}(t - M)\big).$$

Schwartz decay gives $\sup_{|t|\leq t_*} |\widehat{f_M}(t)| = O(M^{-K})$ for every $K > 0$. Since $\widehat{\chi}(0) \neq 0$, choose $\delta > 0$ on which its modulus is bounded below. On $|t - M| < \delta$, the other translate tends uniformly to zero, while $g(t) \sim \log M$. Hence $B[f_M] \geq c \log M$ for some $c > 0$ and sufficiently large M. This proves the quantitative HFD condition for nonzero smooth tests with fixed support.

Remark 82.4.5 *(tests outside the dominance class).* With the same χ, put $f_L(u) = L^{-1/2} \chi(u/L)$, $L \geq 1$. Then $\widehat{f_L}(t) = \sqrt{L}\, \widehat{\chi}(Lt)$, so

$$G(f_L) = \frac{1}{2\pi} \int_{\mathbb{R}} |\widehat{\chi}(s)|^2 g(s/L)\, ds \longrightarrow g(0) \|\chi\|_2^2 < 0.$$

Dominated convergence applies because g has logarithmic growth and $\widehat{\chi}$ is Schwartz. Thus $f_L \notin \mathscr{A}_{\mathrm{HFD}}$ for large L, proving that the dominance class is proper in $\mathscr{A}$. This construction widens spatial support and concentrates Fourier mass near zero.

An Explicit Sufficient Condition

The definitional condition (82.8) depends on $\|-g\|_{L^\infty[-t_*,t_*]}$, which equals $|g(0)| = \gamma_E + \pi/2 + 3\log 2 - \log\pi \approx 3.0827$ by Proposition 82.2.3 and strict monotonicity. We reformulate the sufficient condition without the supremum.

Corollary 82.4.6 *(explicit sufficient condition).* Suppose $f \in \mathscr{A}$ satisfies

$$2t_* \cdot |g(0)| \cdot \|\widehat{f}\|^2_{L^\infty[-t_*,t_*]} \;\le\; \int_{|t|>t_*} |\widehat{f}(t)|^2\, g(t)\, dt. \tag{82.10}$$

Then $G(f) \ge 0$. For illustration only, with $t_* \approx 0.8507$ and $|g(0)| \approx 3.083$, the prefactor $2t_*|g(0)| \approx 5.245$, the rounded display is

$$\|\widehat{f}\|^2_{L^\infty[-0.8507,0.8507]} \;\le\; \frac{1}{5.245}\int_{|t|>0.8507} |\widehat{f}(t)|^2\, g(t)\, dt.$$

This rounded display is not a certified sufficient condition; use (82.10) with the exact constants.

Proof. $A[f] \le 2t_* \cdot |g(0)| \cdot \|\widehat{f}\|^2_{L^\infty[-t_*,t_*]}$ by $|g(t)| \le |g(0)|$ on $|t| \le t_*$. Combine with Lemma 82.3.2. □

Remark 82.4.7 *(interpretation).* The sufficient condition (82.10) asserts: the peak core L^∞-norm of $\widehat{f}$, scaled by a fixed constant depending only on t_* and $g(0)$, is dominated by the high-frequency tail L^2-mass weighted by g. Every $f \in \mathscr{A}$ satisfying the displayed quantitative dominance condition lies in $\mathscr{A}_{\mathrm{HFD}}$, and Theorem 82.4.3 gives $G(f) \ge 0$.

82.5 The Full Signed Weil Inequality

Core, Tail and Arithmetic Terms

Theorem 82.5.1 *(signed core-tail reduction).* On the test domain of the Weil formula, put

$$R[f] = \widehat{f * \widetilde{f}}(1/(2i)) + \widehat{f * \widetilde{f}}(-1/(2i)) - W_{\mathrm{fin}}(f * \widetilde{f}).$$

Then $W(f * \widetilde{f}) \ge 0$ is equivalent to

$$\frac{A[f]}{2\pi} + 2\log\pi\|f\|_2^2 \le \frac{B[f]}{2\pi} + R[f]. \tag{$\star$}$$

Thus A-TP on a specified full test class is the assertion that ($\star$) holds for every test in that class. Any equivalence with RH uses the full test class in Theorem 78.2.4; restriction to one smaller class is not automatically an equivalent criterion.

Proof. All integrals are defined on the stated test domain: the digamma densities grow logarithmically and the Fourier transforms decrease rapidly. The signed Weil formula and Plancherel give

$$\begin{aligned} W(f * \widetilde{f}) &= R[f] - W_\infty(f * \widetilde{f}) \\ &= R[f] - 2\log\pi\|f\|_2^2 + G(f) \\ &= R[f] - 2\log\pi\|f\|_2^2 + \frac{B[f] - A[f]}{2\pi}. \end{aligned} \tag{82.11}$$

Rearranging this equality proves both directions of ($\star$). No positive zero-square sum is assumed in this calculation. □

Remark 82.5.2 *(the zero-side functional).* The Weil functional is evaluated on the actual zero divisor $z_\rho = -i(\rho - 1/2)$. Replacing it by $\sum_\rho |\widehat{f}(\gamma_\rho)|^2$ uses the critical-line specialization $z_\rho = \gamma_\rho \in \mathbb{R}$. The unconditional identity used here is (82.11).

Remark 82.5.3 *(the remaining inequality).* The negative part of the auxiliary kernel is supported on $[-t_*, t_*]$, but the signed Weil inequality also includes the full norm term $2\log\pi\|f\|_2^2$, the polar terms and the finite-prime functional. Positivity of $G(f)$ alone does not control their sum. On the high-frequency dominance class it gives $W(f * \widetilde{f}) \geq R[f] - 2\log\pi\|f\|_2^2$; a sufficient additional condition is $R[f] \geq 2\log\pi\|f\|_2^2$.

Three Elementary Estimates and Their Limits

Proposition 82.5.4 *(projection to compact Fourier support).* If a Paley–Wiener Fourier transform vanishes for every real $t > t_*$, it is identically zero. Thus exact projection to core-supported Fourier transforms leaves only the zero test in this entire-function class.

Proof. The Fourier transform is entire. Its zeros on the open real interval (t_*, ∞) have accumulation points in its domain, so the identity theorem applies. □

Proposition 82.5.5 *(a majorant gives a sufficient bound).* For any non-negative measurable $h \geq -g$ on $[-t_*, t_*]$, put $A_h[f] = \int_{-t_*}^{t_*} |\widehat{f}(t)|^2 h(t)\,dt$, assuming this integral is finite. Then $A[f] \leq A_h[f]$. Consequently

$$\frac{A_h[f]}{2\pi} + 2\log\pi\|f\|_2^2 \leq \frac{B[f]}{2\pi} + R[f]$$

is sufficient for (⋆). It is not asserted to be necessary.

Proof. Integrate the pointwise inequality against $|\widehat{f}|^2 \geq 0$. Replacing the left-hand side by a larger quantity proves the stated implication. For the constant majorant $h = |g(0)|$, this also gives $A[f] \leq 2t_*|g(0)| \sup_{|t|\leq t_*} |\widehat{f}(t)|^2$, the bound used in the high-frequency dominance condition. □

Proposition 82.5.6 *(support bound).* If f is supported in $[-T', T']$, then $\sup_t |\widehat{f}(t)|^2 \leq 2T'\|f\|_2^2$. In particular $A[f] \leq 4t_*T'|g(0)|\|f\|_2^2$. These estimates alone give no bound on $R[f]$.

Proof. Cauchy–Schwarz gives the Fourier supremum bound, and substitution in the preceding majorant estimate gives the bound for $A[f]$. The calculation has used only f, its support and the kernel g; it has not estimated the polar or finite-prime terms in $R[f]$. □

Remark 82.5.7 *(scope of the estimates).* The projection statement is an obstruction to exact compact Fourier support. The majorant and support estimates are useful sufficient bounds. They do not exclude other elementary estimates or prove that every approach to (⋆) must take a prescribed form.

82.6 Auxiliary Positivity and Full Weil Positivity

Theorem 82.6.1 *(auxiliary positivity and the remaining signed form).* On $\mathscr{A}_{\mathrm{HFD}}$, one has $G(f) \geq 0$. On the full Weil test domain, positivity of $W(f * \widetilde{f})$ is equivalent to (⋆), including its norm, polar and finite-prime terms. The first assertion does not establish the second.

Proof. The first assertion is Theorem 82.4.3. The second is the signed identity (82.11). □

Remark 82.6.2 *(constructed quantities).* The Hurwitz series proves monotonicity of g, and its unique positive zero defines the non-negative energies $A[f]$ and $B[f]$. Their difference computes $G(f)$ exactly. The high-frequency dominance estimate proves positivity of this auxiliary form on its stated class. The full inequality $(\star)$ remains a separate question on the full Weil test class.

Further Comparison Problems

Remark 82.6.3 *(zero distributions, Gaussian tests and spectral spaces).* Three natural further constructions concern the actual zero divisor, Gaussian families, and Hermite–Biehler or de Branges spaces. A zero-distribution argument must estimate the unconditional functional in (82.11), before specializing the zeros to real ordinates. Gaussian calculations must retain the finite-prime and polar terms and justify passage from their test family to the desired full class. A spectral-space approach requires an actual positive kernel and a map identifying its form with the signed Weil functional; writing a kernel formula alone proves no such identification. None of these comparisons is supplied by the core-tail decomposition.

Remark 82.6.4 *(relation to the full Weil form).* Chapter 78 fixes the signed normalization. The present kernel calculation adds explicit estimates for G. To use them for full positivity one must still establish $R[f] + G(f) \geq 2\log\pi\|f\|_2^2$ on the required full test class.

82.7 The Remaining Construction

Remark 82.7.1 *(the exact positivity problem).* The positive result is the explicit auxiliary-form estimate on the high-frequency dominance class. The original problem is positivity of the full signed Weil form, with its polar and finite-prime terms, on the full test class. Its equivalence with RH does not turn the auxiliary estimate into a proof. A further construction must control $R[f] + G(f) - 2\log\pi\|f\|_2^2$ on that domain.

Chapter 83

Weil–Petersson Kernel Comparison: Dense Test-Class Limits

The compact-test moment conditions admit explicit projections and precise closure theorems. These depend on the topology: all three moments persist under compact convergence, whereas only the mean persists under unrestricted Schwartz convergence. Automorphic weight limits require their own maps and measures. The complete Weil form retains its polar, finite-prime, and signed gamma terms.

83.1 Restricted-Class Baseline and Residual

Use $\mathscr{A} = C_c^\infty(\mathbb{R})$, $\mathscr{P} = \mathcal{F}_+\mathscr{A}$, and $q_W(f,g) = W(f * g^*)$ as in Chapter 78.1.1. The topology on $\mathscr{A}$ is the usual inductive-limit topology. The full form contains its polar, signed gamma, and finite-prime terms.

Theorem 83.1.1 *(the compact coefficient comparison).* The compact multiplier $U_F(f)$ of Chapter 78.4.2 is a finite Fourier polynomial. It is a cusp form of the specified positive weight only when it vanishes. The distinct entire multiplier $\Upsilon_F(h)$ requires its own modular transformation law. For an actual cusp form, the Rankin–Selberg unfolding is Chapter 78.5.1.

Proof. The compact multiplier obstruction and exact unfolding in Chapter 78 give the assertions. □

Remark 83.1.2 *(three comparison requirements).* For compact tests, Mellin transforms are entire and rapidly decreasing on every closed vertical strip. Thus their strip holomorphy does not depend on the modular weight. Three separate requirements remain. A coefficient prescription must satisfy the modular transformation law. A comparison with holomorphic or Maass forms must specify its archimedean representation and realization map. A projection to the discrete spectrum must come from a specified Hilbert decomposition. The last projection is constructed in Chapter 78.7. None of these maps follows from the moment conditions defining $\mathscr{A}_{13}$.

83.2 Construction I: Maass-Form Lift on Tempered Eigenforms

Archimedean Local Factor for Principal-Series Maass

Let ϕ be a Maass cuspidal Hecke eigenform on $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}$ with Laplace eigenvalue $\lambda_\phi = 1/4 + r_\phi^2$, $r_\phi \in \mathbb{R}$ tempered at ∞. The Fourier–Whittaker expansion is

$$\phi(z) \;=\; \sum_{n\neq 0} a_\phi(n)\,\sqrt{y}\,K_{ir_\phi}(2\pi|n|y)\,e^{2\pi i n x},$$

where K_ν is the Macdonald K-Bessel function (Iwaniec 2002 *Spectral Methods of Automorphic Forms* §1.9). The normalised Hecke eigenvalues $\widetilde{a}_\phi(n) = a_\phi(n)/a_\phi(1)$, for $n > 0$, satisfy $\widetilde{a}_\phi(1) = 1$ and are real if ϕ is a newform at level 1. Deligne's bound is not available for Maass forms; the Kim–Sarnak estimate is $\theta_\phi \le 7/64$, and temperedness at every prime is the Ramanujan conjecture, open at $\mathrm{GL}_2/\mathbb{Q}$.

Definition 83.2.1 *(Maass Mellin lift).* . Fix a tempered Maass Hecke eigenform ϕ of eigenvalue $\lambda = 1/4 + r^2$ with $r \in \mathbb{R}$. For $f \in \mathscr{A}$, put

$$\Upsilon_\phi(f)(z) := \sum_{n\geq 1} f(\log n)\, \widetilde{a}_\phi(n)\, \sqrt{y}\, K_{ir}(2\pi n y) \cos(2\pi n x). \tag{83.1}$$

The cosine is the symmetrisation under ϕ even (the + part of the Maass space; the odd case replaces cosine by sine with the same K-Bessel factor).

For compact tests, put $M_f(s) = \int_{\mathbb{R}} f(t) e^{st}\, dt$.

LEMMA 83.2.2 *(the compact Maass coefficient series).* Use the compact real even moment space

$$\mathscr{A}_{13} = \{f \in C_c^\infty(\mathbb{R}) : f \text{ real and even},\ M_f(0) = M_f(1) = M_f'(1) = 0\}.$$

For every such f, the series (83.1) has only finitely many terms. It is smooth on $\mathbb{H}$, periodic in x, decreases exponentially as $y \to \infty$, and satisfies the local weight-zero Laplace eigenvalue equation of parameter r. These assertions require no finite-prime temperedness hypothesis. They do not establish invariance under $z \mapsto -1/z$.

Proof. Compact support bounds the positive integers with $f(\log n) \neq 0$. Each summand is smooth and periodic. The modified Bessel equation $u^2 K_{ir}'' + u K_{ir}' - (u^2 - r^2) K_{ir} = 0$ gives eigenvalue $1/4 + r^2$ for $-y^2(\partial_x^2 + \partial_y^2)$ on $\sqrt{y} K_{ir}(2\pi n y)\cos(2\pi n x)$. The decay of K_{ir} at infinity gives the cusp decay of the finite sum. These computations impose no modular transformation under inversion. A quotient-space Petersson integral requires that transformation law separately. □

The Mellin transform of a compact smooth test is entire, so the Kim–Sarnak parameter bound supplies no additional strip condition on this carrier. The moment equations are independent of the modular transformation law and do not cancel the actual polar moments at $\pm 1/2$.

PROPOSITION 83.2.3 *(the local Bessel norm and its Mellin transform).* For real r and $\Re s > 0$,

$$B_r(s) := \int_0^\infty K_{ir}(u)^2 u^{s-1}\, du = \frac{2^{s-3}\Gamma(s/2)^2 \Gamma(s/2 + ir)\Gamma(s/2 - ir)}{\Gamma(s)}.$$

For a finite cosine series $V(z) = \sum_{n\geq 1} c_n \sqrt{y} K_{ir}(2\pi n y)\cos(2\pi n x)$ and a real $s > 0$,

$$\int_0^\infty \int_{-1/2}^{1/2} |V(x + iy)|^2 y^{s-1} \frac{dx\, dy}{y} = \frac{B_r(s)}{2(2\pi)^s} \sum_{n\geq 1} |c_n|^2 n^{-s}.$$

This is a strip integral, not an integral over a modular fundamental domain.

Proof. Use the Schlaefli integral representation of K_ν (DLMF 10.32.10) with orders ir and $-ir$. Their powers of $u/2$ cancel since $K_{-ir} = K_{ir}$. Integration in u gives

$$2^{s-3}\Gamma(s/2) \int_0^\infty \int_0^\infty e^{-v-w} v^{s/2 - ir - 1} w^{s/2 + ir - 1} (v + w)^{-s/2}\, dv\, dw.$$

Absolute convergence holds for $\Re s > 0$. Set $v = xq$, $w = x(1 - q)$, where $x > 0$ and $0 < q < 1$. The x integral is $\Gamma(s/2)$, and the q integral is $\Gamma(s/2 - ir)\Gamma(s/2 + ir)/\Gamma(s)$. This proves the first formula. For the second, orthogonality of cosines on $[-1/2, 1/2]$ gives a factor $1/2$ on each diagonal. The substitution $u = 2\pi n y$ gives the stated factor n^{-s}. Only finitely many terms occur. □

Remark 83.2.4 *(the Maass critical-line comparison).* A proposed arithmetic comparison would specify a complex test domain $D_\phi \subset \mathscr{A}$ and a linear automorphic realization $I_\phi : D_\phi \to L^2_{\mathrm{cusp}}(SL_2(\mathbb{Z})\backslash\mathbb{H})$. The intended critical-line norm identity is

$$\langle I_\phi f, I_\phi g\rangle_{\mathrm{Pet}} = \int_{\mathbb{R}} h_f(t)\overline{h_g(t)}K_\phi^{\mathrm{prop}}(1/2+it)dt, \qquad f, g \in D_\phi.$$

One scalar prescription to compare with such an integral is

$$K_\phi^{\mathrm{prop}}(s) = \frac{\zeta(2s)L(s,\phi\otimes\overline{\phi})}{\zeta(s)\xi_{\mathbb{R}}(s)\xi_{\mathbb{R}}(1-s)}G_\phi^{\mathrm{prop}}(s),$$

where the auxiliary scalar factor is

$$G_\phi^{\mathrm{prop}}(s) = \frac{|\Gamma(s/2+ir)\Gamma(s/2-ir)|}{|\Gamma(s/4+ir/2)\Gamma(s/4-ir/2)|^2}$$

where finite. Absolute values make this prescription different from the holomorphic Bessel Mellin transform $B_r(s)$ above. Constructing I_ϕ, proving the critical-line identity, and specifying a convergent domain or regularization at every singularity are unresolved requirements. A nonnegative norm does not make an unidentified scalar expression pointwise nonnegative. The finite coefficient series alone supplies no modular inversion law. On a fundamental domain the lower y boundary depends on x, so the cosine orthogonality used on the strip cannot be applied there. Rankin–Selberg unfolding requires an actual automorphic function and an Eisenstein integral with its convergence hypotheses (Iwaniec, *Spectral Methods*, Ch. 10; Zagier 1981).

Corollary 83.2.5 *(positivity on an actual Maass carrier).* Any specified linear map $I_\phi : D_\phi \to L^2_{\mathrm{cusp}}$ defines the positive semidefinite form $\langle I_\phi f, I_\phi g\rangle$ without a Ramanujan hypothesis. It realizes the Weil form on D_ϕ only if its full pairing identity with $P - W_\infty - W_{\mathrm{fin}}$ is proved.

Proof. The diagonal is $\|I_\phi f\|_2^2 \geq 0$. The finite-prime counterexample in Chapter 78.5.5 excludes an identification of W_{fin} alone with a positive norm on all compact tests. Bounds on the Hecke parameters do not change that counterexample. □

Remark 83.2.6 *(domains across Maass eigenforms).* The cuspidal subspace of $L^2(\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}, dx\,dy/y^2)$ has a complete orthonormal basis of Maass cusp eigenfunctions for the positive Laplacian $\Delta = -y^2(\partial_x^2 + \partial_y^2)$. Count eigenvalues with multiplicity, using both parities, and choose one parameter $r_j \geq 0$ for every eigenvalue $1/4 + r_j^2 \geq 1/4$; the finitely many lower eigenvalues do not change the asymptotic. Then $N(R) = \#\{j : 0 \leq r_j \leq R\} \sim R^2/12$. Indeed Selberg's cuspidal Weyl law, as stated in Müller, *Annals of Mathematics* 165 (2007), p. 277, equation (0.1), is $N_{\mathrm{cusp}}(\lambda) \sim \mathrm{area}(\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H})\lambda/(4\pi)$. The standard domain has area $\int_{-1/2}^{1/2}(1-x^2)^{-1/2}dx = \pi/3$; putting $\lambda = 1/4 + R^2$ gives the coefficient $1/12$. This statement concerns the full cuspidal spectrum, not one parity and not the continuous Eisenstein spectrum. The same compact moment space $\mathscr{A}_{13}$ can parameterize finite coefficient series for different Maass eigenforms. Changing their spectral parameters or finite-prime bounds does not alter its Mellin holomorphy. Automorphic realization domains must instead be determined by actual transformation laws and maps. A union of such domains is not known to be dense merely from these coefficient prescriptions.

83.3 Moment-preserving approximation and varying weights

The moment equations restrict the test space independently of a modular weight. Their kernel admits an explicit continuous projection. Write $\mathscr{A}_{\mathbb{R}}^{\mathrm{ev}}$ for real even compact smooth tests, and define

$$\ell(f) = \left(\int f(t)dt,\ \int f(t)\cosh t\, dt,\ \int f(t)t\sinh t\, dt \right).$$

Then $\mathscr{A}_{13} = \ker \ell$. Indeed these are $M_f(0)$, $M_f(1)$, $M_f'(1)$, and $M_f'(0) = 0$ by evenness.

PROPOSITION 83.3.1 *(a continuous moment projection).* There exist real even compact smooth functions η_0, η_1, η_2 with $\ell_i(\eta_j) = \delta_{ij}$. The map

$$\Pi f = f - \sum_{j=0}^{2} \ell_j(f)\eta_j$$

is a continuous projection onto $\mathscr{A}_{13}$. This kernel is closed of codimension three in $\mathscr{A}_{\mathbb{R}}^{\mathrm{ev}}$. If $f_n \to f \in \mathscr{A}_{13}$ in the compact-test topology, then $\Pi f_n \to f$ in the same topology. The same construction holds on the real even part of $\mathscr{G}$.

Proof. Let $w(t) = (1, \cosh t, t\sinh t)$. The matrix with columns $w(0), w(1), w(2)$ has determinant $2\sinh(1)(\cosh(1)-1)^2 > 0$. Choose a nonnegative even mollifier b_ε of integral one, supported in $[-\varepsilon, \varepsilon]$. Use the three functions $b_\varepsilon(t)$ and $[b_\varepsilon(t-j) + b_\varepsilon(t+j)]/2$ for $j = 1, 2$. Their moment matrix tends to the displayed invertible matrix. For sufficiently small ε, invert that moment matrix to obtain the η_j. All moments are continuous on compact tests, so Π is continuous, $\ell\Pi = 0$, and $\Pi f = f$ on the kernel. Surjectivity of ℓ gives codimension three. These statements imply the approximation assertion. On $\mathscr{G}$, an exponential seminorm controls each moment integral, so the same proof applies. □

PROPOSITION 83.3.2 *(a projection preserving a prescribed support).* Fix $a > 0$. The moment right inverse can be chosen with all η_j supported in $[-a, a]$. The resulting projection preserves the space of smooth real even tests supported in this interval.

Proof. Choose a smooth even function $\chi \geq 0$, supported in $[-a, a]$ and positive on $(-a, a)$. With $w_0 = 1$, $w_1 = \cosh t$, $w_2 = t\sinh t$, form $G_{ij} = \int \chi(t)w_i(t)w_j(t)dt$. For a nonzero real vector c, the analytic function $\sum c_i w_i$ cannot vanish on an interval: independence follows, for example, from its growth at positive infinity. Therefore $c^T G c = \int \chi(\sum c_i w_i)^2 > 0$. Set $\eta_j = \chi \sum_i (G^{-1})_{ij} w_i$. Then $\ell_i(\eta_j) = \delta_{ij}$, and the support assertion follows. □

PROPOSITION 83.3.3 *(the moment quotient algebra).* On the complex even compact convolution algebra, the map

$$f \longmapsto \big(M_f(0), M_f(1) + M_f'(1)\epsilon\big), \qquad \epsilon^2 = 0,$$

is a continuous surjective algebra homomorphism onto $\mathbb{C} \times \mathbb{C}[\epsilon]/(\epsilon^2)$. Its kernel is the complexification of $\mathscr{A}_{13}$. The involution is coefficient conjugation with $\epsilon^* = \epsilon$. A linear functional on this quotient is positive on xx^* exactly when it has the form $\lambda(a, b + c\epsilon) = \alpha a + \beta b$ with $\alpha, \beta \geq 0$.

Proof. Compact support permits Fubini, giving $M_{f*g} = M_f M_g$. Differentiating at one gives the dual-number multiplication rule. The moment right inverse proves surjectivity. Evenness makes the involution coefficient conjugation at these real evaluation points. Write a linear functional as $\alpha a + \beta b + \gamma c$. Since

the quotient is unital, positivity on squares makes it Hermitian: expanding $(1+tx)(1+tx)^*$ and $(1+itx)(1+itx)^*$ for real t gives $\lambda(x^*)=\overline{\lambda(x)}$. Thus its three coefficients are real. For $x=(a,b+c\epsilon)$ its squared value is $\alpha|a|^2+\beta|b|^2+2\gamma\Re(b\bar{c})$. Varying c with $b=1$ forces $\gamma=0$. Varying a,b independently then gives $\alpha,\beta\geq 0$, which also suffices. No factorization of the Weil functional through this finite-dimensional quotient is assumed. □

For every compact f, differentiation under the integral makes $M_f(s)=\int f(t)e^{st}\,dt$ entire. Integration by parts gives rapid decay on each closed vertical strip. Consequently, imposing the reality, evenness, and double-zero conditions at 0, 1 for any family of weights always gives $\mathscr{A}_{13}$. This union is not dense in the compact-test space. It is not dense in its ambient real even Schwartz topology either: the continuous functional $f\mapsto\int f$ vanishes on the union and not on a nonnegative bump. A bounded moment correction need not tend to zero. The projection above converges to the original limit only when that limit has the required moments.

Theorem 83.3.4 *(the closure in the weaker Schwartz topology).* The closure of $\mathscr{A}_{13}$ in the real even Schwartz space is

$$\{f\in\mathcal{S}(\mathbb{R}) : f \text{ real and even, } \int f=0\}.$$

In the relative Schwartz topology on compact tests, intersect this space with $\mathscr{A}$. The exponential moments need not vanish at a limit in this weaker topology.

Proof. The mean is Schwartz-continuous, so every limit has mean zero. Choose a nonnegative even compact smooth β with $\int\beta=1$. Put $A=\int\beta(t)\cosh t\,dt>0$ and $B=\int\beta(t)t\sinh t\,dt$. For $R>0$ define $\beta_R(t)=[\beta(t-R)+\beta(t+R)]/2$ and $v_R=\beta_R-\beta$. Direct translation gives

$$\ell(v_R)=(0,A(\cosh R-1),B(\cosh R-1)+AR\sinh R).$$

The determinant of the last two moments of v_R, v_{2R} is

$$A^2[(\cosh R-1)2R\sinh(2R)-(\cosh(2R)-1)R\sinh R]=2A^2R\sinh R(\cosh R-1)^2>0.$$

Thus any fixed pair of moments can be prescribed by $c_Rv_R+d_Rv_{2R}$ with $c_R=O(e^{-R})$ and $d_R=O(e^{-2R})$ as $R\to\infty$. Every Schwartz seminorm of v_R grows at most polynomially in R, so this prescribed-moment correction tends to zero in Schwartz space. For a compact real even mean-zero f, choose the correction with moments $-(\ell_1(f),\ell_2(f))$. Its sum with f lies in $\mathscr{A}_{13}$ and converges to f in Schwartz space. Finally, real even compact mean-zero tests are dense in the mean-zero real even Schwartz space: use even cutoffs and subtract their mean times β. For the nth such approximation, choose R large enough that the correction has its first n Schwartz seminorms below $1/n$. This diagonal choice proves the full assertion. □

Definition 83.3.5 *(a family of cusp forms with varying weights).* Choose an increasing sequence of even weights $k_j\to\infty$ for which $S_{k_j}(SL_2(\mathbb{Z}))\neq 0$, and normalized Hecke cusp forms F_j in these spaces. Define probability measures on $Y=SL_2(\mathbb{Z})\backslash\mathbb{H}$ by

$$d\nu_j=\frac{|F_j(z)|^2y^{k_j}\,d\mu(z)}{\|F_j\|_{\mathrm{Pet}}^2},\qquad d\mu=dx\,dy/y^2.$$

Their masses equal one by definition.

Pairing limits on a common carrier

For a bounded measurable scalar function a on Y, multiplication by a defines a section $J_j a = aF_j/\|F_j\|_{\mathrm{Pet}}$ of the weight-k_j line bundle. It is square integrable, and

$$\langle J_j a, J_j b\rangle = \int_Y a\overline{b}\, d\nu_j.$$

Holomorphy is not required for this Hilbert-space map.

PROPOSITION 83.3.6 *(limits of the actual normalized measures).* If ν_j converges weakly to a probability measure ν against bounded continuous functions on Y, then for bounded continuous a, b,

$$\lim_j \langle J_j a, J_j b\rangle = \int_Y a\overline{b}\, d\nu.$$

The limiting form is positive semidefinite.

Proof. The product $a\overline{b}$ is bounded and continuous, so weak convergence gives the equality. Its diagonal is an integral of $|a|^2$. □

A limit of total mass one on this noncompact quotient requires control of escape into the cusp. Weight growth alone supplies neither weak convergence nor this control.

THEOREM 83.3.7 *(limits of specified positive pairings).* Let D be a complex vector space. Let $I_j : D \to H_j$ be linear maps to positive Hilbert spaces and $c_j > 0$. Suppose $Q(f) = \lim_j c_j^{-1}\|I_j f\|^2$ exists and is finite for every $f \in D$. Then Q is the diagonal of a positive semidefinite Hermitian form q on D, and

$$q(f, g) = \lim_j c_j^{-1}\langle I_j f, I_j g\rangle.$$

Proof. For a form linear in its first variable, polarization is $q(f, g) = \frac{1}{4}\sum_{r=0}^{3} i^r Q(f + i^r g)$. Apply this finite sum to the assumed limits. The resulting pointwise limit of sesquilinear forms is sesquilinear and Hermitian. The diagonal is nonnegative as a limit of nonnegative real numbers. □

Remark 83.3.8 *(the proposed symmetric-square density).* For the unitary Hecke normalization one may consider the proposed meromorphic ratio $K_{F_j}^{\mathrm{prop}}$ in Chapter 78.7 and the proposed real density

$$R(t) = \frac{\zeta(1 + 2it)\zeta(1 - 2it)}{\xi_{\mathbb{R}}(1/2 + it)\xi_{\mathbb{R}}(1/2 - it)}.$$

For a level-one holomorphic eigenform with unitary automorphic normalization, the Euler factors give $L(s, \pi_j \times \overline{\pi}_j) = \zeta(s)L(s, \mathrm{sym}^2 \pi_j)$. Indeed the tensor Satake parameters are $1, 1, \alpha_p^2, \alpha_p^{-2}$, where $\alpha_p\alpha_p^{-1} = 1$; the symmetric square has parameters $\alpha_p^2, 1, \alpha_p^{-2}$. The weight-limit question asks for a normalized factorization $K_j(1/2 + it) = c_j R(t) A_j(t)$ with $c_j > 0$ and $A_j(t) \to 1$ locally uniformly away from singularities, together with domination of the complete tested integrands. The scalar c_j must be fixed by the actual pairing normalization. This factorization and limit are additional requirements, not consequences of the Euler factors. An identity with normalized Petersson pairings requires actual maps I_j on a common domain, all local factors, and a proved integral identity. A density limit additionally requires convergence and an integrable majorant for the complete integrands, including varying tests and singular factors. The ratio R has a singularity at zero from the pole of $\zeta(1 + 2it)$, and may have

further singularities at critical-line zeros of ξ. Thus no integral of $|h|^2 R$ is specified without a domain or regularization. A Selberg trace identification would also have to match its spectral and geometric terms. None of these assertions follows from moment projection.

Corollary 83.3.9 *(the arithmetic comparison for a limit).* Under the preceding limit theorem, the quotient of D by the nullspace of q, followed by completion, is a positive Hilbert realization of q. It realizes the restricted Weil form exactly when $q(f, g) = W(f * g^*)$ on D.

Proof. Use Cauchy–Schwarz for q to form its Hilbert quotient. The last equality is the required pairing identity. □

83.4 The polar form and its finite-dimensional realization

The two evaluations in the Weil formula determine a signed finite-dimensional form. Write $a(f) = M_f(-1/2)$, $b(f) = M_f(1/2)$ and $r(f) = (a(f), b(f))$.

Lemma 83.4.1 *(the exact polar map).* For $f, g \in \mathscr{A}$,

$$P(f * g^*) = a(f)\overline{b(g)} + b(f)\overline{a(g)}.$$

The map $r : \mathscr{A} \to \mathbb{C}^2$ is continuous and surjective. Its common kernel is closed of codimension two.

Proof. Evaluate $h_f h_g^\sharp$ at $\pm i/2$. The functions $e^{-t/2}$, $e^{t/2}$ are linearly independent, so the two moment functionals are independent. This makes r surjective. Their continuity gives the remaining assertions. □

Proposition 83.4.2 *(signed polar realization and even restriction).* The polar form is the pullback by r of the Hermitian matrix $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. It has one positive and one negative direction, so no map into a positive Hilbert space realizes it on all compact tests. On the complex even tests it has the one-dimensional positive realization $f \mapsto \sqrt{2}\, M_f(1/2)$.

Proof. The matrix eigenvalues are $1, -1$, and surjectivity gives both signs on compact tests. For even functions $a = b$, so the pairing is $2a(f)\overline{a(g)}$, proving the last assertion. □

Remark 83.4.3 *(moment restrictions and arithmetic residual sectors).* The H3 moments at 0, 1 are different from these polar moments. For a nonzero nonnegative even bump v, set $f = D^2(D^2 - 1)^2 v$, where $D = d/dt$. Then $f \in \mathscr{A}_{13}$ but $M_f(1/2) = 9M_v(1/2)/64 > 0$. Thus $P(f * f^*) = 2M_f(1/2)^2 > 0$ despite H3. The exact polar kernel can instead be projected onto by choosing a right inverse $S : \mathbb{C}^2 \to \mathscr{A}$ of r and using $\Pi_{\mathrm{pol}} = 1 - Sr$. The vector $M_f(1)|0\rangle$ has norm square $|M_f(1)|^2$ and does not realize the polar form. A comparison with an automorphic residual spectrum must specify its central character, subspace, measure, and map. The finite-dimensional signed realization above supplies the complete polar pairing without making that identification.

83.5 Construction IV: Jacquet–Piatetski-Shapiro–Shalika on $GL_n \times GL_m$

Higher-Rank Rankin–Selberg

Higher-rank Rankin–Selberg integrals compare specified automorphic representations through Whittaker models and local factors. Their convergence regions concern those integrals. Compact test Mellin transforms are already entire at every rank.

Definition 83.5.1 *(higher-rank coefficient prescription).* Fix a cuspidal automorphic representation π of $GL_r/\mathbb{Q}$ and Hecke coefficients $a_\pi(m)$ in a specified unitary Satake normalization. A vector-valued coefficient prescription requires actual vectors $v_{\pi,m}$ in a specified representation space:

$$U_\pi(f) = \sum_{m\geq 1} f(\log m) a_\pi(m) v_{\pi,m}, \qquad f \in \mathscr{A}.$$

This sum is finite. A scalar Whittaker value $W_\pi(m)$ instead gives a scalar-valued sum; it does not by itself define an automorphic vector. Choosing Whittaker vectors, their translates, and a global realization is part of the higher-rank problem.

PROPOSITION 83.5.2 *(a specified higher-rank pairing).* Suppose a complex test domain $D_\pi \subset \mathscr{A}$ has a linear map I_π to a cuspidal automorphic Hilbert space with fixed central character and quotient measure. Suppose a measurable function $\kappa_\pi(t)$ satisfies the absolutely convergent identity

$$\langle I_\pi f, I_\pi g\rangle_{\mathrm{Pet}} = \int_{\mathbb{R}} h_f(t)\overline{h_g(t)}\kappa_\pi(t)\,dt \qquad (f, g \in D_\pi).$$

Then the tested form on the right is positive semidefinite. This conclusion does not require temperedness of π.

Proof. Its diagonal equals $\|I_\pi f\|^2_{\mathrm{Pet}}$. □

The required comparison with JPSS Rankin–Selberg integrals is open for this coefficient prescription. In particular the suggested ratio $L(s, \pi \times \overline{\pi})/(\zeta(rs)\prod_v G_{v,\pi}(s))$ needs specified normalized local factors $G_{v,\pi}$, a convergence meaning for their product, and a proof that its critical-line value is κ_π. The local Whittaker models and measures, the Eisenstein or Rankin–Selberg integration domain, and any continuation or regularization must be fixed before that equality can be tested. JPSS integrals provide their own L-function identities; they do not identify an arbitrary coefficient prescription with a norm. Temperedness alone does not imply positivity of an unconstructed critical-line scalar ratio.

PROPOSITION 83.5.3 *(compact Mellin transforms and local convergence).* For $f \in \mathscr{A}$, its Mellin transform $M_f(s)$ is entire and rapidly decreasing on each closed vertical strip, independently of a rank parameter. A convergence half-plane of a specified Rankin–Selberg integral does not impose a strip of holomorphy on this compact test transform.

Proof. Differentiate the integral $M_f(s) = \int f(t)e^{st}\,dt$ on its fixed compact support. Repeated integration by parts gives rapid decay in $\Im s$, uniformly on a bounded range of $\Re s$. The rank does not appear in this calculation. □

A higher-rank comparison must still specify its automorphic map, Whittaker vectors, local measures, convergence region and analytic continuation. Those are properties of the specified integral, not additional holomorphy restrictions on M_f.

Remark 83.5.4 *(temperedness and the higher-rank comparison).* A separate parameter question asks for temperedness of the chosen cuspidal representation at every finite place. For a functorial symmetric-power lift of a holomorphic eigenform, unit-modulus normalized Satake parameters give unit-modulus symmetric-power parameters. This follows directly by taking their monomials. Constructing the lift and deciding its cuspidal decomposition are additional automorphic questions; references include Gelbart–Jacquet, Kim–Shahidi, Kim and Newton–Thorne. For a general Maass or higher-rank representation, the required parameter assertion remains a Ramanujan hypothesis. Neither this assertion nor its special symmetric-power cases constructs I_π or proves the critical-line pairing identity.

83.6 Closed moment kernels and full positivity

Definition 83.6.1 *(domains of specified comparisons).* For each constructed comparison map $I_\alpha : D_\alpha \to H_\alpha$, let $D_\alpha \subset \mathscr{A}$ be its actual domain and put

$$D_{\mathrm{ext}} = \bigcup_\alpha D_\alpha.$$

An identity with $W(f * g^*)$ must be specified on each D_α. The union is a set of tests and is not necessarily a vector space.

Theorem 83.6.2 *(moment-preserving density).* If S is dense in $\mathscr{A}_{\mathbb{R}}^{\mathrm{ev}}$ in the compact-test topology, then ΠS is dense in $\mathscr{A}_{13}$. The kernel $\mathscr{A}_{13}$ is a proper closed subspace. On the real even exponential space, its compact members are dense in the corresponding moment kernel.

Proof. Apply the continuous projection Π to an approximating net for any member of its image. Closedness and properness follow from its three independent moments. In $\mathscr{G}$, use even compact cutoffs f_R and then Πf_R. The cutoff convergence of Chapter 95.1.2 and continuity of Π prove $\Pi f_R \to f$ for a member of the kernel. □

Proposition 83.6.3 *(positivity on a union of comparison domains).* Suppose each specified map I_α satisfies $W(f * g^*) = \langle I_\alpha f, I_\alpha g\rangle$ on D_α. Then $q_W(f, f) \geq 0$ on D_{ext} and its closure. Positivity on the linear span additionally requires control of cross terms between different domains.

Proof. Each diagonal is a norm square. Continuity passes its sign to the closure. For tests from two domains, their sum has diagonal $q_W(f, f) + 2\Re q_W(f, g) + q_W(g, g)$. The separate norm identities specify no bound on that cross term. □

Theorem 83.6.4 *(continuity of the complete Weil form).* If sequences $f_j \to f$ and $g_j \to g$ in $\mathscr{A}$ or $\mathscr{G}$, then

$$W(f_j * g_j^*) \longrightarrow W(f * g^*).$$

The same convergence holds separately for P, W_∞, W_{fin}.

Proof. For compact convergence all supports lie in one compact interval, and the prime functional is a finite sum of continuous evaluations. For exponential convergence, the bound

$$\sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}} |v(\pm \log n)| \leq p_{2,0,0}(v) \sum_{n\geq 2} \frac{\log n}{n^{5/2}}$$

proves continuity of the prime term. The polar and gamma terms, convolution and involution are continuous by Chapter 95.1.2. The formula follows. □

Remark 83.6.5 *(the topology of the prime term).* Ordinary Schwartz seminorms give only inverse powers of $1 + |\log n|$ at prime arguments. Such bounds do not supply the summable majorant above. The stated continuity therefore uses the compact-test or exponential topology. It does not assert a tempered extension of the uncentered critical prime measure.

Theorem 83.6.6 *(extension across a finite moment complement).* Let D be a complex vector space with a Hermitian form q, linear in the first variable. Let $\Pi : D \to K$ be a projection, and put $E = (1 - \Pi)D$, so $D = K \oplus E$. Then q is positive semidefinite on D if and only if

$$q(u, u) \geq 0, \quad q(e, e) \geq 0, \quad |q(u, e)|^2 \leq q(u, u)q(e, e) \qquad (u \in K,\ e \in E).$$

Proof. Necessity is Cauchy–Schwarz for a positive semidefinite form. For sufficiency, the cross bound gives $q(u+e,u+e) \geq (\sqrt{q(u,u)} - \sqrt{q(e,e)})^2 \geq 0$. Every member of D has this decomposition. □

For the complexification of $\mathscr{A}_{13}$ inside the complex even tests, the projection has a three-dimensional complement. Thus positivity on that kernel leaves a finite complement and all its cross terms to determine. Odd tests require their own comparison when the target is the full complex space $\mathscr{A}$. The polar kernel on the full space has the two-dimensional complement constructed above. Neither finite codimension nor a projection establishes the missing cross inequalities.

83.7 The arithmetic realization problem

Theorem 83.7.1 *(the full comparison criterion).* A positive Hilbert realization of q_W on $\mathscr{A}$ exists if and only if

$$W_\infty(f * f^*) \leq P(f * f^*) - W_{\mathrm{fin}}(f * f^*) \qquad (f \in \mathscr{A}).$$

This condition is equivalent to RH.

Proof. The signed explicit formula identifies the difference with $q_W(f,f)$. A positive form has its Hilbert quotient realization, as in Chapter 78.8.1. Weil's criterion gives RH. □

Corollary 83.7.2 *(a sufficient comparison route).* A dense family of tests with proved nonnegative full Weil diagonals in the compact or exponential topology suffices for RH. For a dense linear span, positivity must hold for every finite linear combination, not only the chosen generators.

Proof. Use continuity and Chapter 83.7.1. □

Remark 83.7.3 *(native comparison requirements).* A holomorphic comparison requires modularity of the entire coefficient multiplier. A Maass comparison requires an automorphic realization with its correct Whittaker expansion. A higher-rank comparison requires its Whittaker model, integral domain, and normalized local factors. Ordinary cusp-form L^2 norms are positive without a Ramanujan hypothesis. Bounds on Hecke parameters address different questions. None of these norms identifies a zeta pairing without an explicit map and equality of all its terms. Weight variation admits the actual probability measures and conditional pairing limit above. The residual polar term has its explicit signed rank-two realization. These constructions retain the holomorphic, Maass, residual, and higher-rank comparison questions, with their domains and maps specified separately.

Chapter 84

Langlands–Shahidi Normalisation of the Eisenstein Koszul Density

The bounded-interval reduction, construction C. Chapter 76 (the restricted-class comparison) reduced Koszul–Petersson compatibility on the discrete-spectrum core by domain restriction: the Eisenstein continuous sector was placed outside the P3 identity, and the Li trace was separated from it under the H-P^{Ar} spectral realisation. The Langlands–Shahidi alternative was sketched as the second normalisation of §76.4. The exact conditional normalisation problem is this: multiplication by a Langlands–Shahidi scalar removes the unitary phase only after a choice of positive Plancherel measure has been fixed; the boundary Euler product on $\mathrm{Re}(s) = 1/2$ *is meromorphic, not absolutely convergent. Thus the Langlands–Shahidi normalisation is a conditional construction, not an unconditional closure of the Eisenstein residual.*

84.1 Setup and the LS Normalisation

The Residual Mismatch

The explicit mismatch of Proposition 76.3.1 (Chapter 76) is as follows. On the Eisenstein continuous spectrum $L^2_{\mathrm{cont}}([GL_2])$ parametrised by $\mathrm{Re}(s) = 1/2$, the Petersson-side Maass–Selberg normalisation and the Koszul-side bar–cobar coefficient are recorded in the unnormalised spherical convention by

$$\begin{aligned} \mathrm{lead}^{\mathrm{Pet}}_{\mathrm{cont}}(s) &= \big(1 + |M(s)|^2\big)|\xi(2s)|^{-2} \qquad (\mathrm{Re}(s) = 1/2), \\ \mathrm{lead}^{\mathrm{Koszul}}_{\mathrm{cont}}(s) &= \frac{\xi(2s)}{\xi(2s-1)} \cdot |\xi(2s)|^{-2} \qquad (\mathrm{Re}(s) = 1/2). \end{aligned}$$

The ratio $\xi(2s)/\xi(2s-1)$ has modulus 1 on the critical line (lemma below). Thus the mismatch is a normalisation and phase problem between the Maass–Selberg scattering coefficient and the Koszul coefficient; it is not removed by treating the diagonal as an ordinary L^2-density.

Lemma 84.1.1 *(unit modulus of* $\xi(2s)/\xi(2s-1)$ *on the critical line).* For $s = 1/2 + it$, away from the Tate boundary and common zeros of the two factors,

$$\big|\xi(2s)/\xi(2s-1)\big| = 1.$$

Proof. For $s = 1/2 + it$, write $2s = 1 + 2it$ and $2s - 1 = 2it$. The completed zeta ξ satisfies $\xi(w) = \xi(1-w)$ (functional equation; Titchmarsh 1986 §2.1), giving $\xi(1+2it) = \xi(-2it)$. Complex conjugation gives $\overline{\xi(1+2it)} = \xi(1-2it)$ (Schwarz reflection: ξ is real on the real axis, hence $\overline{\xi(w)} = \xi(\overline{w})$). Combining, $\xi(1+2it)\cdot\overline{\xi(1+2it)} = \xi(1+2it)\xi(1-2it) = \xi(1+2it)\xi(2it)$ by the functional equation. Similarly $\xi(2it)\cdot\overline{\xi(2it)} = \xi(2it)\cdot\xi(\overline{2it}) = \xi(2it)\cdot\xi(-2it) = \xi(2it)\cdot\xi(1+2it)$ by FE. Therefore $|\xi(2s)|^2 = |\xi(2s-1)|^2$, giving (84.1.1). □

The Langlands–Shahidi Normalisation Factor

We follow Shahidi 2010 *Eisenstein Series and Automorphic L-Functions* Chapter 2 and Moeglin–Waldspurger 1995 §IV.3 for the intertwining operator normalisation.

Definition 84.1.2 *(Langlands–Shahidi normalisation factor on GL_2 Eisenstein).* The *Langlands–Shahidi normalisation factor* on the Eisenstein summand $\mathrm{Ind}_B^G(\chi_s)$ of GL_2 at spectral parameter s with $\mathrm{Re}(s) = 1/2$ is

$$N^{\mathrm{LS}}(s) \;:=\; \frac{\xi(2s-1)}{\xi(2s)}.$$

Its inverse is $N^{\mathrm{LS}}(s)^{-1} = \xi(2s)/\xi(2s-1)$.

Remark 84.1.3 *(origin and canonicity of the factor).* The factor $N^{\mathrm{LS}}(s)$ is the global Langlands–Shahidi normalisation of the standard intertwining operator $M(s)\colon \mathrm{Ind}_B^G(\chi_s) \to \mathrm{Ind}_B^G(\chi_s^w)$, with three essential properties.

(LS1) *Local factor decomposition.* For each place v, $N^{\mathrm{LS}}(s)$ is a product of local Langlands factors $N_v^{\mathrm{LS}}(s)$ as specified by Casselman–Shalika 1980 *Compositio Math.* 41 at unramified finite v and by Shahidi 2010 §2.2 at ramified and archimedean v. Restricted tensor product factorisation: $N^{\mathrm{LS}}(s) = \prod_v N_v^{\mathrm{LS}}(s)$.

(LS2) *Functional equation.* $N^{\mathrm{LS}}(s)\cdot N^{\mathrm{LS}}(1-s) = 1$ on the critical line. Explicitly:

$$N^{\mathrm{LS}}(s)\cdot N^{\mathrm{LS}}(1-s) = \frac{\xi(2s-1)}{\xi(2s)}\cdot\frac{\xi(1-2s)}{\xi(2-2s)} = \frac{\xi(2s-1)\cdot\xi(2s)}{\xi(2s)\cdot\xi(2s-1)} = 1,$$

using the functional equation $\xi(1-2s) = \xi(2s)$ and $\xi(2-2s) = \xi(2s-1)$ (Titchmarsh 1986 §2.1). The Shahidi global normalisation satisfies $n(s)\cdot n(1-s) = 1$ (Shahidi 2010 Thm 3.5.1). No Maass–Selberg measure scalar is part of N^{LS}.

(LS3) *Unitarity of the normalised intertwiner.* After division by $N^{\mathrm{LS}}(s)$, the normalised intertwiner $\widetilde{M}(s) = M(s)/N^{\mathrm{LS}}(s)$ is unitary on the principal-series representation at each critical parameter (Moeglin–Waldspurger §IV.3.10).

84.2 The Redefined Koszul Pairing on the Eisenstein Summand

Definition 84.2.1 *(LS-corrected Koszul pairing on the Eisenstein summand).* Let $\phi_{s_1}, \phi_{s_2} \in \mathrm{Ind}_B^G(\chi_s)$ be spherical vectors at Eisenstein parameters s_1, s_2 with $\mathrm{Re}(s_i) = 1/2$. Assume an actual bivariate arithmetic pairing has been constructed on these vectors, and restrict to parameters for which the scalar below is finite and nonzero. Using the convention of Chapter 76, define the *Langlands–Shahidi-corrected Koszul pairing* by

$$\big\langle \phi_{s_1}, \sigma^{\mathrm{BC}}(\phi_{s_2})\big\rangle^{\mathrm{Koszul,LS}} \;:=\; N^{\mathrm{LS}}\!\left(\tfrac{1}{2}(s_1+s_2)\right)\cdot\big\langle \phi_{s_1}, \sigma^{\mathrm{BC}}(\phi_{s_2})\big\rangle^{\mathrm{Koszul}}.$$

On the diagonal $s_1 = s_2 = s$ this reduces to

$$\big\langle \phi_s, \sigma^{\mathrm{BC}}(\phi_s)\big\rangle^{\mathrm{Koszul,LS}} \;=\; \frac{\xi(2s-1)}{\xi(2s)}\cdot\big\langle \phi_s, \sigma^{\mathrm{BC}}(\phi_s)\big\rangle^{\mathrm{Koszul}}.$$

Theorem 84.2.2 *(conditional LS Plancherel normalisation match on the continuum). (conditional on the bar–cobar Eisenstein pairing being transported to the positive Langlands–Shahidi Plancherel measure).* For spherical vectors $\phi_s \in \mathrm{Ind}_B^G(\chi_s)$ with $\mathrm{Re}(s) = 1/2$,

$$\mathsf{Sh}_{\mathrm{LS}}\Big(\mathrm{lead}_{\mathrm{cont}}^{\mathrm{Koszul,LS}}(s)\Big) \;=\; \mathrm{lead}_{\mathrm{cont}}^{\mathrm{Pet}}(s). \tag{84.1}$$

Equivalently,

$$\mathsf{Sh}_{\mathrm{LS}}(\text{Koszul continuum}) \;=\; \text{Petersson continuum} \qquad (\mathrm{Re}(s) = 1/2),$$

after this measure identification. Here $\mathsf{Sh}_{\mathrm{LS}}$ denotes the Shahidi Plancherel transport. No pointwise equality of raw scalar densities is asserted before applying $\mathsf{Sh}_{\mathrm{LS}}$.

Proof. On the critical-line domain U where both zeta factors are finite and nonzero, Definition 67.5.2 defines the scalar model

$$d = |\xi(2s)|^{-2} > 0, \qquad M = N^{\mathrm{LS}}(s), \qquad K = M^{-1}d, \qquad P = 2d.$$

Consequently $N^{\mathrm{LS}}K = d = P/2$. This calculation concerns scalars; it neither constructs a bivariate arithmetic pairing nor regularises its diagonal. The theorem additionally assumes an actual transport of the corrected arithmetic quadratic form to the positive Plancherel measure, including its domain and normalization. With that transport supplied, (84.1) is the asserted normalization of that transport. □

Remark 84.2.3 *(why no scalar square proves the match).* The diagonal pairing is only a distributional Maass–Selberg object before truncation is regularised. Since $\xi(2s)/\xi(2s-1)$ has unit modulus on the critical line, taking absolute values removes the phase but does not identify the underlying Plancherel normalisation. The non-formal point is exactly the identification of the bar–cobar Eisenstein quadratic form with the Shahidi positive Plancherel measure.

Corollary 84.2.4 *(conditional normalisation match via LS). (same hypothesis as Theorem 84.2.2).* Under the LS redefinition Definition 84.2.1, the Koszul and Petersson normalisations on the Eisenstein continuous spectrum of $L^2([GL_2])$ coincide after the positive Plancherel-measure identification.

Proof. Theorem 84.2.2 is the stated measure-identification hypothesis written in the LS normalisation. No Ramanujan input is used on the continuum; the continuum is Eisenstein-induced and tempered on the unitary axis by construction. □

84.3 Compatibility Checks

The scalar functional equation, a conditional transport of obstruction classes, the meromorphic factorisation, and the unchanged discrete summand impose distinct compatibility requirements.

Compatibility Check (i): Heisenberg Self-Duality

Proposition 84.3.1 *(Conditional transport of Heisenberg self-duality).* Suppose a specified comparison of obstruction complexes induces a linear map $F : H \to H_{\mathrm{Ar}}$ taking two classes $c, c^! \in H$, with $c + c^! = 0$, to the arithmetic Heisenberg classes $\kappa_{\mathsf{G}}^{\mathrm{Ar}}$ and $(\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}}$, respectively. Assume this comparison remains defined for the corrected pairing. Then

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0.$$

The scalar correction itself satisfies $N^{\mathrm{LS}}(s)N^{\mathrm{LS}}(1-s) = 1$ wherever the ratios are finite and nonzero. This scalar identity supplies no comparison of obstruction complexes.

Proof. Linearity gives $F(c) + F(c^!) = F(0) = 0$. Independently, the completed zeta functional equation gives

$$N^{\mathrm{LS}}(s)N^{\mathrm{LS}}(1-s) = \frac{\xi(2s-1)\xi(1-2s)}{\xi(2s)\xi(2-2s)} = 1.$$

The first calculation requires the stated class comparison; the second proves only the scalar functional equation. Constructing the arithmetic obstruction complexes and this comparison remains necessary before applying the first calculation to the Eisenstein summand. □

Remark 84.3.2 *(no modification to the discrete sector).* On a specified decomposition into discrete and continuous summands, define the correction to be the identity on the discrete summand and to multiply by N^{LS} on the continuous domain U. Thus the discrete pairing of Chapter 76 is unchanged. This is a choice of extension to the direct sum, not the assertion that a meromorphic value of N^{LS} equals one at discrete parameters.

Compatibility Check (ii): Tate Factorisation

Proposition 84.3.3 *(LS factorises over places as a Tate restricted tensor product). (as a meromorphic Langlands–Shahidi factorisation, not as an absolutely convergent Euler product on the critical line).* The global Langlands–Shahidi factor $N^{\mathrm{LS}}(s)$ of Definition 84.1.2 admits a place-by-place decomposition

$$N^{\mathrm{LS}}(s) \;=\; \prod_{v \in |\overline{\mathrm{Spec}\,\mathbb{Z}}|} N_v^{\mathrm{LS}}(s),$$

with local factors

$$N_v^{\mathrm{LS}}(s) \;=\; \begin{cases} \zeta_p(2s-1)/\zeta_p(2s) & (v = p \text{ finite, unramified}) \\ \zeta_p(2s-1)/\zeta_p(2s)\cdot \varepsilon_p(s,\pi_p,\psi_p) & (v = p \text{ finite, ramified}) \\ \Gamma_{\mathbb{R}}(2s-1)/\Gamma_{\mathbb{R}}(2s) & (v = \infty), \end{cases}$$

where $\zeta_p(s) = (1-p^{-s})^{-1}$ is the Euler factor, $\Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2)$ the archimedean Tate factor, and ε_p the local Jacquet–Piatetski-Shapiro–Shalika epsilon factor at the principal-series induction. The product is interpreted by meromorphic continuation of the completed L-factor.

Proof. The completed zeta factorises $\Lambda_\zeta(s) = \Gamma_{\mathbb{R}}(s)\prod_p \zeta_p(s)$ (Tate 1950 §4.2). Applying the factorisation to the ratio $\Lambda_\zeta(2s-1)/\Lambda_\zeta(2s)$:

$$\frac{\Lambda_\zeta(2s-1)}{\Lambda_\zeta(2s)} \;=\; \frac{\Gamma_{\mathbb{R}}(2s-1)}{\Gamma_{\mathbb{R}}(2s)} \cdot \prod_p \frac{\zeta_p(2s-1)}{\zeta_p(2s)}.$$

Unramified local factors are $\zeta_p(2s-1)/\zeta_p(2s)$; ramified local factors pick up an additional local epsilon factor ε_p from the Jacquet–Piatetski-Shapiro–Shalika 1983 local-functional-equation correction, which has absolute value 1 and does not affect the Plancherel normalisation match (Theorem 84.2.2). The restricted tensor product $\prod_v N_v^{\mathrm{LS}}(s)$ is not an absolutely convergent Euler product on $\mathrm{Re}(s) = 1/2$; it is the boundary value of the meromorphic completed ratio, giving (84.3.3). □

Remark 84.3.4 *(Casselman–Shalika at unramified finite places).* The local factor at an unramified finite prime p, $N_p^{\mathrm{LS}}(s) = \zeta_p(2s-1)/\zeta_p(2s) = (1-p^{-2s})/(1-p^{1-2s})$, is precisely the Casselman–Shalika 1980 formula for the unramified spherical Whittaker function at principal-series parameter s (Casselman–Shalika *Compositio Math.* 41 Thm 5.4 with w the non-trivial Weyl element). This identifies N_p^{LS} as the local intertwining operator normalisation, canonically and without convention choice.

Compatibility Check (iii): Discrete-Core Fixation

Proposition 84.3.5 *(LS correction preserves the discrete-core identity). (with the hypotheses of the discrete-core identity).* The discrete-spectrum Koszul–Petersson identity of Theorem 76.3.3 is preserved under the substitution $\langle\cdot,\cdot\rangle^{\mathrm{Koszul}} \rightsquigarrow \langle\cdot,\cdot\rangle^{\mathrm{Koszul,LS}}$ extended to the Eisenstein summand:

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul,LS}} \qquad \forall v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}.$$

Proof. $\mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$ is orthogonal to the Eisenstein continuous summand in the Langlands decomposition (Langlands 1966 §6; Moeglin–Waldspurger 1995 Ch. II). The substitution $\langle\cdot,\cdot\rangle^{\mathrm{Koszul,LS}} = N^{\mathrm{LS}}(s)\cdot\langle\cdot,\cdot\rangle^{\mathrm{Koszul}}$ is defined only on the Eisenstein summand; on the discrete core, the pairing is unmodified: $\langle v, w\rangle^{\mathrm{Koszul,LS}} = \langle v, w\rangle^{\mathrm{Koszul}}$ for $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}}$. Combining with Theorem 76.3.3 gives (84.3.5). □

The fixed scalar models satisfy $MK = P/2$, as shown in Remark 67.5.4. A phase correction alone supplies no equality of the continuous measures.

84.4 Full $\mathcal{V}^{\mathrm{prim}}$ Koszul–Petersson Identity (Including Eisenstein)

The three compatibilities give the full-sector identity.

Theorem 84.4.1 *(full Koszul–Petersson compatibility via LS normalisation).* Assume the arithmetic placement, local pairing maps and adelic extension of Hypothesis 67.1.1 on the selected discrete domain, including its orthogonal decomposition, as well as the continuous measure transport below. *(conditional on Ramanujan for Maass cusp forms on the Maass cuspidal discrete sector; conditional on the LS Plancherel-measure identification on the Eisenstein continuous sector).* For all $v, w \in \mathcal{V}^{\mathrm{prim}}$,

$$\langle v, w\rangle^{\mathrm{Pet}} \;=\; \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul,LS}}, \tag{84.2}$$

with $\langle\cdot,\cdot\rangle^{\mathrm{Koszul,LS}}$ the Langlands–Shahidi-corrected Koszul pairing of Definition 84.2.1 on the Eisenstein summand and the unmodified Koszul pairing on the discrete core. The identity extends Theorem 76.3.3 from the discrete core to the full $\mathcal{V}^{\mathrm{prim}}$ including the Eisenstein continuum under the stated LS normalisation hypothesis.

Proof. Decompose $\mathcal{V}^{\mathrm{prim}} = \mathcal{V}^{\mathrm{prim}}_{\mathrm{disc}} \oplus \mathcal{V}^{\mathrm{prim}}_{\mathrm{cont}}$ by Langlands orthogonality (Langlands 1966 §6). On the discrete core, Proposition 84.3.5 gives (84.2) with the arithmetic comparison hypotheses and the additional Maass temperedness assumptions inherited from Theorem 76.3.3. On the Eisenstein continuum, Corollary 84.2.4 supplies the conditional spectral density normalisation match, which by the Plancherel formula for the continuous spectrum (Moeglin–Waldspurger §IV.2) yields (84.2) on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cont}}$. Compatibility of the two on their intersection (zero, by orthogonality) is trivial. □

Corollary 84.4.2 *(Eisenstein density mismatch reduced by LS normalisation). (conditional on the LS Plancherel-measure identification).* The Eisenstein density mismatch of Proposition 76.3.1 and Corollary 67.5.5 is reduced under the LS redefinition Definition 84.2.1: the density mismatch on $\mathrm{Re}(s) = 1/2$ between Koszul and Petersson vanishes pointwise once the LS-corrected quadratic form is identified with the positive Plancherel measure. No Ramanujan input is used on the continuum, but the measure identification is an extra hypothesis.

Proof. Corollary 84.2.4 gives the pointwise density match. The domain of the modification is only the Eisenstein summand (Remark 84.3.2); the Tate factorisation (Proposition 84.3.3) and the Heisenberg self-duality (Proposition 84.3.1) confirm the redefinition is compatible with the rest of the arithmetic Koszul structure. □

84.5 Pairing Conventions and Hypotheses

Remark 84.5.1 *(pairing conventions and hypotheses).* Both sides of (84.2) are $\mathbb{C}$-valued sesquilinear pairings on $\mathcal{V}^{\mathrm{prim}} \times \mathcal{V}^{\mathrm{prim}}$. Equivalently, they are complex-linear functionals on $\mathcal{V}^{\mathrm{prim}} \otimes \overline{\mathcal{V}^{\mathrm{prim}}}$. The Koszul construction uses Beilinson–Drinfeld 2004, Positselski 2009, and Bost–Connes 1995. The Petersson construction uses Langlands 1966, Moeglin–Waldspurger 1995, Shahidi 2010, Casselman–Shalika 1980, Jacquet–Piatetski-Shapiro–Shalika 1983, Tate 1950, Weil 1967, and Titchmarsh 1986. These two source lists are disjoint.

The factor $N^{\mathrm{LS}}(s) = \xi(2s-1)/\xi(2s)$ is a unitary scattering normalisation on the critical line, with the conventions of Shahidi 2010, Theorem 3.5.1, and Moeglin–Waldspurger, §IV.3.10. A positive measure requires the Shahidi Plancherel transport in Theorem 84.2.2.

The identity of Theorem 84.4.1 requires the LS Plancherel-measure identification on the Eisenstein continuum and the arithmetic placement and pairing maps on the discrete sector, with Ramanujan additionally required for the Maass domain. These discrete hypotheses are those of Theorem 76.3.3. The Eisenstein summand is orthogonal to the discrete core under both Petersson (Langlands 1966, §6) and Koszul (Proposition 84.3.5). The LS correction is supported on the Eisenstein summand only.

Shahidi's global normalisation, the Casselman–Shalika local formula, and Moeglin–Waldspurger's unitarity on the critical line are classical theorems. They do not by themselves identify the bar–cobar Eisenstein pairing with the positive Plancherel measure.

Remark 84.5.2 *(discrete-core and Eisenstein normalisations).* Chapter 76 (the restricted-class comparison) reduces the Koszul–Petersson identity on the discrete core and excludes the Eisenstein continuum by domain restriction. The Li-criterion path (Corollary 76.3.6) uses this restriction only after the H-P^{Ar} determinant-trace realisation. The bounded-interval reduction gives a conditional extension to the continuum: one must insert the LS scalar N^{LS} and identify the resulting quadratic form with the positive Plancherel measure.

84.6 Sources

The primary sources enter in the following order.

Shahidi, F. *Eisenstein Series and Automorphic L-Functions*, AMS Colloquium Publications 58, 2010. The Langlands–Shahidi method for normalising intertwining operators; Theorem 3.5.1 for the global normalisation we denote $N^{\mathrm{LS}}(s)$.

Moeglin, C. and Waldspurger, J.-L. *Spectral Decomposition and Eisenstein Series: A Paraphrase of the Scriptures*, Cambridge Tracts 113, 1995. §II.1.7 for the intertwining operator $M(s)$; §IV.2 for the Plancherel formula; §IV.3.10 for unitarity of the normalised intertwiner on the critical line.

Langlands, R. P. *On the Functional Equations Satisfied by Eisenstein Series*, Lecture Notes in Math. 544, Springer 1976 (manuscript 1966). Foundational spectral decomposition of $L^2([GL_n])$ into discrete and continuous summands; Maass–Selberg relations; functional equation of Eisenstein series.

Casselman, W. and Shalika, J. *The unramified principal series of p-adic groups. II. The Whittaker function*, Compositio Math. 41 (1980), 207–231. Unramified spherical Whittaker formula used for the local factor $N_p^{\mathrm{LS}}(s) = \zeta_p(2s-1)/\zeta_p(2s)$ at unramified finite p.

Jacquet, H., Piatetski-Shapiro, I., and Shalika, J. *Rankin–Selberg convolutions*, Amer. J. Math. 105 (1983), 367–464. Local ε-factors at ramified principal series.

Tate, J. *Fourier analysis in number fields and Hecke's zeta functions*, Ph.D. thesis, Princeton 1950; reprinted Cassels–Fröhlich 1967 Ch. XV. Adelic restricted tensor product; local-global factorisation of completed zeta.

Weil, A. *Basic Number Theory*, Springer 1967. Tamagawa normalisation.

Bost, J.-B. and Connes, A. *Hecke algebras, type III factors and phase transitions with spontaneous symmetry breaking in number theory*, Selecta Math. 1 (1995), 411–457. The Bost–Connes C^*-algebra; KMS_1 state; involution σ^{BC}.

Beilinson, A. and Drinfeld, V. *Chiral Algebras*, AMS Colloquium 51, 2004. Chiral bar–cobar construction and parabolic-induction compatibility (§3.5).

Positselski, L. *Two kinds of derived categories, Koszul duality, and comodule-contramodule correspondence*, arXiv:0905.2621, 2009. Koszul duality input for the arithmetic bar–cobar.

Disjoint sources. The proof sources for the arithmetic Koszul pairing (Beilinson–Drinfeld 2004, Positselski 2009, Bost–Connes 1995) are disjoint from the analytic sources for the Langlands–Shahidi normalisation and Plancherel measure (Shahidi 2010, Moeglin–Waldspurger 1995, Langlands 1966, Casselman–Shalika 1980, Jacquet–Piatetski-Shapiro–Shalika 1983, Tate 1950, Weil 1967, Titchmarsh 1986). No source appears on both sides of the identification.

Chapter 85

L_{ACD} on the Eisenstein / Continuous Spectrum

The Eisenstein comparison begins with a local operator whose domain, normalization and degeneration can be computed. For unramified nonarchimedean principal series, the normalized intertwiner acts on every smooth vector, and on the unitary axis it extends to a unitary Hilbert operator. Algebraic coefficient categories then supply coherent Weyl descent and a common symmetric parameter across finite places. Tensor sectors retain mixed terms; a nonorthogonal decomposition must also retain its connecting spectra. These constructions do not supply the analytic automorphic enhancement or its comparison functor. The cuspidal comparison of Theorem 70.6.4 remains conditional, and the full Eisenstein destination is Conjecture 70.6.6.

85.1 Local Operators and Global Comparison Data

Inherited Objects

Prior statements deployed here:

- cuspidal sph-finite adelic categorical descent (Theorem 70.6.4), the cuspidal LACD comparison core theorem;

- F2.c tightened restricted tensor product (Theorem 50.1.3) supplying the pointed E_2-monoidal base;
- Langlands–Shahidi correction factor definition (Definition 76.4.1) on principal-series inductions;
- discrete-core Koszul–Petersson identity (Theorem 76.3.3), conditional on the arithmetic placement, local pairing maps and adelic extension of Hypothesis 67.1.1. This discrete identity makes no assertion about the continuous pairing.

Relation to the Langlands–Shahidi normalisation

The Koszul–Petersson comparison of Proposition 76.4.2 requires a specified transform and measure identification. The local operator below is separate data: its normalization fixes the spherical vector. The comparison of a global scalar factor, spectral measure and transported pairing remains an additional construction, described in Proposition 85.8.5. No categorical lift follows merely from the equality of scalar normalizations.

Wallach 1988/1992 *Real Reductive Groups I–II*. Volume II (1992), Chapter 13, especially Section 13.4, treats Plancherel. Chapter 11 treats completions.

Bernstein–Zelevinsky (1977), *Induced representations of reductive p-adic groups I*, Ann. Sci. ENS 10, supplies the normalized induction convention and Theorem 4.2 irreducibility criterion used below. Lurie's presentable tensor and monadic results supply the categorical inputs with the precise locators given in the proofs. The extension-gluing statements below are proved directly.

Representation and categorical inputs

Flath's restricted tensor theorem concerns actual cuspidal representations. Langlands and Mœglin–Waldspurger concern global Eisenstein families and spectral decomposition. Shahidi concerns local factors and Plancherel normalization; Harish-Chandra and Wallach supply real-group harmonic analysis. Passing from those representation objects to an enhanced automorphic category requires a construction of the category, its functors, derived morphisms and generators. The algebraic parameter and gluing constructions below identify some of these inputs on their explicitly stated local carriers.

85.2 Module (E0): Langlands–Shahidi Intertwining Normalisation

Local Intertwining Data for GL_2

Setup 85.2.1 *(local induction convention).* For a finite place v, let q_v be the residue cardinality and ϖ a uniformizer. Write $q = q_v$. For unramified characters χ_1, χ_2, put

$$I_v(s, \chi) = \mathrm{Ind}_{B(\mathbb{Q}_v)}^{GL_2(\mathbb{Q}_v)}(\chi_1|\cdot|^{s/2} \otimes \chi_2|\cdot|^{-s/2}),$$

with normalized smooth induction. To apply the compact-picture construction below, use the effective inducing characters $\alpha_1 = \chi_1|\cdot|^{s/2}$ and $\alpha_2 = \chi_2|\cdot|^{-s/2}$ in place of its character arguments. Their ratio is $z = \alpha_1(\varpi)/\alpha_2(\varpi) = \chi_1(\varpi)\chi_2(\varpi)^{-1}q^{-s}$. Ramified characters and the archimedean place remain separate operator constructions with their own Haar, epsilon-factor and analytic-domain data.

85.3 Normalized intertwining for unramified principal series

An Eisenstein comparison must distinguish the normalization of an intertwining operator from its passage to a category of representations. For unramified principal series over a nonarchimedean field, the

operator can be computed on every locally constant vector. The computation also determines its poles and its degenerations.

Let F be a finite extension of $\mathbb{Q}_p$. Write O for its ring of integers, ϖ for a uniformizer, and $q = |O/\varpi O|$. Normalize $|\varpi| = q^{-1}$ and the additive Haar measure by $\mathrm{vol}(O) = 1$. Fix an additive character $\psi : F \to \mathbb{C}^\times$ that is trivial on O and nontrivial on $\varpi^{-1}O$. The operator below does not depend on ψ. This choice fixes the additive convention for subsequent local-factor comparisons. All representations and function spaces have coefficients in $\mathbb{C}$.

Put $G = \mathrm{GL}_2(F)$, $K = \mathrm{GL}_2(O)$, and let B be the upper triangular subgroup. For unramified smooth characters $\chi_1, \chi_2 : F^\times \to \mathbb{C}^\times$, let $I(\chi_1, \chi_2)$ consist of locally constant functions $f : G \to \mathbb{C}$ satisfying

$$f\left(\begin{pmatrix} a & b \\ 0 & d \end{pmatrix} g\right) = |a/d|^{1/2} \chi_1(a)\chi_2(d) f(g).$$

The action is right translation, $(\pi(g)f)(h) = f(hg)$. Thus $I(\chi_1, \chi_2)$ is normalized smooth induction. Set

$$z = \frac{\chi_1(\varpi)}{\chi_2(\varpi)}, \qquad w = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad n(x) = \begin{pmatrix} 1 & x \\ 0 & 1 \end{pmatrix}.$$

For $|z| < 1$, define

$$(M_z f)(g) = \int_F f(wn(x)g)\, dx. \tag{85.1}$$

The target is $I(\chi_2, \chi_1)$. The subscript z specifies the ratio parameter. The source and target characters remain part of the operator's data.

The compact picture and ball averages

Restriction to K identifies every $I(\chi_1, \chi_2)$ with

$$V = C^\infty(X; \mathbb{C}), \qquad X = (B \cap K)\backslash K = \mathbb{P}^1(F).$$

Here C^∞ means locally constant. The identification of X sends a matrix to its bottom row, up to scalar. It follows from $G = BK$ and the triviality of unramified characters on $O^\times$. A primitive row has at least one unit coordinate. For primitive representatives $u, v \in O^2$, define

$$\rho([u], [v]) = |\det(u, v)|.$$

This function is independent of the primitive representatives and is invariant under the right action of K. Let ν be the K-invariant probability measure on X.

For $n \geq 1$, reduction modulo ϖ^n gives a finite set

$$X_n = \mathbb{P}^1(O/\varpi^n O), \qquad |X_n| = (q+1)q^{n-1}.$$

Let $V_n \subset V$ be the functions that factor through X_n. Put $V_0 = \mathbb{C}\mathbf{1}$ and $H = L^2(X, \nu)$, with inner product linear in the first variable. The orthogonal projection $E_n : H \to V_n$ averages over each reduction fiber. The projection E_0 is global averaging. The fibers are the balls $\rho(x, y) \leq q^{-n}$, each of measure

$$b_n = \frac{1}{(q+1)q^{n-1}}.$$

Every locally constant function factors through some X_n. Consequently $V = \bigcup_{n\geq 0} V_n$ is dense in H. Define mutually orthogonal finite-dimensional spaces

$$H_0 = V_0, \qquad H_n = V_n \cap V_{n-1}^{\perp} \quad (n \geq 1).$$

Then

$$V = \bigoplus_{n\geq 0}^{\mathrm{alg}} H_n, \qquad H = \widehat{\bigoplus}_{n\geq 0} H_n.$$

In particular, $\dim H_1 = q$ and $\dim H_n = (q+1)(q-1)q^{n-2}$ for $n \geq 2$.

LEMMA 85.3.1 *(Integral kernel and meromorphic continuation).* For $|z| < 1$, the integral in (85.1) converges absolutely. It defines a smooth G-intertwiner. In the compact picture it is

$$M_z = (1+q^{-1})E_0 + (z-q^{-1})\sum_{n\geq 1} z^{n-1}E_n. \tag{85.2}$$

The series converges in operator norm on H. On the orthogonal summands it acts by

$$M_z|_{H_0} = c(z), \qquad c(z) = \frac{1-q^{-1}z}{1-z}, \qquad M_z|_{H_n} = \frac{(z-q^{-1})z^{n-1}}{1-z} \quad (n \geq 1).$$

These formulas give a meromorphic continuation on every V_N. On every nonzero V_N, its only pole in $z \in \mathbb{C}^\times$ is the simple pole at $z = 1$. Here meromorphic continuation means continuation on each finite level, not a family of bounded operators on H for all parameters.

Proof. Let $x_0 = [(0,1)]$. For $|x| \leq 1$, the matrix $wn(x)$ belongs to K. For $|x| > 1$, the factorization

$$wn(x) = \begin{pmatrix} -x^{-1} & 1 \\ 0 & x \end{pmatrix}\begin{pmatrix} 1 & 0 \\ x^{-1} & 1 \end{pmatrix}$$

shows that the inducing factor on $|x| = q^n$ is $q^{-n}z^n$. The shell has additive measure $(1-q^{-1})q^n$. Since compact-picture functions are bounded, the tail is dominated by $a\sum_{n\geq 1}|z|^n$ for a finite constant a. The same argument applies to each right translate of f.

The integral commutes with right translations. Changing x to $x+y$ proves invariance under left multiplication by $n(y)$. For $a, d \in F^\times$, use

$$wn(x)\begin{pmatrix} a & 0 \\ 0 & d \end{pmatrix} = \begin{pmatrix} d & 0 \\ 0 & a \end{pmatrix} wn(xd/a).$$

The substitution $u = xd/a$ contributes $|a/d|$. The resulting factor is $|a/d|^{1/2}\chi_2(a)\chi_1(d)$, which is the target induction law. Right local constancy is preserved by the integral. Thus M_z is the stated smooth intertwiner.

The chart $[(1,x)]$, $x \in \mathcal{O}$, has measure $q(q+1)^{-1}dx$. The chart $[(y,1)]$, $y \in \varpi\mathcal{O}$, has the same density. For example, reduction modulo ϖ^N divides either chart into sets of additive measure q^{-N} and ν-measure $((q+1)q^{N-1})^{-1}$. This proves the density assertion on locally constant functions.

In the second chart, the substitution $y = x^{-1}$ has Jacobian $dx = |y|^{-2}dy$. On $|y| = q^{-n}$, the resulting density in the raw integral is $q^n z^n\, dy$. Thus its kernel, relative to ν, has value $1+q^{-1}$ when $\rho(x_0, y) = 1$, and value $(1+q^{-1})q^n z^n$ when $\rho(x_0, y) = q^{-n}$. The diagonal has measure zero. Right K-equivariance gives the same radial kernel about every point.

For $\rho(x, y) = q^{-m}$, telescope the kernel as

$$(1 + q^{-1})\left[1 + \sum_{n=1}^{m}\left(q^n z^n - q^{n-1} z^{n-1}\right)\right].$$

Integration of the nth ball indicator is $b_n E_n$. Since $(1 + q^{-1})b_n = q^{-n}$, its coefficient is $(z - q^{-1})z^{n-1}$. Absolute convergence justifies the sum and proves (85.2). The projection norms are one, so the series also converges in operator norm.

On H_0, every E_n acts as the identity. On H_m, $m \geq 1$, the projection E_n is zero for $n < m$ and is the identity for $n \geq m$. Summing the geometric series gives the displayed eigenvalues. Each V_N is a finite sum of these spaces. The rational formulas therefore give its meromorphic continuation. At $z = 1$, every numerator has nonzero value $1 - q^{-1}$. The pole is simple on every nonzero summand. □

Normalization, composition, and domains

The spherical vector is $\mathbf{1} \in H_0$. The scalar in the preceding lemma equals the unramified local ratio

$$c(z) = \frac{L(0, \chi_1\chi_2^{-1})}{L(1, \chi_1\chi_2^{-1})}, \qquad L(u, \chi_1\chi_2^{-1}) = (1 - zq^{-u})^{-1}.$$

Normalizing the spherical vector therefore requires division by $c(z)$. Define the meromorphic family

$$R_z = c(z)^{-1} M_z.$$

Theorem 85.3.2 *(The normalized unramified intertwiner).* The compact-picture eigenvalues of R_z are

$$r_0(z) = 1, \qquad r_n(z) = z^{n-1}\frac{z - q^{-1}}{1 - q^{-1}z} \quad (n \geq 1). \tag{85.3}$$

The operator is holomorphic on each V_N away from $z = q$. It has a simple pole on every H_n with $n \geq 1$ at $z = q$. The value at $z = 1$ is id_V. The value at $z = q^{-1}$ is E_0. For $z \notin \{q, q^{-1}\}$, the smooth maps satisfy

$$R_{z^{-1}} R_z = \mathrm{id}_V, \qquad R_z R_{z^{-1}} = \mathrm{id}_V .$$

Here the second operator uses the swapped inducing characters.

If χ_1 and χ_2 are unitary, R_z extends uniquely to a unitary intertwiner between their induced Hilbert representations on H. Its Hilbert domain is all of H. In particular, the equal-character point $z = 1$ is regular.

Proof. Division of the preceding eigenvalues by $c(z)$ gives (85.3). This calculation cancels the apparent singularity at $z = 1$. At $z = q$, the denominator has a simple zero and the numerator is nonzero on every H_n, $n \geq 1$. Substitution gives the stated values at 1 and q^{-1}.

For $n \geq 1$, direct cancellation gives

$$r_n(z) r_n(z^{-1}) = \frac{(z - q^{-1})(1 - q^{-1}z)}{(1 - q^{-1}z)(z - q^{-1})} = 1.$$

The identity also holds on H_0. Every smooth vector has finitely many components, so both compositions are defined on all of V at the stated parameters. Intertwining holds first on the convergence domain of the raw integral. On each smooth vector and each fixed group element, the compact-picture formulas

are rational in the two nonzero unramified character values. For a fixed $g \in G$, right translation sends V_N into some V_M independently of the unramified character values. Indeed, an open subgroup of $K \cap gK_N g^{-1}$ fixes the translated vectors, where $K_N = 1 + \varpi^N M_2(O)$ for $N \geq 1$. On the resulting finite partition of K, the Iwasawa factors have fixed diagonal valuations. Their character values are Laurent monomials. The integral intertwining identity therefore continues meromorphically. This also proves intertwining at every regular specialization.

If the inducing characters are unitary, $|z| = 1$. Then $|z - q^{-1}| = |1 - q^{-1}z|$, so $|r_n(z)| = 1$ for every n. The orthogonal decomposition of H gives a unique unitary extension. Its inverse has parameter z^{-1}.

For completeness, the induced action preserves the stated Hilbert norm. In the open Bruhat chart put $F_f(x) = f(wn(x))$. For unitary inducing characters, the chart measures above give

$$\|f|_K\|_H^2 = \frac{q}{q+1} \int_F |F_f(x)|^2 \, dx.$$

Right translation by $n(y)$ gives $F_f(x + y)$. Right translation by $\mathrm{diag}(a, d)$ gives

$$|d/a|^{1/2} \chi_1(d) \chi_2(a) F_f(xd/a).$$

Right translation by w, away from $x = 0$, gives

$$|x|^{-1} \chi_1(-x^{-1}) \chi_2(x) F_f(x^{-1}).$$

Translations, dilations, and inversion preserve the displayed norm with these factors and their respective Jacobians. These elements generate G. Each smooth vector has an open stabilizer. Density and unitarity therefore imply strong continuity of the extended action. The smooth equivariance of R_z extends by density to these induced unitary representations. □

For nonunitary parameters, the same compact-picture formulas also specify an operator on a fixed Hilbert space. This assertion does not equip the induced representation with an invariant positive inner product.

PROPOSITION 85.3.3 *(Closed compact-picture realization).* For $z \neq q$, write $h = \sum_{n \geq 0} h_n$ with $h_n \in H_n$. The closure of $R_z|_V$ on H is the normal operator with domain

$$\mathrm{Dom}(\overline{R}_z) = \left\{ h \in H : \sum_{n \geq 0} |r_n(z)|^2 \|h_n\|^2 < \infty \right\}, \qquad \overline{R}_z h = \sum_{n \geq 0} r_n(z) h_n.$$

The space V is a core. This operator is bounded exactly when $|z| \leq 1$. The composition assertions of the preceding theorem hold on V. On the unit circle they hold on all of H.

Proof. The orthogonal sum of scalar operators with the displayed maximal domain is closed and normal. Its adjoint has coefficients $\overline{r_n(z)}$ and the same domain. Truncating the expansion after $n = N$ converges in its graph norm. Thus this maximal operator is the closure of its restriction to V. Boundedness is equivalent to $\sup_n |r_n(z)| < \infty$. Formula (85.3) proves boundedness for $|z| \leq 1$. For $|z| > 1$ and $z \neq q$, the nonzero factor $(z - q^{-1})/(1 - q^{-1}z)$ is fixed and $|z|^{n-1}$ is unbounded. □

Reducibility and the unitary axis

The poles of a normalization and the reducibility of the induced representation are different loci. They can both be determined in the present unramified family.

Proposition 85.3.4 *(Reducibility locus).* The smooth representation $I(\chi_1, \chi_2)$ is reducible exactly when

$$\chi_1\chi_2^{-1} = |\cdot| \quad \text{or} \quad \chi_1\chi_2^{-1} = |\cdot|^{-1}.$$

Equivalently, $z \in \{q^{-1}, q\}$. For $z = q^{-1}$, the regular intertwiner R_z has image H_0 in $I(\chi_2, \chi_1)$ and kernel in $I(\chi_1, \chi_2)$ equal to $\bigoplus_{n\geq 1}^{\mathrm{alg}} H_n$. For $z = q$, the swapped regular intertwiner $R_{z^{-1}}$ has image H_0 in $I(\chi_1, \chi_2)$. The stated kernel at $z = q^{-1}$ and image at $z = q$ are nonzero proper invariant subspaces of $I(\chi_1, \chi_2)$.

Proof. The kernel and image assertions follow from (85.3) and the regular intertwining identity. They prove reducibility at the two displayed ratios. Away from these ratios, apply Bernstein–Zelevinsky's irreducibility criterion to the two characters of $\mathrm{GL}_1(F)$: *Induced representations of reductive p-adic groups I*, Theorem 4.2, p. 454, with the induction conventions of §1.8(a), p. 444, and §§2.2–2.3, p. 446. For the upper triangular parabolic, their modulus on the unipotent radical is $|a/d|$, so their square-root factor is the one used here. Every character of $\mathrm{GL}_1(F)$ is irreducible and cuspidal. The criterion excludes exactly the relations $\chi_j = |\cdot|\chi_i$ for distinct i, j. Thus it proves irreducibility on the stated complement. Only this direction of their criterion is used. □

For the symmetric family $\chi_1 = |\cdot|^{s/2}$, $\chi_2 = |\cdot|^{-s/2}$, one has $z = q^{-s}$. The raw integral converges for $\Re(s) > 0$. Its poles occur at

$$s \in \frac{2\pi i}{\log q}\mathbb{Z}.$$

On every smooth finite level, the normalized operator is regular on $\Re(s) \geq 0$. Its poles occur at

$$s \in -1 + \frac{2\pi i}{\log q}\mathbb{Z},$$

and reducibility occurs at

$$s \in \left(1 + \frac{2\pi i}{\log q}\mathbb{Z}\right) \cup \left(-1 + \frac{2\pi i}{\log q}\mathbb{Z}\right).$$

Neither reducibility locus meets the unitary axis $\Re(s) = 0$. These statements concern local unramified induction. Poles of a global Eisenstein series require a separate global construction.

Example 85.3.5 *(The first nonconstant vectors).* Let $q = 2$ and $z = -1$. The three reduction fibers of $X \to \mathbb{P}^1(\mathbb{F}_2)$ have equal measure. On V_1, the raw integral and normalized operator are

$$M_{-1} = \frac{1}{4}\begin{pmatrix} -1 & 2 & 2 \\ 2 & -1 & 2 \\ 2 & 2 & -1 \end{pmatrix}, \qquad R_{-1} = \frac{1}{3}\begin{pmatrix} -1 & 2 & 2 \\ 2 & -1 & 2 \\ 2 & 2 & -1 \end{pmatrix}.$$

The spherical scalar is $c(-1) = 3/4$. The normalized matrix fixes constants and negates their orthogonal complement. Its square is the identity. At $z = 1/2$, the normalized matrix is the rank-one averaging projection. At $z = 1$, its continued value is the identity matrix.

The automorphic comparison

A categorical Eisenstein comparison requires categories and functors in addition to these operators. One must specify the coefficient field, the local parameter spaces, and the global automorphic quotient with its central character and level. The global category must carry its Hecke actions and its Eisenstein subcategory. A comparison functor must identify the relevant derived mapping objects and determine its essential image. The shared global induction parameter must also be imposed on local families.

The construction above supplies the full smooth intertwiner and its Hilbert extension only for unramified nonarchimedean induction. Ramified characters and the archimedean place require their own operators, normalizations, and analytic domains. A global restricted product requires compatible distinguished vectors and an explicit global family. The categorical comparison further requires functors implementing these maps and their Weyl coherences. No equivalence of automorphic categories follows from the compact-picture Hilbert isomorphism alone.

The place-indexed operator notation

Definition 85.3.6 *(the raw place-indexed operator).* For the base characters $\chi = (\chi_1, \chi_2)$ of Setup 85.2.1, put $\alpha_1 = \chi_1|\cdot|^{s/2}$, $\alpha_2 = \chi_2|\cdot|^{-s/2}$ and $z = \alpha_1(\varpi)/\alpha_2(\varpi)$. With $\chi^w = (\chi_2, \chi_1)$, the notation is

$$M_v(s,\chi) = M_z : I_v(s,\chi) = I(\alpha_1,\alpha_2) \longrightarrow I(\alpha_2,\alpha_1) = I_v(-s,\chi^w).$$

The integral is defined for $|z| < 1$ and continued on each smooth finite level by Lemma 85.3.1.

Definition 85.3.7 *(the normalized place-indexed operator).* On the same source and target, define

$$N_v(s,\chi) = R_z = c(z)^{-1}M_z, \qquad c(z) = \frac{1-q^{-1}z}{1-z}.$$

Cancellation and continuation at $z = 1$ are part of Theorem 85.3.2; the expression is not a pointwise product of undefined values there. Its poles, domains and unitary specializations are those proved in that theorem.

85.4 Algebraic parameters for unramified induction

The normalized unramified intertwiner varies with the inducing characters. A category of coefficient complexes records this variation and its Weyl symmetry. Its relation to smooth induction is a functor defined by tensoring with universal smooth induction. The resulting category concerns local algebraic parameters. An automorphic comparison requires further constructions.

Retain the nonarchimedean field F, residue cardinality q, group $G = \mathrm{GL}_2(F)$, and compact subgroup K of the unramified calculation. In particular, $|\varpi| = q^{-1}$ and $\mathrm{vol}(O) = 1$. Let a, b denote the values at ϖ of the two unramified characters. Their ratio is $z = a/b$. To make both normalized intertwining directions regular and invertible, put

$$A = \mathbb{C}[a^{\pm1}, b^{\pm1}, (a-qb)^{-1}, (b-qa)^{-1}], \qquad T = \operatorname{Spec} A.$$

Thus T omits precisely the two divisors $z = q, q^{-1}$. The Weyl group $W = \{1, w\}$ acts through the ring involution $\sigma(a) = b$, $\sigma(b) = a$. The involution exchanges the two inverted divisors. At a complex point (a_0, b_0), define $\chi_{a_0}(x) = a_0^{v_F(x)}$, where $v_F(\varpi) = 1$. The corresponding representation is the normalized induction $I(\chi_{a_0}, \chi_{b_0})$.

The ratio alone determines the normalized operator in the compact picture. It does not determine the representation. Replacing (a_0, b_0) by (ta_0, tb_0) twists the representation by $\chi_t \circ \det$. For example, the central element $\mathfrak{C}$ id acts by $a_0 b_0$ before the twist and by $t^2 a_0 b_0$ afterwards. Both characters must therefore remain in the parameter space.

Coefficient complexes and their unit

For a ring D, write $\mathcal{D}(D)$ for the stable ∞-category of unbounded cochain complexes of left D-modules, with quasi-isomorphisms inverted. The differential has degree 1. We use $P[1]^n = P^{n+1}$ with differential $-d_P$. For commutative D, tensor products are derived over D. Their symmetry has sign $(-1)^{ij}$ on degrees i, j. Let $\mathrm{Perf}(D)$ be a small skeleton of the full subcategory generated by $D[0]$ under finite sums, shifts, cones, and retracts.

Proposition 85.4.1 *(The coefficient category).* The category $\mathrm{Perf}(A)$ is stable, idempotent complete, and symmetric monoidal under $\otimes^{\mathbf{L}}_A$. There is a canonical equivalence

$$\mathrm{Ind}(\mathrm{Perf}(A)) \simeq \mathcal{D}(A).$$

The compact objects of $\mathcal{D}(A)$ are exactly $\mathrm{Perf}(A)$. The monoidal unit is $A[0]$. The functor

$$e : \mathcal{D}(\mathbb{C}) \longrightarrow \mathcal{D}(A), \qquad U \longmapsto A \otimes_{\mathbb{C}} U$$

is a colimit-preserving symmetric monoidal pointing and preserves compact objects.

Proof. The category of derived modules is stable and presentable. For a commutative ring its symmetric monoidal identification with modules over the associated discrete ring spectrum is established in Lurie, *Higher Algebra* (2017), Theorem 7.1.2.13, pp. 1212–1213. Its shifts of A detect zero objects, since $\mathrm{Hom}_{\mathcal{D}(A)}(A[-n], P) = H^n(P)$. These shifts are compact because cohomology commutes with filtered colimits of modules. The compact-generation theorem for module categories identifies their finite stable retract closure with all compact objects and gives the Ind equivalence (Lurie, *Higher Algebra* (2017), Definition 7.2.4.1 and Proposition 7.2.4.2, pp. 1260–1261). For ordinary rings these are bounded complexes of finitely generated projective modules (The Stacks Project, Tag 07LQ, Lemma 15.80.1 and Proposition 15.80.3). Tensoring two such complexes gives another such complex. The associativity, unit, and symmetry are those of derived tensor product. Extension of scalars preserves colimits and takes a finite complex of finite-dimensional vector spaces to a finite free complex. Its tensor and unit identities prove the assertion about e. □

A point of T gives the specialization functor $\mathbb{C} \otimes^{\mathbf{L}}_{A,(a_0,b_0)} (-)$. The point module $A/(a - a_0, b - b_0)$ is also perfect. Its length-two Koszul resolution follows because $a - a_0$, $b - b_0$ form a regular sequence. Indeed, the quotient by the first element is a localization of $\mathbb{C}[b^{\pm 1}]$, and the second element is nonzero there. The inverted elements remain nonzero at the chosen point. This point module differs from the monoidal unit A. For two distinct points, its tensor product with the other point module is zero, as follows by localizing at their disjoint supports. The unit cannot have this property.

The universal smooth representation

Let $X = (B \cap K)\backslash K$ and $V = C^\infty(X; \mathbb{C})$, where B is the upper triangular subgroup and functions are locally constant. The compact-picture calculation gives $V = \bigoplus_{n \geq 0} H_n$ and $V_N = \bigoplus_{n=0}^{N} H_n$, with $H_0 = \mathbb{C}\mathbf{1}$ and finite-dimensional H_n. Put $E = A \otimes_{\mathbb{C}} V$ and $E_N = A \otimes V_N$. All these modules are in cochain degree zero.

PROPOSITION 85.4.2 *(Induction over the parameter ring).* There is an A-linear smooth action π_A of G on E. Its specialization at $(a_\circ, b_\circ)$ is $I(\chi_{a_\circ}, \chi_{b_\circ})$. The normalized intertwiner defines an A-linear isomorphism

$$R : E \longrightarrow E^{\mathrm{sw}}, \qquad R|_{A\otimes H_\circ} = 1, \qquad R|_{A\otimes H_n} = z^{n-1}\frac{z - q^{-1}}{1 - q^{-1}z} \quad (n \geq 1),$$

where E^{sw} has the inducing parameters b, a. Its inverse has the displayed coefficients with z replaced by z^{-1}. The coefficient module E is free and is not compact in $\mathcal{D}(A)$. Every E_N is compact and K-stable.

Proof. Use the universal unramified characters $\chi_a(x) = a^{v_F(x)}$ and $\chi_b(x) = b^{v_F(x)}$ in the induction law. The factor $|x/y|^{1/2}$ is a fixed positive real scalar. For $g \in G$, extend a function from K to $BK = G$ by this law, then translate it on the right by g. Independence of the Iwasawa factorization follows because the characters and modulus are trivial on $B \cap K$. For each fixed g, N, compactness and local constancy give a finite partition on which all diagonal valuations are constant. The resulting coefficients are Laurent monomials in a, b. Thus $\pi_A(g)E_N \subset E_M$ for some finite M. Right translation satisfies the group law before restriction to K, and consequently defines an action on E. Each vector has an open stabilizer in K. Specializing the induction law proves the fiber assertion.

The stated coefficients belong to A and are units in A. The normalized intertwiner calculation proves the intertwining identity and $r_n(z^{-1})r_n(z) = 1$. These identities apply over A: for fixed g, N they are finite matrix identities in rational functions of a, b. They hold at every regular complex specialization, hence hold in A. This proves the asserted isomorphism and inverse.

Each E_N is finite free. The decomposition of V makes E free of infinite rank. If E were compact, its identity would factor through some term of $E = \operatorname{colim}_N E_N$. That would express an infinite-rank free module as a retract of a finite-rank module, which is impossible after tensoring with the fraction field of A. The compact-picture K-action preserves each V_N. The full G-action need not preserve these finite levels. □

Let $\mathcal{D}_{\mathrm{sm}}(G, A)$ denote the derived ∞-category of smooth A-linear G-representations. Here smooth means that every vector has an open stabilizer, and G acts trivially on A. Tensoring with the flat module E gives an actual functor

$$\mathcal{F} : \mathcal{D}(A) \longrightarrow \mathcal{D}_{\mathrm{sm}}(G, A), \qquad P \longmapsto E \otimes_A P.$$

It is well-defined on quasi-isomorphisms since E is free over A. Its specialization is $I(\chi_{a_\circ}, \chi_{b_\circ}) \otimes_{\mathbb{C}} (\mathbb{C} \otimes^{\mathbf{L}}_A P)$. The spherical map $A \to E, c \mapsto c\mathbf{1}$, is K-equivariant. It is generally not G-equivariant when A has trivial G-action. For example, the central element ϖ id acts on E by ab. Thus neither the spherical vector nor the representation E replaces the coefficient category's monoidal unit.

Weyl descent

The involution σ acts on coefficient complexes by restriction of scalars. On the underlying complex the new scalar action is $c \cdot m = \sigma(c)m$. Applying this operation twice is the identity. It preserves derived tensor products and the unit, with their usual canonical identifications. This is a specified coherent action of W on $\mathcal{D}(A)$. Its descent category is the homotopy limit $\mathcal{D}(A)^{hW}$.

PROPOSITION 85.4.3 *(An explicit descent category).* Let $D = A \rtimes W = A \oplus Au$, with multiplication given by $u^2 = 1$ and $uc = \sigma(c)u$ for $c \in A$. There is an equivalence

$$\mathcal{D}(A)^{hW} \simeq \mathcal{D}(D).$$

This category is stable and presentable. An object is compact if and only if its underlying A-complex is perfect. Its symmetric monoidal product is derived tensor over A, with diagonal Weyl action. Its compact monoidal unit is A with $u(c) = \sigma(c)$.

Proof. A strict D-module is an A-module with a semilinear involution θ: $\theta(cm) = \sigma(c)\theta(m)$ and $\theta^2 = 1$. The same description applies to complexes with a chain involution. To identify the derived category with coherent descent, consider the evaluation functor from the homotopy limit to $\mathcal{D}(A)$. It is conservative and has the free-equivariant left adjoint $P \mapsto P \oplus \sigma^* P$ with its permutation action. Colimits are computed on underlying complexes since σ^* preserves them. In particular, evaluation preserves geometric realizations of split simplicial objects. The monadicity theorem therefore applies (Lurie, *Higher Algebra* (2017), Theorem 4.7.3.5, p. 685). Its monad is $P \mapsto P \oplus \sigma^* P$, with multiplication from W. This is also the monad of restriction from D-modules to A-modules, whose left adjoint is $D \otimes^{\mathbf{L}}_A (-)$. Restriction is conservative and preserves geometric realizations. The two monadic descriptions prove the equivalence, including all higher coherences.

As a left or right A-module, D is free of rank two. Thus every perfect D-complex becomes perfect over A. Conversely, a D-complex M is a retract of $D \otimes_A M$. The action map is a retraction of the D-linear chain map

$$m \longmapsto \tfrac{1}{2}(1 \otimes m + u \otimes \theta(m)).$$

The relations $uc = \sigma(c)u$ and $\theta^2 = 1$ verify linearity directly. If the underlying A-complex is perfect, extension of scalars makes $D \otimes^{\mathbf{L}}_A M$ perfect over D. The retract is therefore perfect. The compact-object characterization in the coefficient proposition applies to D as well. The diagonal involution on $M \otimes^{\mathbf{L}}_A N$ is $\theta_M \otimes \theta_N$. Semilinearity makes it well-defined, and the usual tensor constraints are equivariant. The module A with involution σ is the unit and is perfect over A. This proves its compactness after descent. □

The involution is not free on T. Every point (a_0, a_0) is fixed and belongs to T. The modules A with involutions σ and $-\sigma$ specialize there to the trivial and sign representations of W. These are not isomorphic: an intertwining scalar would satisfy $c = -c$. Consequently descent retains stabilizer representations. It cannot be replaced by the category of modules on the coarse orbit space through ordinary pullback, which has trivial stabilizer action on every fiber.

The representation E has its own compatible descent datum. Let $S : E \to E$ apply σ to coefficients and fix V. Define $\Theta = SR$, using the common compact-picture module. Then

$$\Theta(cf) = \sigma(c)\Theta(f), \qquad \Theta^2 = 1, \qquad \Theta\pi_A(g) = \pi_A(g)\Theta.$$

Indeed, $S\pi_A(g) = \pi_A^{\mathrm{sw}}(g)S$ and $R\pi_A(g) = \pi_A^{\mathrm{sw}}(g)R$. Conjugating R by S replaces z by z^{-1}, so its inverse is obtained. These identities prove all three assertions. Moreover, $\Theta(c\mathbf{1}) = \sigma(c)\mathbf{1}$. For an equivariant coefficient complex (P, θ), the formula $(E \otimes_A P, \Theta \otimes \theta)$ therefore defines equivariant smooth induction. This is a construction of a functor, without an assertion of full faithfulness or essential surjectivity.

A common complex parameter

For the symmetric inducing characters $|\cdot|^{s/2}$, $|\cdot|^{-s/2}$, the two parameters are $a = q^{-s/2}$ and $b = q^{s/2}$. Here $q^s = \exp(s \log q)$, with the real logarithm of q. The ratio $z = q^{-s}$ has period $2\pi i/\log q$. The ordered pair (a, b) has period $4\pi i/\log q$. A shift by the smaller period changes both character values by -1. This explains why the ratio does not encode the whole family.

Let $\Omega = \{s \in \mathbb{C} : |\operatorname{Re} s| < 1\}$ and $B_\Omega = \mathcal{O}(\Omega)$, treated as an ordinary commutative ring. There is a ring map

$$\phi_q : A \longrightarrow B_\Omega, \qquad a \longmapsto e^{-s \log q/2}, \qquad b \longmapsto e^{s \log q/2}.$$

The inverted factors have no zeros in Ω because $|q^{-s}| = q^{-\operatorname{Re} s}$ lies strictly between q^{-1} and q. Their reciprocals are holomorphic, which proves that the map is defined. The involution $\tau(h)(s) = h(-s)$ satisfies $\phi_q \sigma = \tau \phi_q$. Derived extension of scalars gives a compact-preserving functor

$$B_\Omega \otimes^{\mathbf{L}}_A (-) : \mathcal{D}(A) \longrightarrow \mathcal{D}(B_\Omega)$$

and an equivariant version on descent categories. The latter sends (P, θ) to the complex with involution $h \otimes p \mapsto \tau(h) \otimes \theta(p)$. All finite-level matrices of E and R pull back to holomorphic matrices. Evaluating at s gives exactly the smooth representation and normalized operator at $z = q^{-s}$. On $s \in i\mathbb{R}$, the previously constructed Hilbert extension is unitary. No topology on B_Ω or Hilbert completion is part of this scalar-extension functor.

For a finite set of finite places S, allow independent local character parameters and put $A_S = \bigotimes_{v \in S, \mathbb{C}} A_v$. The common symmetric family gives a single map

$$\phi_S : A_S \longrightarrow B_\Omega, \qquad \bigotimes_v f_v \longmapsto \prod_v \phi_{q_v}(f_v).$$

It imposes the same variable s at every place. For $S \subset S'$, scalar extension along $A_S \to A_{S'}$ supplies compatible coefficient functors, and $\phi_{S'}$ restricts to ϕ_S. Thus these maps also define a map from the filtered union of the rings A_S. They give actual base-change functors for independent local parameters. The compatible Weyl action is the simultaneous swap at all places. An individual local swap generally does not preserve the common family.

For example, with $q_2 = 2$ and $q_3 = 3$, the independent unitary ratios $(z_2, z_3) = (1, -1)$ do not come from any common s. The first equation forces $s = 2\pi i n / \log 2$ for an integer n. The second would give $2n \log 3 = (2m + 1) \log 2$ for an integer m, after changing signs of the indices if necessary. Exponentiation contradicts unique factorization of rational numbers. Thus tensoring independent unitary axes does not impose the global parameter.

After common base change, put $E_{v,\Omega} = B_\Omega \otimes_{A_v} E_v$. Write $R_{v,\Omega}$ for the scalar extension of R_v. The local semilinear involution $\Theta_v = S_v R_v$ induces

$$\Theta_{v,\Omega}(h \otimes f) = \tau(h) \otimes \Theta_v(f).$$

This formula is balanced because $\phi_{q_v} \sigma_v = \tau \phi_{q_v}$. It squares to the identity, commutes with G_v, and fixes $\mathbf{1}_v$. For finite S, put $E_{S,\Omega} = \bigotimes_{v \in S, B_\Omega} E_{v,\Omega}$. The B_Ω-linear operator $\bigotimes_{v \in S} R_{v,\Omega}$ has target the family with every inducing pair swapped. The semilinear involution on $E_{S,\Omega}$ is instead defined by

$$\Theta_S\Big(\bigotimes_{v \in S} f_v\Big) = \bigotimes_{v \in S} \Theta_{v,\Omega}(f_v).$$

For $S = \varnothing$, set $E_{S,\Omega} = B_\Omega$ and $\Theta_S = \tau$. For nonempty S, moving a scalar between two tensor factors changes both resulting expressions by its image under τ. Thus the displayed map is balanced and τ-semilinear. Applying it twice gives the identity on pure tensors, hence on the whole module. It commutes with the action of $\prod_{v \in S} G_v$. Insertion of $\mathbf{1}_v$ defines compatible maps as S grows. These maps intertwine Θ_S and $\Theta_{S'}$ because each $\Theta_{v,\Omega}$ fixes the inserted vector. This also holds for the insertion from the empty

set, by semilinearity. The algebraic filtered colimit is the restricted tensor product of these smooth families over finite places, relative to $\mathbf{1}_v$. It therefore inherits a semilinear involution from the maps Θ_S. It carries the restricted product group relative to K_v: outside finitely many places an element belongs to K_v and fixes $\mathbf{1}_v$. Every tensor and every group action is computed at some finite stage. No infinite product of operator norms is needed for this algebraic construction.

The automorphic comparison problem

The common family above fixes the two global inducing characters to be trivial before the powers of the absolute value are inserted. For general inducing characters, their local components must arise from specified Hecke characters, and the Weyl action must also swap that character pair. Independent local characters do not by themselves supply these global data.

An analytic coefficient category still requires a choice of sheaf theory, topology, growth conditions, and derived completion on a complex parameter domain. The ring category $\mathcal{D}(B_\Omega)$ specifies none of those choices. An automorphic target further requires the adelic quotient, central character, level, archimedean factor, and an Eisenstein functor with analytic domains. To compare that target with the parameter category, one must construct the functor on complexes and compare its derived mapping objects and essential image. Compactness of coefficient complexes does not prove admissibility or finite generation over local Hecke algebras after induction. The local smooth family, its coherent Weyl descent, and common-parameter base change provide the input maps for this comparison. They do not identify a category of automorphic representations.

Remark 85.4.4 *(global normalizations and the pairing comparison).* The local operator $N_v(s,\chi) = R_z$ divides the raw operator by its spherical scalar $c(z)$. A global product requires Hecke characters, compatible spherical insertions, the archimedean and ramified factors, and an analytic continuation on a specified global family. In a classical Eisenstein parameter u with unnormalized spherical factor $\xi(2u-1)/\xi(2u)$, the symmetric induction variable is $s = 2u - 1$. The global epsilon product and its phase must be computed for that character and additive convention; it is not universally 1. An operator, a scalar phase and a Plancherel density are different data. The conditional Koszul–Petersson transport in Proposition 76.4.2 requires its own measure identity. If an even measure on the full axis has density $\frac{1}{2}w(t)dt$, pushforward under $t \mapsto |t|$ has density $w(t)dt$ off zero. This folding identity does not determine w.

Definition 85.4.5 *(local degeneration and the regular unitary locus).* For the symmetric unramified family at a finite place, define

$$\Sigma_v^{\mathrm{exc}} = \left(1 + \frac{2\pi i}{\log q_v}\mathbb{Z}\right) \cup \left(-1 + \frac{2\pi i}{\log q_v}\mathbb{Z}\right).$$

These are reducibility parameters. The normalized operator has poles only on the second set and is a projection at the first set. The non-exceptional unitary locus is all of $i\mathbb{R}$. The point 0 is regular and 1 is not on the unitary axis.

Remark 85.4.6 *(local degeneration and global residues).* A residue of a global Eisenstein series is not a pole of every normalized local operator. Its parameter, global quotient and central character must be specified. The local kernel/image sequences at $z = q^{\pm 1}$ are given by Proposition 85.3.4; comparison of their extension classes with arithmetic deformation data remains a separate coefficient-compatible construction.

85.5 MODULE (E1): PALEY–WIENER SYNTHESIS ON THE UNITARY AXIS

The Global Spectral Transform

Conjecture 85.5.1 *(global continuous spectral comparison).* Fix a unitary central character ω and the Hilbert quotient $L^2(GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A}), \omega)$ modulo the centre. Choose the level, archimedean types and Haar measures. The intended Eisenstein transform must identify its continuous part with a direct integral

$$L^2_{\mathrm{cont}}([GL_2], \omega) \simeq \bigoplus_{[\chi]} \int_{i\mathbb{R}_{\geq 0}}^{\oplus} V_{\chi,s}\, d\mu_\chi(s),$$

where $[\chi]$ ranges over the appropriate Weyl classes of global unitary Hecke-character pairs with central character ω. The measurable fibres $V_{\chi,s}$, the spectral measure μ_χ and the synthesis domain must be specified. Finite-dimensional spherical or Iwahori levels are not the full induced representations. A Paley–Wiener test space, its support and growth conditions, and its dense embedding in this Hilbert space are additional data. The shared parameter and global characters must be imposed before comparing local families, and the Weyl identification must use the actual normalized global operator.

The global spectral references are Langlands (1976), Part I, Sections 5–7, and Mœglin–Waldspurger (1995), Chapters II and IV. Shahidi's local normalization, Harish-Chandra's real-group Plancherel theorem and Wallach's treatment require their local hypotheses. They do not make an arbitrary Hilbert completion into a Paley–Wiener space or prove a universal ξ-density for all character pairs.

Remark 85.5.2 *(a scalar functional-equation identity).* For the completed Riemann function satisfying $\xi(s) = \xi(1-s)$ and $\xi(\bar{s}) = \overline{\xi(s)}$, one has $|\xi(2it)| = |\xi(1+2it)|$: apply the functional equation and then complex conjugation. Thus the two expressions $|\xi(2it)|^{-2}$ and $|\xi(1+2it)|^{-2}$ agree wherever defined. This algebraic identity does not identify either expression with the measure $d\mu_\chi$ above. The change from a classical parameter u to symmetric induction is $s = 2u - 1$, and its Jacobian and normalizing factors must be retained in any pairing comparison. A unit-modulus scattering phase is not an absolute-value spectral density.

Categorical Lift of the Paley–Wiener Space

Definition 85.5.3 *(data for an analytic continuous-spectrum category).* The intended analytic category requires a complex parameter domain containing the relevant unitary parameters, a sheaf theory, a topology, growth conditions and a derived completion, together with its local representation family. Write, provisionally,

$$C_v^{\mathrm{cont}} = D(\mathcal{A}_v^{\mathrm{an}}),$$

where $\mathcal{A}_v^{\mathrm{an}}$ must be constructed with the claimed admissibility and local Hecke-finiteness properties. The half-axis $i\mathbb{R}_{\geq 0}$ is not itself a complex manifold. Coherent finite-type objects are not closed under arbitrary colimits, so their Ind-completion, if used, must be specified. A spherical representation vector is also distinct from the coefficient unit and from a point module. In particular, $1/2$ is not on the unitary axis.

PROPOSITION 85.5.4 *(conditional presentability and pointing).* If an actual Grothendieck abelian coefficient category $\mathcal{A}_v^{\mathrm{an}}$ is supplied, its unbounded derived category is stable and presentable. Compact generation and a compact monoidal unit require separate proofs for that choice. For the bounded algebraic alternative already constructed, these assertions hold for $\mathcal{D}(A)$ and its unit A as in Proposition 85.4.1; this does not identify $\mathcal{D}(A)$ with the intended analytic category.

Proof. The derived category of a Grothendieck abelian category is stable and presentable (Lurie, Higher Algebra, Section 1.3.5). The algebraic assertions follow from the explicit module and perfect-complex proof of Proposition 85.4.1. No compactness assertion about the unspecified analytic sheaf theory is used. □

Conjecture 85.5.5 *(analytic Weyl descent).* Construct a coherent Weyl action on the intended analytic restricted tensor category, with a specified functor

$$N : \bigotimes_v{}' C_v^{\mathrm{cont}} \longrightarrow \bigotimes_v{}' C_v^{\mathrm{cont}},$$

and its involution coherence, compatible with the global inducing characters, common parameter and distinguished insertions. The already constructed coefficient action is $\mathcal{D}(A)^{hW} \simeq \mathcal{D}(A \rtimes W)$; its equivariant smooth induction and simultaneous common-parameter involution are explicit. An individual local swap need not preserve that common parameter. A representation intertwiner is not itself an E_∞ morphism of categories, and the analytic action above is additional to the algebraic coefficient action.

Theorem 85.5.6 *(conditional enhanced Paley–Wiener comparison).* Construct the analytic automorphic category and a global-character, common-parameter version of the analytic tensor category. Denote these intended enhanced carriers by

$$\mathcal{A}_{\mathrm{Eis}}^{\text{sph-fin}} \longrightarrow \left(\bigotimes_v{}' C_v^{\mathrm{cont}} \right)^{hW}.$$

If the arrow is an exact colimit-preserving functor between compactly generated stable presentable categories, takes chosen compact generators to compact objects, induces equivalences on their full mapping spectra, and has generating image, it is an equivalence. Its arithmetic realization must also intertwine the global spectral synthesis, Hecke actions and analytic domains.

Proof. Apply Theorem 70.4.1 to the specified functor. Constructing the Hilbert synthesis, analytic sheaf enhancement, restricted tensor insertions and coherent Weyl action are the four separate prerequisites. A unitary map of Hilbert spaces does not supply the enhanced functor or force degeneration of a descent spectral sequence. The explicit coefficient Weyl proof above uses a monadic description and averaging over a group of order two over $\mathbb{C}$, not a Hilbert-unitarity argument. □

85.6 Module (E2): Langlands Spectral Decomposition Lifted Categorically

The Three Summands

Theorem 85.6.1 *(Langlands spectral decomposition of $L^2([GL_2])$).* For the fixed unitary central-character quotient and Haar measure of Conjecture 85.5.1, the automorphic L^2-space decomposes as a unitary direct sum

$$L^2([GL_2]) \;=\; L^2_{\mathrm{cusp}} \;\oplus\; L^2_{\mathrm{res}} \;\oplus\; L^2_{\mathrm{cont}},$$

with:

- L^2_{cusp} the cuspidal subspace (Bernstein 1988; Mœglin–Waldspurger III.2.1);

- L^2_{res} the residual spectral subspace, indexed by the actual residual automorphic representations for the chosen quotient; the constant function gives a residual line when the central character and quotient allow it (Mœglin–Waldspurger II.2);
- L^2_{cont} the continuous spectrum, parametrised by Weyl-orbits of unitary Hecke characters via Eisenstein series (Langlands 1976 §7; Mœglin–Waldspurger IV.3).

The decomposition is canonical and respects the adelic Hecke action and the archimedean $(\mathfrak{g}, K_\infty)$-structure.

Source. Langlands 1976 §7 (original proof, functional equations); Mœglin–Waldspurger 1995 Ch. II and IV (modern full account). □

Categorical Lift of Each Summand

Definition 85.6.2 *(the coefficient model of one residual line).* For a chosen one-dimensional residual character over $\mathbb{C}$, the coefficient category is $\mathcal{D}(\mathbb{C})$, with compact unit $\mathbb{C}[0]$ and tensor product over $\mathbb{C}$. Its unit endomorphism ring is $\mathbb{C}$. It is not the category of spectra, whose sphere has degree-zero endomorphism ring $\mathbb{Z}$. This coefficient model does not identify the full residual spectrum with a single line.

THEOREM 85.6.3 *(conditional realization of the residual comparison).* The restricted tensor product of copies of $\mathcal{D}(\mathbb{C})$ in complex-linear presentable stable categories, with the unit insertions, is $\mathcal{D}(\mathbb{C})$. Its identification with an actual residual automorphic category additionally requires a chosen residual representation, its compatible local factors and a comparison functor with generating image and equivalences on full mapping spectra. For several residual representations their extension and assembly data must also be supplied.

Proof. Every finite tensor product of the complex-linear tensor unit is that unit, and the insertion maps are the unit identifications. Their filtered colimit is the unit. For the actual residual category apply the compact-generator criterion to the specified comparison; the coefficient calculation does not provide its hypotheses. □

THEOREM 85.6.4 *(conditional continuous-spectrum comparison).* On a specified analytic parameter domain, including the full unitary axis for symmetric unramified induction, the continuous-spectrum comparison is an equivalence under the complete enhanced functor, mapping-spectrum, compactness and generation hypotheses of Theorem 85.5.6.

Proof. Apply that theorem on the chosen domain with its restricted analytic functor and support conditions. The local operator has no unitary-axis poles in the stated unramified family. Algebraic scalar extension to B_Ω proves the coefficient construction, but does not replace the analytic enhancement or supply its automorphic essential image. □

PROPOSITION 85.6.5 *(the sph-finite comparison requirement).* The scalar-extension functor $B_\Omega \otimes^{\mathbf{L}}_{A} (-)$ preserves perfect coefficient complexes, and its equivariant version preserves compact objects. Preservation of the intended automorphic sph-finiteness requires, in addition, the actual induction/analytic functors to preserve the specified admissibility and finite-type local Hecke conditions. These conditions must also be stable under the proposed restricted tensor transition maps and Weyl descent.

Proof. A bounded complex of finitely generated projective modules remains such after derived scalar extension. For Weyl descent the underlying perfect-complex criterion proved above applies over A and over B_Ω, where 2 is invertible. These facts concern coefficient compactness. The universal smooth family E is infinite free and noncompact, so this argument asserts no automatic Hecke-finiteness after induction or arbitrary filtered colimits. □

85.7 Tensor sectors and extension data

An orthogonal decomposition into local sectors gives a direct-sum decomposition of their tensor product. Even with two sectors at each of two places, tensor distributivity gives four terms:

$$(\mathcal{A}_0 \oplus \mathcal{A}_1) \otimes (\mathcal{B}_0 \oplus \mathcal{B}_1) \simeq (\mathcal{A}_0 \otimes \mathcal{B}_0) \oplus (\mathcal{A}_0 \otimes \mathcal{B}_1) \oplus (\mathcal{A}_1 \otimes \mathcal{B}_0) \oplus (\mathcal{A}_1 \otimes \mathcal{B}_1).$$

The middle two terms record different sector choices at the two places. A relation between those choices requires additional structure.

Orthogonal decompositions

Let $\mathcal{V}$ be a symmetric monoidal ∞-category with small colimits. Assume its tensor product preserves colimits separately in each variable. Write $\mathbf{1}$ for its tensor unit and $\coprod$ for its categorical coproduct. The following argument applies to the ∞-category of presentable stable ∞-categories and colimit-preserving functors. Its tensor product is characterized by functors preserving colimits separately in each variable (Lurie, *Higher Algebra* (2017), Remarks 4.8.1.18 and 4.8.1.24, Proposition 4.8.2.18). For finite families of stable categories, this coproduct is their orthogonal direct sum, denoted $\oplus$.

Indeed, in a finite product $\prod_i C_i$, every object is the finite direct sum of its components. A colimit-preserving functor out of this product is therefore determined by its restrictions to the factors. Conversely, functors $F_i : C_i \to \mathcal{D}$ extend by $(x_i)_i \mapsto \bigoplus_i F_i(x_i)$. This proves the coproduct universal property. Distinct factors have zero mapping spectra.

Proposition 85.7.1 *(Finite sector decomposition).* Let S be a finite set. For each $v \in S$, fix a finite set I_v and a specified equivalence $C_v \simeq \coprod_{r \in I_v} C_{v,r}$ in $\mathcal{V}$. There is an equivalence, induced by the given sector inclusions,

$$\bigotimes_{v \in S} C_v \simeq \coprod_{\alpha \in \prod_{v \in S} I_v} \bigotimes_{v \in S} C_{v,\alpha(v)}.$$

For $S = \varnothing$, both sides are $\mathbf{1}$.

Proof. For one factor the assertion is the specified decomposition. Tensoring that decomposition with another factor preserves its coproduct. Applying the same fact to the new factor gives the Cartesian product of the two index sets. Induction proves the formula. The maps are induced by the sector inclusions, so the equivalence respects maps that preserve the specified decompositions. □

Write $D(k)$ for the stable ∞-category of unbounded cochain complexes of k-vector spaces, with quasi-isomorphisms inverted. For example, in complex-linear presentable stable categories, put $\mathcal{A}_i = \mathcal{B}_j = D(\mathbb{C})$ and tensor over $D(\mathbb{C})$. This category is the tensor unit, so the result is $D(\mathbb{C})^{\oplus 4}$. Keeping only the two equal-index factors gives $D(\mathbb{C})^{\oplus 2}$. These categories are not equivalent. Their compact objects have Grothendieck groups $\mathbb{Z}^4$ and $\mathbb{Z}^2$, respectively. Here the Grothendieck group imposes the relation $[y] = [x] + [z]$ for each exact triangle $x \to y \to z$. In $\mathrm{Perf}(\mathbb{C})$, splitting a bounded complex into its cohomology identifies this group with $\mathbb{Z}$, by Euler characteristic. Finite products give the stated ranks. An equivalence preserves compact objects and exact triangles, hence would preserve these groups.

The restricted tensor construction also depends on the sector of each insertion. Let V be a small set. For each $v \in V$, fix a finite nonempty set I_v, an element $o_v \in I_v$, and a specified decomposition of C_v as above. Fix a morphism $e_v : \mathbf{1} \to C_{v,o_v}$ in $\mathcal{V}$. For finite $S \subset V$, set

$$C_S = \bigotimes_{v \in S} C_v.$$

For $S \subset T$, tensor with the morphisms e_v, followed by sector inclusion, for $v \in T \setminus S$. The monoidal coherence maps give a diagram on the poset of finite subsets of V. Define its restricted product by

$$C^{\mathrm{res}} = \operatorname*{colim}_{S \subset V,\, S \text{ finite}} C_S.$$

This is an algebraic colimit in $\mathcal{V}$. No analytic or topological completion is implicit.

Let I^{fin} consist of functions α with $\alpha(v) \in I_v$ whose support $\operatorname{supp}(\alpha) = \{v : \alpha(v) \neq o_v\}$ is finite. For such α, define

$$C^{\mathrm{res}}_\alpha = \operatorname*{colim}_{\substack{S \subset V \text{ finite} \\ S \supset \operatorname{supp}(\alpha)}} \bigotimes_{v \in S} C_{v,\alpha(v)},$$

with the same distinguished insertions.

PROPOSITION 85.7.2 *(Restricted sector decomposition).* Under these hypotheses, the sector inclusions induce an equivalence

$$C^{\mathrm{res}} \simeq \coprod_{\alpha \in I^{\mathrm{fin}}} C^{\mathrm{res}}_\alpha.$$

Proof. For each α, extend its displayed diagram to all finite S by assigning the initial object when S does not contain its support. Call the resulting diagram E_α. At a fixed finite S, only functions supported in S contribute noninitial terms. The finite sector decomposition therefore gives $C_S \simeq \coprod_\alpha E_\alpha(S)$. The insertion lies in sector o_v, so the transition maps preserve this identification of diagrams. Colimits commute with coproducts. Thus

$$\operatorname{colim}_S C_S \simeq \coprod_\alpha \operatorname{colim}_S E_\alpha(S).$$

The finite sets containing a fixed support form a cofinal subposet: $S \mapsto S \cup \operatorname{supp}(\alpha)$ supplies a finite upper bound compatible with inclusions. Each inner colimit is consequently C^{res}_α. □

A general insertion need not lie in one sector. If it has several components, its transition maps need not preserve the finite-support indexing above. The finite sector formula still holds. The restricted colimit must then retain the actual transition maps between those finite decompositions.

A nonsplit extension

Orthogonal direct sums exclude extensions between distinct factors. The quiver $1 \to 2$ gives a concrete extension that must be retained when orthogonality is absent. Let k be a field, with no restriction on its characteristic. A representation is a linear map $u : A \to B$ of k-vector spaces. A morphism is a pair (f, g) satisfying $gu = u'f$. Kernels and cokernels are computed at the two vertices.

Consider

$$S_1 = (k \to 0), \qquad S_2 = (0 \to k), \qquad P = (k \xrightarrow{1} k).$$

There is an exact sequence of representations

$$0 \longrightarrow S_2 \longrightarrow P \longrightarrow S_1 \longrightarrow 0.$$

It does not split: a morphism $S_1 \to P$ has source component $f : k \to k$ satisfying $f = 0$. It cannot be a section. Moreover, $\mathrm{Hom}(P, (A \to B)) \cong A$ and $\mathrm{Hom}(S_2, (A \to B)) \cong B$. Both functors are exact, so P and S_2 are projective. The sequence is therefore a projective resolution of S_1. Applying $\mathrm{Hom}(-, S_2)$ gives

$$\mathrm{Hom}(P, S_2) = 0, \qquad \mathrm{Hom}(S_2, S_2) = k, \qquad \mathrm{Ext}^1(S_1, S_2) = k.$$

The displayed sequence represents the image of $1 \in k$ under the connecting isomorphism. Projectivity of S_2 also gives $\mathrm{Ext}^n(S_2, S_1) = 0$ for every $n \geq 0$. Thus one direction is orthogonal, while the opposite direction carries an extension.

Equivalently, these are left modules over

$$T = \left\{ \begin{pmatrix} a & 0 \\ m & b \end{pmatrix} : a, b, m \in k \right\}, \qquad \begin{pmatrix} a & 0 \\ m & b \end{pmatrix}\begin{pmatrix} a' & 0 \\ m' & b' \end{pmatrix} = \begin{pmatrix} aa' & 0 \\ ma' + bm' & bb' \end{pmatrix}.$$

The two diagonal idempotents recover A and B. The lower-left matrix unit acts by $u : A \to B$. Associativity gives exactly the representation relations. Replacing this algebra by $k \times k$ removes its lower-left entry and the extension above.

Stable gluing

To retain extensions in a stable category, the connecting morphism must be part of each object. Let $\mathcal{A}$ and $\mathcal{B}$ be stable ∞-categories and let $F : \mathcal{A} \to \mathcal{B}$ be exact. All mapping objects below are spectra, written $\mathrm{map}_{\mathcal{A}}(-,-)$ and similarly for other categories. The shift $[1]$ denotes suspension. For cochain complexes it has $K[1]^n = K^{n+1}$ and differential $-d_K$.

Define $\mathcal{G}(F)$ to be the pullback

$$\mathcal{G}(F) = (\mathcal{A} \times \mathcal{B}) \underset{\mathcal{B}\times\mathcal{B}}{\times} \mathrm{Fun}(\Delta^1, \mathcal{B}),$$

where the first map is $(a, b) \mapsto (Fa, b)$ and the second records the source and target of an arrow. Thus an object is (a, b, u) with $u : Fa \to b$. A morphism consists of $f : a \to a'$, $g : b \to b'$, and a specified homotopy from $u'Ff$ to gu. The pullback retains all higher coherences.

Proposition 85.7.3 *(Mapping spectra and extensions).* The category $\mathcal{G}(F)$ is stable, with finite limits and colimits computed in the two components. For $x = (a, b, u)$ and $x' = (a', b', u')$,

$$\mathrm{map}_{\mathcal{G}(F)}(x, x') \simeq \mathrm{fib}\Big(\mathrm{map}_{\mathcal{A}}(a, a') \oplus \mathrm{map}_{\mathcal{B}}(b, b') \xrightarrow{d} \mathrm{map}_{\mathcal{B}}(Fa, b') \Big), \qquad d(f, g) = u'Ff - gu. \tag{85.4}$$

The exact fully faithful functors

$$i(b) = (0, b, 0), \qquad j(a) = (a, 0, 0)$$

satisfy

$$\mathrm{map}(i(b), j(a)) = 0, \qquad \mathrm{map}(j(a), i(b)) \simeq \Omega\, \mathrm{map}_{\mathcal{B}}(Fa, b) \simeq \mathrm{map}_{\mathcal{B}}(Fa[1], b).$$

Every object has a natural exact triangle

$$i(b) \longrightarrow (a, b, u) \longrightarrow j(a) \xrightarrow{\delta_u} i(b)[1].$$

Under the induced equivalence $\mathrm{map}(j(a), i(b)[1]) \simeq \mathrm{map}_{\mathcal{B}}(Fa, b)$, the connecting morphism δ_u corresponds to u. The choice of sign in this last equivalence is fixed by this exact triangle.

Proof. Exactness of F allows componentwise finite limits and colimits to supply the required arrows. The zero components give a zero object. Pushout squares are pullback squares componentwise, proving stability. A map between two arrows is a homotopy-commutative square. Its mapping space is the homotopy equalizer of the two compositions $u'Ff$ and gu. The same statement after every suspension gives the homotopy equalizer of mapping spectra. In spectra this is the fiber of their difference, which proves (85.4).

For two objects in the image of i, the formula reduces to $\mathrm{map}_{\mathcal{B}}$. For two in the image of j, it reduces to $\mathrm{map}_{\mathcal{A}}$. The two cross formulas follow by substituting the zero components. In particular, the fiber of $0 \to E$ is ΩE, not E. The cofiber of $i(b) \to (a, b, u)$ is $(a, 0, 0)$ componentwise. Its connecting morphism includes the homotopy encoded by u. The suspension equivalence identifies that homotopy with u and fixes the stated sign convention. □

The triangle splits precisely when δ_u is nullhomotopic, equivalently when u is nullhomotopic. Indeed, a nullhomotopy identifies its fiber with $i(b) \oplus j(a)$. Conversely, a splitting makes the connecting morphism zero in the homotopy category. When $F = 0$, $\mathcal{G}(F) \simeq \mathcal{A} \times \mathcal{B}$. Taking $\mathcal{A} = \mathcal{B} = D(k)$ and $F = \mathrm{id}$ gives the arrow category of complexes. Here $h\mathcal{G}(F)$ denotes the homotopy category. For $a = b = k$ in degree zero, the second cross formula gives

$$\mathrm{Hom}_{h\mathcal{G}(F)}(j(k), i(k)[1]) \cong k.$$

The object $(k, k, 1)$ gives its nonzero connecting class. This recovers the extension mechanism in the quiver calculation, including its degree.

Reconstruction from a semiorthogonal filtration

The same description applies to a category whose extension structure is already specified. Let C be stable and let $i : \mathcal{B} \to C$ and $j : \mathcal{A} \to C$ be exact fully faithful functors. Assume

$$\mathrm{map}_C(i(b), j(a)) = 0 \quad \text{for all } a \in \mathcal{A},\ b \in \mathcal{B}.$$

Assume every $x \in C$ admits an exact triangle

$$i(b) \longrightarrow x \longrightarrow j(a) \longrightarrow i(b)[1].$$

These hypotheses state the orientation of the semiorthogonal filtration. They are stronger than generation by the two subcategories alone.

Let $\mathcal{E}$ be the full pullback of the arrow category of C whose arrows have source $j(a)$ and target $i(b)[1]$. Its objects are triples (a, b, δ) with $\delta : j(a) \to i(b)[1]$. Then

$$\mathrm{map}_{\mathcal{E}}((a, b, \delta), (a', b', \delta')) \simeq \mathrm{fib}\big(\mathrm{map}_{\mathcal{A}}(a, a') \oplus \mathrm{map}_{\mathcal{B}}(b, b') \longrightarrow \mathrm{map}_C(j(a), i(b')[1])\big),$$

where the map sends (f, g) to $\delta' j(f) - i(g)[1]\delta$.

Proposition 85.7.4 *(Semiorthogonal reconstruction).* Under these hypotheses, the functor

$$\mathcal{E} \longrightarrow C, \qquad (a, b, \delta) \longmapsto \mathrm{fib}(\delta)$$

is an equivalence. Suppose, in addition, that i has an exact left adjoint $L : C \to \mathcal{B}$. Put $F = (Lj)[-1]$. Then $C \simeq \mathcal{G}(F)$, with the given embeddings i, j.

Proof. A connecting arrow has a fiber triangle $i(b) \to \mathrm{fib}(\delta) \to j(a)$. The filtration hypothesis gives essential surjectivity. To prove full faithfulness, consider two such triangles with middle objects x, x'. Applying $\mathrm{map}_C(-, j(a'))$ to the first triangle gives an equivalence

$$\mathrm{map}_C(j(a), j(a')) \xrightarrow{\sim} \mathrm{map}_C(x, j(a')),$$

because the mapping spectrum from $i(b)$ to $j(a')$ is zero. Consequently a map $h : x \to x'$ determines, with contractible choices, a map $j(f) : j(a) \to j(a')$ and a homotopy between $j(f)(x \to j(a))$ and $x \xrightarrow{h} x' \to j(a')$. Taking fibers gives a map $i(g) : i(b) \to i(b')$. Taking cofibers supplies the compatible square of connecting arrows. Conversely, a square of connecting arrows gives h by taking fibers. The fiber and cofiber universal properties make these constructions inverse on mapping spaces, including all their higher homotopies. Thus the functor is fully faithful.

For the additional assertion, adjunction and exactness give

$$\mathrm{map}_C(j(a), i(b)[1]) \simeq \mathrm{map}_{\mathcal{B}}(Lj(a), b[1]) \simeq \mathrm{map}_{\mathcal{B}}(F(a), b).$$

This natural equivalence identifies objects, squares, and their higher coherences in $\mathcal{E}$ with those in $\mathcal{G}(F)$. □

In particular, a recollement can supply such a filtration without supplying an orthogonal direct sum. Use the convention $i_* : \mathcal{B} \to C$ for the closed embedding and $j_! : \mathcal{A} \to C$ for the open extension functor. The recollement adjunctions include $i^* \dashv i_* \dashv i^!$ and $j_! \dashv j^* \dashv j_*$. Its defining vanishing $j^* i_* = 0$ gives $\mathrm{map}(j_! a, i_* b) = 0$, and its exact triangle is

$$j_! j^* x \longrightarrow x \longrightarrow i_* i^* x \longrightarrow j_! j^* x[1].$$

The first assertion of the proposition applies with the roles of the closed and open categories interchanged. It retains the connecting arrow $i_* i^* x \to j_! j^* x[1]$. It does not require a left adjoint to $j_!$ or assert one exists.

The semiorthogonal description becomes an orthogonal direct sum if the other cross mapping spectrum also vanishes. Then every connecting spectrum is zero, and $\mathcal{E} \simeq \mathcal{A} \times \mathcal{B}$. Without this vanishing, tensor assembly must retain the gluing functors or connecting spectra and their composition data. The two sector names alone do not determine the category.

For automorphic categories, applying these propositions requires actual local decompositions or semiorthogonal filtrations and specified insertion functors. An identification with a global automorphic category also requires a comparison functor preserving the Hecke actions, parameter constraints, and extension data. Neither tensor distributivity nor semiorthogonal reconstruction constructs that comparison functor.

85.8 MODULE (E3): ASSEMBLY COMPATIBLE WITH CUSPIDAL LACD

Full Statement

THEOREM 85.8.1 *(conditional Eisenstein categorical assembly).* Suppose the actual local categories, their pointed restricted tensor construction and global automorphic enhancement are supplied. Impose the global Hecke-character and common-parameter conditions and the analytic domains of the intended comparison. Suppose both sides have specified orthogonal decompositions, or specified finite semiorthogonal filtrations retaining the connecting spectra. Require component equivalences and coherent natural equivalences of the connecting mapping-spectrum bifunctors, compatible with composition and each successive filtration stage. For the restricted sector formula, require the pointings to lie in their specified single sectors; otherwise retain the entire finite-stage decompositions and their actual transition maps, together with a compatible equivalence of these filtered diagrams. Then these data induce an equivalence

$$\left(\bigotimes_{v}{}' C_v\right)^{\text{glob,nonexc}} \xrightarrow{\sim} \mathrm{D}^{\text{sph-fin}}([GL_2])^{\text{nonexc}}.$$

Here the global superscript imposes the specified automorphic support; independent local families do not impose it automatically. The non-exceptional condition uses the actual local degeneration divisors and global synthesis domain. For the symmetric unramified family the local degeneration strata lie off the unitary axis. To obtain the structured comparison, require compatibility with:

(i) finite-place Whittaker functors;
(ii) Bernstein-centre and cross-prime Hecke actions;
(iii) the archimedean $(\mathfrak{g}, K_\infty)$ action;
(iv) normalized intertwiners, with their domains and Weyl coherences;
(v) global Paley–Wiener synthesis and its measure normalization.

The cuspidal, residual and continuous category comparisons remain separate hypotheses; their Hilbert spectral names do not construct the local categorical decomposition.

Proof. First retain the conditional cuspidal globalization of Theorem 70.6.4. Second supply the residual comparison of Theorem 85.6.3 on the chosen residual family. Third supply the enhanced continuous comparison of Theorem 85.6.4. Fourth, in the orthogonal case apply the finite sector formula at each stage. For sector-pure pointings the restricted sector formula then applies. For impure pointings, take the filtered colimit of the specified equivalences of full finite-stage diagrams, retaining their actual transition maps. In the semiorthogonal case use Proposition 85.7.4; the component equivalences and compatibility of connecting spectra induce an equivalence of the arrow pullback categories, hence of the original categories. Iterate this argument for the stipulated finite filtration. Finally the five specified natural compatibility maps give the stated structured comparison. The local operator or Hilbert orthogonality alone supplies none of these component or gluing hypotheses. □

Corollaries and degeneration data

COROLLARY 85.8.2 *(conditional adelic descent on the specified domain).* Under all the categorical, analytic, global-support and gluing hypotheses of Theorem 85.8.1, its comparison realizes the intended L_{ACD} on that domain. Extending it to other parameters requires their actual intertwiners and extension data.

Proof. The theorem identifies the two specified global carriers and their five structures. Restricting those maps to the stated domain gives this assertion; no omitted local or global sector is inferred. □

Conjecture 85.8.3 *(arithmetic comparison at degeneration strata).* Construct a coefficient-compatible enhanced comparison between the kernel/image extension data at the actual reducibility strata of local induction and the corresponding arithmetic deformation strata. For symmetric unramified finite-place induction these are $z = q^{\pm 1}$, equivalently the periodic translates of $s = \pm 1$. There is no reducibility at $s = 0$ and neither family meets the unitary axis. Global Eisenstein residue objects require their own global parameter and support calculation. The intended extension to full adelic categorical descent must match full derived morphisms and composition, including but not limited to the degree-one class. A coefficient bridge from the complex analytic family to the p-adic determinant-identified spectral stack is part of this problem.

Remark 85.8.4 *(the domain of the degeneration comparison).* The smooth local kernel and image are explicit in Proposition 85.3.4. The quiver and stable gluing calculations above show how a connecting class changes a category even when its two pieces are fixed. They do not identify that class with an Emerton–Gee cotangent class. The wild comparison in Conjecture 68.7.3 is an analogous arithmetic question with its own coefficient data; neither comparison follows from equality of extension dimensions.

Compatibility with the Langlands–Shahidi normalisation

Proposition 85.8.5 *(conditional Koszul–Petersson transport).* Suppose a global synthesis transform T on a specified common test space and a spectral measure μ have been constructed, and the Koszul pairing and Petersson pairing both pull back under T to $\int f\overline{g}\, d\mu$ with the same scalar normalization. Then T identifies these pairings on that space. Extending this identification to completions additionally requires density and continuity for the stated norms. The normalized local operator R_z is one input to constructing such data; its unitarity is not a formula for μ.

Proof. Both pullbacks have the same integral value for each pair of tests. If the common test space is dense and the pairings continuous, the equality extends by taking convergent test sequences. This uses the stated measure and normalization hypotheses, not an identification of an operator with an absolute-value scalar. □

85.9 Comparison and Hypotheses

The representation-theoretic inputs have different mathematical roles. Flath (1979) factorizes actual cuspidal representations. Bernstein (1988) and Mœglin–Waldspurger (1995), Section III, concern the cuspidal spectrum. Langlands (1976), Shahidi (1990, 2010), Arthur (2013), Harish-Chandra (1976), Wallach (1992) and Mœglin–Waldspurger, Sections II and IV, concern global or local harmonic analysis with their respective quotient, level and character hypotheses. Lurie's presentable tensor products provide a categorical ambient after its objects and insertion functors have been constructed.

The unramified calculation fixes $|\varpi| = q^{-1}$, additive measure $\mathrm{vol}(O) = 1$, normalized induction and the spherical vector. Ramified and archimedean epsilon conventions and a global product remain additional data. The relation $s = 2u - 1$ and any measure Jacobian must be included when comparing to a classical Eisenstein parameter. The global epsilon product need not be 1.

The algebraic Weyl construction is a specified coherent involution on coefficient complexes and smooth families, with one simultaneous swap after common-parameter base change. It does not provide the analytic sheaf theory, Hecke-finiteness or a global automorphic essential image. A Hilbert direct sum

does not make its enhanced categories orthogonal. The required mapping spectra and connecting arrows are the objects of the gluing propositions above. The arithmetic comparison at degeneration strata is additional even after all these global objects exist.

Composite with the cuspidal comparison

THEOREM 85.9.1 *(conditional composite adelic comparison).* Given the cuspidal globalization, residual comparison and analytic continuous-spectrum comparison, together with the complete component and extension compatibility hypotheses of Theorem 85.8.1, their assembly gives the adelic categorical comparison on the specified global support and parameter domain. Extension to the full arithmetic F1 comparison also requires its local categorical and geometric Bernstein-centre maps.

Proof. Apply the assembly theorem to these particular components and gluing maps. Its proof retains all mixed tensor terms or the actual semiorthogonal extension data. Composing with the additional specified local and geometric comparisons gives their conditional consequence. □

85.10 THE EISENSTEIN COMPARISON PROBLEM

Conjecture 85.10.1 *(the arithmetic comparison beyond the local constructions).* The full F1 construction must retain the following problems:

(i) ordinary and non-ordinary local DEG essential images at $p \geq 5$;
(ii) restrictions outside the global Taylor–Wiles hypotheses;
(iii) actual small-prime block functors, support and full derived comparison, including the wild extension-class map;
(iv) global Eisenstein synthesis, analytic enhancement and its categorical comparison, including the degeneration data of Conjecture 85.8.3;
(v) the actual global restricted-tensor support, overlap and extension diagram and its local-global comparison;
(vi) the geometric Bernstein-centre gluing constructions in Chapter 64.

The local results here do not reduce the full Eisenstein question to two extension classes. Proving exhaustion by any list of conditions requires the common carrier and its gluing diagram.

85.11 EISENSTEIN BOUNDARY

The normalized unramified operator is constructed on all smooth vectors, with maximal Hilbert domain stated and a unitary extension on the unit circle. Its equal-character value is regular; reducibility occurs at $z = q^{\pm 1}$. The coefficient category, coherent Weyl descent and common symmetric finite-place family are algebraic constructions. Their analytic and automorphic realizations remain separate. The finite and restricted tensor formulas include mixed sectors. Stable reconstruction retains the connecting spectrum when orthogonality is absent. These results provide actual objects and maps for the conditional global comparison; they do not establish that comparison or a full global-centre identification.

Chapter 86

Non-Ordinary Locus and Removal of the Taylor–Wiles Hypotheses for the DEG Equivalence

A fixed residual representation can have characteristic-zero lifts with different Hodge types. The ordinary condition must retain its flag and determinant before a local categorical comparison can be stated. This chapter constructs the quotient lifting equations and their fixed-type intersections, and computes restrictions of quadratic inductions, including nonsplit local places with reducible restriction. The non-ordinary DEG essential image and removal of Taylor–Wiles hypotheses remain arithmetic generator-comparison problems. Neither modularity nor deformation-ring geometry alone provides the required spectral objects or their generation.

86.1 Sources and Objects

Inherited Objects and Notation

The unramified ordinary ∞-category $\mathrm{D}^{\text{sph-fin,unr-ord}}([GL_2(\mathbb{Q}_p)])_\chi$, the Dotto–Emerton–Gee functor $\Phi^{\mathrm{DEG}}_{p,\chi}$ (Theorem 61.3.1), the Emerton–Gee stack $\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2}$ and its Breuil–Mézard cycle comparison problem, and the Taylor–Wiles setup (Setup 70.2.1) are taken as stated in Chapters 61 and 70.

Paškūnas 2013 *The image of Colmez's Montreal functor*, Publ. Math. IHES 118, 1–191, arXiv:1005.2008. Projective envelopes in the specified pseudocompact blocks require an additional comparison before they can be used as compact generators of a derived category.

The deformation and automorphic comparisons

Kisin's lifting rings and Gee–Kisin's cycle multiplicities concern fixed characteristic-zero types. Emerton–Gee supplies the spectral moduli problem. Colmez and Paškūnas concern representation objects and projectives in their specified coefficient categories. Khare–Wintenberger, Langlands–Tunnell, Arthur–Clozel, Skinner–Wiles, Taylor and Barnet-Lamb–Gee–Geraghty concern modularity, base change or potential automorphy under their own local and global hypotheses. The maps relating these objects to the actual DEG functor and its spectral essential image must be constructed separately.

86.2 Essential Surjectivity on the Non-Ordinary Locus at $p \geq 5$

Structural Decomposition of the Non-Ordinary Locus

The ordinary comparison of Theorem 70.2.4 is conditional on its actual support and essential-image data. Dropping (TW4) does not partition a residual stack by Hodge types. The following lifting constructions fix their determinant, residual quotient and characteristic-zero type before asking for a categorical realization.

A fixed determinant and a residual quotient

Fix $p \geq 5$. Let $E/\mathbb{Q}_p$ be finite, with integer ring $\mathcal{O}$, uniformizer ϖ, and finite residue field k. Put $G = G_{\mathbb{Q}_p}$ and let $I \subset G$ be inertia. Fix a continuous representation $\bar{\rho} : G \to \mathrm{GL}_2(k)$, a basis of k^2, and a continuous character $\delta : G \to \mathcal{O}^\times$ lifting $\det \bar{\rho}$.

For an Artinian local $\mathcal{O}$-algebra A with residue field k and its discrete topology, a framed lift is a continuous homomorphism $\rho_A : G \to \mathrm{GL}_2(A)$ reducing to the specified matrix representation $\bar{\rho}$. Framed lifts are not divided by conjugation. The framed deformation ring $R^\square$ is a complete Noetherian local $\mathcal{O}$-algebra with universal representation $\rho^\square$. Its existence is the framed representability statement in (Kisin, *The structure of potentially semi-stable deformation rings*, §1.2). Set

$$R = R^{\square,\delta} = R^\square / \overline{(\det \rho^\square(g) - \delta(g) : g \in G)}.$$

The bar denotes closure in the maximal-ideal topology. This quotient represents framed lifts of determinant δ. Write its universal matrices as

$$\rho_R(g) = \begin{pmatrix} a_g & b_g \\ c_g & d_g \end{pmatrix}.$$

Assume a chosen residual quotient $\bar{q} : k^2 \twoheadrightarrow k(\bar{\eta})$ is unramified. Here $k(\bar{\eta})$ is the one-dimensional representation with character $\bar{\eta}$, and unramified means $\bar{\eta}|_I = 1$. Choose the basis so that $\bar{q} = (0, 1)$. Then

$$\bar{\rho}(g) = \begin{pmatrix} \bar{\alpha}(g) & * \\ 0 & \bar{\eta}(g) \end{pmatrix}, \qquad \bar{\alpha} = \bar{\delta}\bar{\eta}^{-1}.$$

An ordinary lift relative to $\bar{q}$ is a framed lift together with a free rank-one quotient lifting $\bar{q}$, on which inertia acts trivially. Quotients are identified up to an equivariant target isomorphism. Each such quotient has a unique normalized row $q = (t, 1)$, where $t \in \mathfrak{m}_A$. Its character is allowed to vary with A.

Proposition 86.2.1 *(explicit ordinary deformation equations).* Suppose $\bar{\alpha} \neq \bar{\eta}$. Choose $g_0 \in G$ with $\bar{\alpha}(g_0) \neq \bar{\eta}(g_0)$. There is a unique $t_0 \in \mathfrak{m}_R$ satisfying

$$b_{g_0} t_0^2 + (d_{g_0} - a_{g_0}) t_0 - c_{g_0} = 0. \tag{86.1}$$

Let $J_{\mathrm{ord}} \subset R$ be the closed ideal generated by

$$\begin{aligned} b_g t_0^2 + (d_g - a_g) t_0 - c_g \quad & (g \in G), \\ t_0 b_h + d_h - 1 \quad & (h \in I). \end{aligned}$$

Then $R^{\mathrm{ord}} = R/J_{\mathrm{ord}}$ represents ordinary lifts relative to $\bar{q}$. The quotient line is uniquely determined by the framed representation. Thus forgetting the quotient gives a closed immersion $\operatorname{Spf} R^{\mathrm{ord}} \hookrightarrow \operatorname{Spf} R$.

Proof. The polynomial in (86.1) vanishes at zero modulo $\mathfrak{m}_R$. Its derivative there is $\bar{\eta}(g_0) - \bar{\alpha}(g_0) \neq 0$. Completeness and Hensel's lemma give the unique root t_0. For completeness, successive correction modulo powers of $\mathfrak{m}_R$ solves a linear equation with this invertible coefficient. These corrections converge in R. If two roots lie in $\mathfrak{m}_R$, their difference times $b_{g_0}(t + t') + d_{g_0} - a_{g_0}$ is zero. The second factor is a unit, so the roots agree.

For a row $q = (t, 1)$, stability of its kernel under $\rho_A(g)$ is equivalent to

$$q\rho_A(g) = \eta_A(g) q, \qquad \eta_A(g) = t b_g + d_g,$$

where the matrix entries are specialized to A. The first component is exactly $b_g t^2 + (d_g - a_g)t - c_g = 0$. Since $\eta_A(g)$ reduces to $\bar{\eta}(g) \neq 0$, it is a unit. Surjectivity of q and multiplication of the matrices show that η_A is a character. It is continuous because ρ_A is continuous. The equations indexed by I make it unramified.

Every ordinary quotient satisfies the equation for g_0. The uniqueness argument over the Artinian local ring A forces t to be the image of t_0. The remaining equations are precisely the images of J_{ord}. Conversely, a map $R^{\mathrm{ord}} \to A$ gives the quotient $(t_0, 1)$ with these properties. Both constructions commute with local O-algebra maps of Artinian coefficient rings. The construction also applies to complete Noetherian local coefficient rings by passage to their Artinian quotients; the normalized rows are compatible by uniqueness. □

The kernel of this quotient is freely generated by $(1, -t_0)$. Consequently every ordinary lift has an exact sequence

$$0 \longrightarrow A(\delta\eta_A^{-1}) \longrightarrow A^2_{\rho_A} \longrightarrow A(\eta_A) \longrightarrow 0, \qquad \eta_A|_I = 1. \tag{86.2}$$

Indeed the action on the kernel is multiplication by $a_g - b_g t_0$, and the determinant is the product of the two characters. The sequence need not split. To prescribe an unramified lift $\eta : G \to O^\times$, add the equations $t_0 b_g + d_g = \eta(g)$ for $g \in G$.

Remark 86.2.2 *(coincident residual characters).* Without $\bar{\alpha} \neq \bar{\eta}$, the quotient must be retained as part of the deformation problem. That problem is still represented by

$$R[[t]] \big/ \overline{\big(b_g t^2 + (d_g - a_g)t - c_g \ (g \in G), \quad t b_h + d_h - 1 \ (h \in I)\big)}.$$

Here t maps into the maximal ideal of each coefficient ring. The same row calculation proves the assertion. For the trivial residual representation and trivial determinant, take the constant trivial lift to $k[u]/(u^2)$. The rows $(au, 1)$ for $a \in k$ give distinct ordinary quotient lines lifting $(0, 1)$. Thus the forgetful map need not be injective on deformation functors when the residual characters coincide.

Hodge types on characteristic-zero lifts

The ordinary equations make sense over Artinian coefficient rings. Hodge and inertial types require characteristic-zero period modules. For a continuous representation V on a finite-dimensional vector space over a finite extension E'/E, put

$$D_{\mathrm{dR}}(V) = (B_{\mathrm{dR}} \otimes_{\mathbb{Q}_p} V)^G.$$

Here B_{dR} is Fontaine's filtered de Rham period field. The representation is de Rham when $\dim_{E'} D_{\mathrm{dR}}(V) = \dim_{E'} V$. We use filtration degrees as Hodge–Tate weights, so the cyclotomic character ε has weight -1. A type $\mathbf{h} = \{h_1, h_2\}$ prescribes the dimensions of $\mathrm{gr}^j D_{\mathrm{dR}}(V)$. Equivalently, Kisin's cocharacter is the conjugacy class of $z \mapsto \mathrm{diag}(z^{-h_1}, z^{-h_2})$.

Let $B_{\mathrm{cris}} \subset B_{\mathrm{st}}$ be Fontaine's crystalline and semistable period rings. For a finite extension $K'/\mathbb{Q}_p$ with maximal unramified subfield K'_0, set

$$D_{\mathrm{st},K'}(V) = (B_{\mathrm{st}} \otimes_{\mathbb{Q}_p} V)^{G_{K'}}, \qquad D_{\mathrm{cris},K'}(V) = (B_{\mathrm{cris}} \otimes_{\mathbb{Q}_p} V)^{G_{K'}}.$$

The representation is potentially semistable, respectively potentially crystalline, when for some K' the corresponding module is free of rank $\dim_{E'} V$ over $K'_0 \otimes_{\mathbb{Q}_p} E'$. Its potentially semistable period module is

$$D_{\mathrm{pst}}(V) = \varinjlim_{K'} D_{\mathrm{st},K'}(V).$$

Inertia acts linearly on this module over $\overline{\mathbb{Q}}_p^{\mathrm{nr}} \otimes_{\mathbb{Q}_p} E'$. An inertial type is a continuous representation $\tau : I \to \mathrm{GL}_2(E)$ with open kernel; V has this type when its inertia representation on $D_{\mathrm{pst}}(V)$ is isomorphic to τ after scalar extension. Here $\overline{\mathbb{Q}}_p^{\mathrm{nr}}$ is the maximal unramified extension of $\mathbb{Q}_p$ inside its chosen algebraic closure. This is the period-module action, not the inertia action on V. Choose E large enough to define τ and the Hodge type. Kisin constructs quotients $R_{\mathrm{pst}}^{\square,\mathbf{h},\tau}$ and $R_{\mathrm{pcris}}^{\square,\mathbf{h},\tau}$ of $R^{\square}$. Their characteristic-zero points specify potentially semistable and potentially crystalline lifts of these types, respectively (Kisin, *The structure of potentially semi-stable deformation rings*, Theorems 1.2.1–1.2.2, pp. 6–7).

For $\star \in \{\mathrm{pst}, \mathrm{pcris}\}$ define the actual fixed-determinant intersection ring and its generic fibre by

$$S_\star = R_\star^{\square,\mathbf{h},\tau} \otimes_{R^{\square}} R, \qquad X_\star = \operatorname{Spec} S_\star[1/p].$$

Both factors are quotient rings, so this tensor product is an ordinary quotient of $R^{\square}$. It is already complete and Noetherian. A continuous map $S_\star \to \mathcal{O}_{E'}$ gives a framed lattice of determinant δ whose rational representation has the indicated type. Conversely, every such lattice with a chosen frame reducing to the given residual frame gives this map: Kisin's factorization criterion first applies over E', and the defining ideal then vanishes already in the torsion-free ring $\mathcal{O}_{E'}$. Here coefficient extensions carry a fixed residue-field embedding, and all integral maps are continuous local $\mathcal{O}$-algebra maps. The scheme $X_\star$ also retains the infinitesimal structure of the intersection. No flatness or reducedness of $S_\star$ is needed for this construction. Incompatible determinant and type conditions can give an empty generic fibre.

The schematic closure of the generic fibre in $\operatorname{Spec} S_\star$ is defined by the p-power torsion ideal. Its coordinate ring is $S_\star/S_\star[p^\infty]$, where $S_\star[p^\infty] = \{x : p^n x = 0 \text{ for some } n\}$. This quotient is p-torsion-free, hence flat over the discrete valuation ring $\mathcal{O}$. It has no effect after inverting p, but can change the special fibre. The integral intersection and its generic fibre must therefore remain distinct.

Under the distinguished quotient hypothesis, define

$$X_\star^{\mathrm{ord}} = \operatorname{Spec}\big((S_\star/J_{\mathrm{ord}}S_\star)[1/p]\big), \qquad X_\star^{\mathrm{rest}} = X_\star \setminus X_\star^{\mathrm{ord}}.$$

The first is a closed subscheme and the second its open complement. This gives a two-piece decomposition within the specified lifting space. The ordinary condition is relative to the chosen residual quotient $\bar{q}$.

Corollary 86.2.3 *(ordinary lifts of a prescribed type).* A continuous point $S_\star \to \mathcal{O}_{E'}$ lies in the ordinary piece precisely when its framed lattice has an unramified quotient lifting $\bar{q}$. On this piece its rational representation has an exact sequence

$$0 \longrightarrow E'(\delta\eta^{-1}) \longrightarrow V \longrightarrow E'(\eta) \longrightarrow 0, \qquad \eta|_I = 1,$$

and has the prescribed Hodge and inertial types.

Proof. Factoring through R^{ord} is equivalent to the ordinary quotient property by the proposition. Apply (86.2) and invert p. The quotient $R_\star^{\square,\mathbf{h},\tau}$ imposes the type. If the equations vanish only after inverting p, they already vanish in the torsion-free ring $\mathcal{O}_{E'}$. □

For the potentially Barsotti–Tate problem in the Tate-module convention, take $\star = \mathrm{pcris}$ and $\mathbf{h} = \{-1, 0\}$, with a specified inertial type. The dual convention has weights $\{0, 1\}$. Other Hodge types require other quotient rings. These spaces do not give an exhaustive decomposition of all residual points. They describe lifts above a fixed residual representation. For example, with $a = p - 1$, the representations $1 \oplus \varepsilon$ and $\varepsilon^a \oplus \varepsilon^{1-a}$ have the same reduction and determinant. Their Hodge–Tate multisets are $\{0, -1\}$ and $\{1 - p, p - 2\}$, respectively.

The categorical comparison

To compare these deformation spaces with categorical local Langlands, fix a continuous central character $\zeta : \mathbb{Q}_p^\times \to O^\times$. Use local reciprocity sending a uniformizer to geometric Frobenius, and require the already fixed determinant to satisfy $\delta = \zeta\varepsilon^{-1}$ as a Galois character. These are the conventions of (Dotto–Emerton–Gee, arXiv:2603.26887, §1.3, p. 8).

Let $\mathcal{A}_\zeta$ be smooth $\mathrm{GL}_2(\mathbb{Q}_p)$ representations on p-power torsion O-modules with central character ζ. Let $\mathcal{X}_\delta$ be the formal stack of rank-two projective étale (φ,Γ)-modules with a specified isomorphism of their determinant with the rank-one module attached to δ. Morphisms preserve this isomorphism; this is the fibre-product definition in (Dotto–Emerton–Gee, arXiv:2603.26887, Definition C.1.1, p. 265). The Dotto–Emerton–Gee functor is

$$F : D(\mathcal{A}_\zeta) \longrightarrow \mathrm{Ind}\, D^b_{\mathrm{coh}}(\mathcal{X}_\delta).$$

It is exact, colimit-preserving and fully faithful (Dotto–Emerton–Gee, arXiv:2603.26887, Theorem 1.1.1 and its following paragraph, p. 3).

Let $\bar\theta$ be the residual pseudorepresentation of $\bar\rho$. The completion of $\mathcal{X}_\delta$ along the fibre over $\bar\theta$ is the moduli stack of Galois representations deforming that pseudorepresentation, with the specified determinant identification (Dotto–Emerton–Gee, arXiv:2603.26887, §1.1.6, p. 4). The universal representation defines a morphism

$$\mathrm{Spf}\, R \longrightarrow \widehat{\mathcal{X}}_{\delta,\bar\theta} \longrightarrow \mathcal{X}_\delta$$

as follows. Reduce ρ_R modulo each power of its maximal ideal, apply the equivalence between continuous Galois representations and étale (φ,Γ)-modules over these finite coefficient rings, and retain the determinant identification sending the wedge of the two frame vectors to 1 in the character module of δ. This construction is compatible with tensor products and base change (Dotto–Emerton–Gee, arXiv:2603.26887, Appendix C.2, especially (C.2.1)–(C.2.2), p. 268, and Remark C.2.17, p. 272). The compatible objects define the displayed formal morphism. Their residual pseudorepresentation is $\bar\theta$, so the map factors through the indicated completion. A change of basis preserving the determinant identification gives an isomorphism in that stack; scalar automorphisms ± 1 remain. The ordinary and type quotients give morphisms into this diagram. For the type quotients these are the maps from $\mathrm{Spf}\, S_\star$; the ordinary intersection uses $\mathrm{Spf}(S_\star/J_{\mathrm{ord}}S_\star)$. These are morphisms of formal moduli problems, whereas $X_\star$ denotes the separately defined scheme after inverting p. They do not identify the source formal schemes with the stack, which retains automorphisms.

Essential surjectivity on a specified ordinary or potentially Barsotti–Tate category requires a full stable source subcategory, a full stable target subcategory, and a proof that F restricts between them. The deformation maps alone do not specify these categories or their generators. The functor on the entire target is not an equivalence (Dotto–Emerton–Gee, arXiv:2603.26887, Remark 1.1.2, p. 3). This statement does not decide equivalence on a specified smaller target.

Proposition 86.2.4 *(generation criterion for a restricted functor).* Let $\mathcal{C},\mathcal{D}$ be presentable stable ∞-categories. Suppose an exact colimit-preserving fully faithful functor $F_0 : \mathcal{C} \to \mathcal{D}$ is supplied. If objects $P_i \in \mathcal{C}$ have images generating $\mathcal{D}$ under colimits, shifts and cofibres, then F_0 is an equivalence.

Proof. Full faithfulness makes the essential image a full subcategory equivalent to $\mathcal{C}$. Every diagram in that image can therefore be lifted to $\mathcal{C}$. Preservation of colimits makes its colimit in $\mathcal{D}$ another image object. Exactness gives closure under shifts and cofibres. The essential image contains the specified generators and hence all of $\mathcal{D}$. □

The local arithmetic construction needed for this criterion is the identification of $F(P_i)$ with actual spectral objects, together with a proof of target generation. If lifting conditions overlap, their union must generate all required extension objects. A direct-sum assembly additionally requires orthogonality. Neither modularity of a lift nor a ring of scalar actions establishes these categorical properties.

Line and quotient conventions. The ordinary lifting problem just constructed retains an unramified *quotient*. Its kernel has character $\delta\eta^{-1}$ and need not be unramified. The ordinary-line comparison of Chapter 70 uses a different flag condition: an unramified subrepresentation. Dualizing a quotient of V gives an unramified subrepresentation of $V^\vee$, with determinant δ^{-1}; it does not identify the two conditions on the same V. Any use of the line convention in the comparison below must specify this dualization or another proved flag comparison, including the central-character and Hodge-sign changes.

Definition 86.2.5 *(fixed-type non-ordinary comparison loci).* For a specified framed residual representation, determinant, inertial type and Hodge type, use the actual lifting space $X_\star$ and its relative ordinary closed subspace $X_\star^{\mathrm{ord}}$ constructed above. Its open complement is $X_\star^{\mathrm{rest}}$. The potentially Barsotti–Tate case uses weights $\{-1, 0\}$ in the Tate-module convention, or $\{0, 1\}$ after dualization. The higher-weight supersingular comparison concerns suitable crystalline lifts of dual weights $\{0, k-1\}$, $2 \leq k \leq p-1$, and the relevant equal-slope condition $((k-1)/2, (k-1)/2)$ in that dual convention. Such slope conditions belong to period modules of lifts with a specified Frobenius and valuation normalization, not directly to residual points. Write $\mathcal{X}^{\mathrm{pBT}}_{\bar\rho,\chi}$ and $\mathcal{X}^{\mathrm{ss}}_{\bar\rho,\chi}$ only for the intended arithmetic support categories or loci once their maps have been constructed; these symbols do not assert a partition of the full Emerton–Gee stack.

Remark 86.2.6 *(coverage and residual points).* The two lifts with identical residual representation and determinant but different Hodge types above show why residual points have no unique Hodge type. Neither the pBT type nor the bounded weight range exhausts all lifts. To realize the proposed union $\mathcal{X}^{\mathrm{pBT}} \cup \mathcal{X}^{\mathrm{ss}}$ as a full non-ordinary locus one must construct those loci in a common carrier and prove coverage. The Newton–Hodge comparison remains an additional geometric question, not a consequence of this notation.

Potentially Barsotti–Tate geometry and generators

Lemma 86.2.7 *(the fixed-determinant lifting intersection).* For the prescribed pBT Hodge and inertial type, the ring S_{pcris} constructed above represents the integral fixed-determinant intersection on continuous lattice points; its generic fibre retains that intersection's infinitesimal structure. Its quotient by p-power torsion is flat over $\mathcal{O}$. The map to the determinant-identified spectral stack is a formal moduli morphism, not an identification of the framed ring with that stack.

Proof. The two type/determinant ideals give the displayed quotient intersection. Its lattice-point factorization and formal map were proved above. After dividing by its p-power torsion the ring is torsion-free over a discrete valuation ring, hence flat. No complete-intersection, reducedness, Cohen–Macaulay or relative-dimension-three assertion for this fixed intersection follows from that argument; any such geometric property requires its actual type and determinant hypotheses. □

Conjecture 86.2.8 *(pBT Breuil–Mézard cycle realization).* For each specified inertial type τ, construct the cycle $\mathcal{X}^{\mathrm{BM},\tau}_{p,\chi,\bar\rho}$ and its realization in the chosen pBT support problem, with multiplicities and intersections. Determine coverage and the actual coherent objects attached to these cycles. A cycle does not by itself define a smooth divisor or a transverse scheme-theoretic intersection. The intended cycle and coverage assertions require these additional constructions.

The relevant geometric input is Gee–Kisin (2014), Theorem A, with its fixed-type hypotheses; the relation to the Emerton–Gee stack requires the specified support maps.

Conjecture 86.2.9 *(projective and spectral generators for pBT).* Construct the actual block or pseudocompact carrier, projective covers $\widetilde{\pi}_\tau$ associated to the relevant types $\sigma(\tau)$, and their compact-generating property. Construct spectral objects Q_τ on the chosen pBT support, identify when they can be realized as $\mathcal{O}_{\mathcal{X}^{\mathrm{BM},\tau}}$, prove their singular support and target generation, and construct natural identifications $F(\widetilde{\pi}_\tau) \simeq Q_\tau$ with full derived morphisms. A type is not automatically a projective cover and its cycle is not a coherent generator object without these data.

Colmez (2010), Sections 9.3–9.6, Paškūnas (2013), Kisin and Gee–Kisin retain their representation and deformation roles in this question; numerical cycle multiplicities do not identify these generators.

Theorem 86.2.10 *(conditional pBT non-ordinary essential image).* For $p \geq 5$ under (TW1)–(TW3), suppose full stable presentable source and target subcategories for the chosen pBT non-ordinary lifting condition have been constructed inside the actual DEG source and target. Assume the exact colimit-preserving fully faithful DEG functor restricts between them and that the objects $Q_\tau = F(\widetilde{\pi}_\tau)$ of Conjecture 86.2.9 generate the target. Then the intended restriction

$$\Phi^{\mathrm{DEG}}_{\bar{\rho},\chi}|_{\text{pBT-non-ord}} : \mathrm{D}^{\text{sph-fin,pBT}}([GL_2(\mathbb{Q}_p)])_\chi \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{pBT}}_{\bar{\rho},\chi})$$

is an equivalence, where these names denote those specified carriers. Comparing them with the actual $D(\mathcal{A}_\zeta)$ and $\mathrm{Ind}\, D^b_{\mathrm{coh}}(\mathcal{X}_\delta)$ is part of the hypotheses, not a silent change of category.

Proof. First supply the restricted fully faithful functor. Second specify the spectral support condition; Cohen–Macaulayness does not imply an automatic nilpotent singular support. Third construct the actual $\widetilde{\pi}_\tau$ and Q_τ and their target generation. Fourth the stipulated natural image identifications place the Q_τ in the image. Fifth apply Proposition 86.2.4. These are the five distinct steps of the conditional implication. The lifting rings and modularity statements alone do not supply steps two through four. □

The supersingular comparison

Corollary 86.2.11 *(the pBT range under its full comparison data).* Under all the carrier, restriction and generation hypotheses of Theorem 86.2.10, the pBT restriction is an equivalence. Describing its complement as a supersingular support requires an additional common-carrier and coverage theorem; this is not implied by the pBT comparison.

Proof. Apply that theorem. The two different Hodge-type lifts above prevent a residual point from determining a unique such complement by its type. □

Conjecture 86.2.12 *(the supersingular generator comparison).* Construct the intended supersingular support and source subcategory, including the proposed difference $\mathcal{X}^{\mathrm{ss}}_{\bar{\rho},\chi} \setminus \mathcal{X}^{\mathrm{pBT}}_{\bar{\rho},\chi}$ once both are in a common carrier. Identify the images of supersingular projective covers with actual Breuil–Mézard–Newton spectral objects and prove support, full derived morphism comparison and target generation. The resulting restricted DEG functor is then subject to the generation criterion; the construction of these arithmetic data remains open.

Remark 86.2.13 *(nonreduced cycles and supersingular objects).* Nonreduced cycle multiplicities require an actual derived or coherent realization before a generator comparison can be made. A possible Breuil-module or Jordan–Hölder analysis must identify objects and extension maps, not only a multiplicity

list. Kisin's integral p-adic Hodge constructions concern those lifting problems, but do not make the supersingular category the known complement of pBT.

Conventions and comparison hypotheses

The explicit lifting construction uses filtration degrees, in which ε has weight -1. The dual-normalized weights in the intended arithmetic comparison have cyclotomic weight $+1$; dualize both representation and determinant when using them. Newton slopes require the corresponding period Frobenius and valuation normalization. Inertial types belong to the period module, not the residual inertia action. The ordinary unramified-line and quotient conventions are related only by the explicit flag comparison above.

The intended pBT target is a support subcategory, and its comparison with $\mathrm{Ind}\, D^b_{\mathrm{coh}}(\mathcal{X}_\partial)$ must be supplied. Its compact generators, nilpotent support, Hecke action and image maps are the precise missing data. Big image (TW2) and local distinguishedness (TW3) remain separate from the pBT lifting condition. Colmez's functor, Kisin's rings and Gee–Kisin's cycles provide different objects; their existence alone does not prove that the Hecke actions or derived images agree. The supersingular construction remains Conjecture 86.2.12.

86.3 Removal of the Taylor–Wiles Conditions: Dihedral, Nearly-Ordinary, and Serre-Modular Sectors

Global residual sectors and their local restriction

Let S_{fail} be the set of continuous odd irreducible representations $\bar\rho : G_{\mathbb{Q}} \to GL_2(\bar{\mathbb{F}}_p)$ for which (TW2) or the local condition (TW3) fails, with the specified ramification and determinant restrictions. Restriction at p maps these global parameters to local residual representations or pseudorepresentations; it need not be injective.

Definition 86.3.1 *(the non-Taylor–Wiles comparison sectors).* Within S_{fail} consider:

- S^{dihedral}, retaining the notation for the solvable projective-image comparison sector. Its dihedral part consists of quadratic inductions; the tetrahedral A_4 and octahedral S_4 cases are separate solvable cases, not quadratic inductions.
- $S^{\text{nearly-ord}}$, parameters with reducible local restriction and coincident characters for which the specified global nearly-ordinary lifting problem has a lift. The hypotheses of any Skinner–Wiles application are additional requirements.
- $S^{\text{Serre-res}}$, the odd irreducible residual parameters in S_{fail} with reducible restriction to $G_{\mathbb{Q}(\zeta_p)}$, considered with their Serre modularity data.

These are sets of global parameters. Their images under local restriction do not define three orthogonal local categories.

Remark 86.3.2 *(overlap and coverage).* These sets may overlap. A dihedral global parameter can also admit a nearly-ordinary lift, and different global parameters can have the same local restriction. Coverage of S_{fail}, or of a specified local essential-image problem, requires a separate theorem. The non-solvable cases, including A_5, and potential automorphy and descent remain additional questions. Overlap is mathematically significant for a categorical union because extension objects and compatible maps must be retained.

The solvable projective-image comparison

Lemma 86.3.3 *(the Artin modularity input under its actual lift hypotheses).* Suppose an odd irreducible characteristic-zero finite-image Artin lift of the chosen residual parameter has been supplied, with the coefficient and ramification hypotheses of the relevant modularity theorem. In the dihedral case its automorphic construction is induction from the corresponding Hecke character of the quadratic extension. The tetrahedral and octahedral cases use the Langlands–Tunnell theorem and the specified solvable base-change data. The existence of such an Artin lift is not inferred from a residual representation alone.

Modularity input. Apply the corresponding representation-level theorem to that specified lift: Langlands, *Base Change for $GL(2)$* (1980), Arthur–Clozel (1989) for cyclic base change and solvable descent, and Tunnell (1981) for the octahedral case. This application gives no categorical generator or local spectral image without an additional comparison construction. □

86.4 Quadratic induction and ordinary lifting spaces

A quadratic global induction can become reducible at a nonsplit local place. The local character determines this behavior. Ordinary lifting conditions require further data: a residual quotient line, a determinant, and a characteristic-zero lifting space. These data specify the local objects whose images under a categorical Langlands functor must be compared.

Restriction of a quadratic induction

Let $K/\mathbb{Q}$ be quadratic. Fix a place v of $\mathbb{Q}$ and compatible decomposition groups. Let L be a coefficient field, and let $\psi : G_K \to L^\times$ be continuous. Here G_F denotes the absolute Galois group of a field F, and L is equipped with its specified field topology. All representation spaces carry the corresponding finite-dimensional topology. Induction from an open subgroup of finite index means ordinary algebraic induction, with its induced continuous action.

If v splits in K, the double-coset decomposition gives

$$\operatorname{Ind}_{G_K}^{G_{\mathbb{Q}}} \psi\Big|_{G_{\mathbb{Q}_v}} \simeq \psi_w \oplus \psi_{w'},$$

where w, w' are the two places above v. The two local characters can coincide. If v is nonsplit, there is one place w above v, and the same decomposition gives

$$\operatorname{Ind}_{G_K}^{G_{\mathbb{Q}}} \psi\Big|_{G_{\mathbb{Q}_v}} \simeq \operatorname{Ind}_{G_{K_w}}^{G_{\mathbb{Q}_v}} \psi_w.$$

These formulas follow by separating functions according to their support on the double cosets $G_K \backslash G_{\mathbb{Q}} / G_{\mathbb{Q}_v}$. There are two cosets in the split case and one in the nonsplit case.

To determine the second representation, let H be an open normal subgroup of index two in a profinite group G. Choose $s \in G \setminus H$. For a continuous character $\chi : H \to L^\times$, put

$$\chi^s(h) = \chi(s^{-1}hs), \qquad c = \chi(s^2).$$

On the induced basis $e_1 = 1 \otimes 1$, $e_2 = s \otimes 1$, the action is

$$\rho(h) = \begin{pmatrix} \chi(h) & 0 \\ 0 & \chi^s(h) \end{pmatrix}, \qquad \rho(s) = \begin{pmatrix} 0 & c \\ 1 & 0 \end{pmatrix}. \tag{86.3}$$

Proposition 86.4.1 *(local irreducibility criterion).* If $\chi \neq \chi^s$, then $\operatorname{Ind}_H^G \chi$ is absolutely irreducible. If $\chi = \chi^s$, its reducibility over L is equivalent to the existence of a root of $T^2 - c$ in L.

Suppose $\chi = \chi^s$ and $b^2 = c$ with $b \in L$. There is a continuous extension $\widetilde{\chi} : G \to L^\times$ with $\widetilde{\chi}|_H = \chi$ and $\widetilde{\chi}(s) = b$. If $\operatorname{char} L \neq 2$, then

$$\operatorname{Ind}_H^G \chi \simeq \widetilde{\chi} \oplus (\widetilde{\chi}\, \omega_{G/H}),$$

where $\omega_{G/H}$ is trivial on H and sends s to -1. In characteristic two the induced representation is a nonsplit self-extension of $\widetilde{\chi}$.

Proof. When the characters differ, choose $h \in H$ with $\chi(h) \neq \chi^s(h)$. Any invariant line over an algebraic closure must be one of the two eigenspaces of $\rho(h)$. The matrix $\rho(s)$ interchanges them, so neither is G-stable.

When the characters agree, H acts by scalars. A G-stable line therefore exists precisely when $\rho(s)$ has an eigenvalue in L. Its characteristic and minimal polynomials are both $T^2 - c$. The prescribed values of $\widetilde{\chi}$ respect conjugation by s and the relation $s^2 \in H$, hence define a character. It is continuous because H is open and χ is continuous. In characteristic different from two the two roots $b, -b$ are distinct, which gives the displayed direct sum. In characteristic two the minimal polynomial is $(T - b)^2$. The matrix is not scalar, so its unique eigenline has no invariant complement. □

Thus over an algebraically closed field, local irreducibility in the nonsplit case is equivalent to $\psi_w \neq \psi_w^s$. Inertness and ramification alone do not decide this equality. Over a smaller coefficient field, an invariant character can instead give an irreducible representation which becomes reducible after scalar extension. Over coefficient rings the matrices in (86.3) still define induction. The field criterion applies after specialization and does not assert an integral direct-sum decomposition.

For a ramified quadratic extension of $\mathbb{Q}_p$ with $p \geq 5$, the ramification index is two, so the extension is tame. A characteristic-zero inducing character can still be nontrivial on wild inertia. For a continuous character valued in $\overline{\mathbb{F}}_p^\times$ with the discrete topology, its image is finite of order prime to p. Its restriction to wild inertia is therefore trivial. Since the quadratic extension is tame, wild inertia lies in the inducing subgroup and acts trivially on the induced residual representation.

Example 86.4.2 *(an inert place with reducible restriction).* Let L_0 be the splitting field of $X^3 - 2$. Eisenstein's criterion at 2 and the discriminant -108 give $\operatorname{Gal}(L_0/\mathbb{Q}) = S_3$. The quadratic subfield is $K = \mathbb{Q}(\sqrt{-3})$. Over $\overline{\mathbb{F}}_5$, induction of a nontrivial character of A_3 gives an absolutely irreducible representation of S_3. Complex conjugation is a transposition, so this representation is odd.

The prime 5 is unramified in L_0, and

$$X^3 - 2 = (X - 3)(X^2 + 3X + 4) \pmod 5.$$

The quadratic discriminant is 3, which is nonsquare modulo 5. Frobenius is consequently a transposition. Also $-3 = 2 \pmod 5$ is nonsquare, so 5 is inert in K. The local representation factors through the order-two decomposition group and splits into its $+1$ and -1 Frobenius eigenspaces.

Lemma 86.4.3 *(restriction of a dihedral residual representation).* For a quadratic induction, the split restriction is the sum of the two local characters, which can coincide. At a nonsplit place the restriction is induced from the local quadratic subgroup and is absolutely irreducible exactly when its two conjugate characters differ over an algebraically closed coefficient field. Ramification of the quadratic extension alone specifies no Hodge type. At $p \geq 5$ that quadratic extension is tame, and a discrete mod-p character is trivial on wild inertia.

Proof. The double-coset decomposition, matrix computation and characteristic-two case in Proposition 86.4.1 prove these statements. The inert prime 5 example shows why inertness alone cannot imply irreducibility. A comparison with the Colmez Montreal functor, including its actual block and coefficient category, remains additional arithmetic data; it is not a consequence of the restriction formula. □

Theorem 86.4.4 *(conditional local comparison on the solvable sector).* For $p \geq 5$ and a full central character, fix a residual parameter in S^{dihedral} and its actual local restriction. Construct full stable source and target subcategories in the DEG carriers, with an exact colimit-preserving fully faithful restricted functor. If specified source objects have images generating that target, the restriction is an equivalence. Hecke compatibility with an Arthur–Clozel or Langlands–Tunnell automorphic realization additionally requires the specified natural comparison of those actions.

Proof. First identify the actual local residual block. For the dihedral part, Lemma 86.4.3 gives its restriction. Second, the split characters can coincide and the inert restriction can be reducible; test the local characters rather than infer a block from the splitting name. Global induced irreducibility need not fail. Third, quadratic ramification at $p \geq 5$ is tame and specifies no Hodge type; the type and spectral generator must be constructed. Fourth, the automorphic realization requires the actual lift and modularity hypotheses of Lemma 86.3.3, plus the natural Hecke comparison. Fifth, once the stipulated restricted functor and image generators exist, apply Proposition 86.2.4. This proves the conditional implication for the named solvable cases, not the existence of their arithmetic generators. □

The Nearly-Ordinary Sector

Conjecture 86.4.5 *(the nearly-ordinary modularity and ring comparison).* For the specified global nearly-ordinary deformation problem, verify the full local and global hypotheses of the applicable Skinner–Wiles theorem and construct its Hecke algebra and comparison $R^{\text{n-ord}}_{\bar{\rho},\chi} \to \mathbf{T}^{\text{n-ord}}_{\bar{\rho}}$. The intended $R = T$ and automorphic Hida-family realization require those hypotheses; existence of a nearly-ordinary lift alone does not establish either. The global deformation ring is distinct from the local determinant-identified stack and the local quotient ring constructed above.

Skinner–Wiles' nearly-ordinary and residually reducible modularity theorems concern these global problems with their stated hypotheses. The local quotient construction above also retains coincident residual characters and the nonunique quotient line.

Theorem 86.4.6 *(conditional nearly-ordinary DEG comparison).* For every $p \geq 5$, full central character and chosen parameter in $S^{\text{nearly-ord}}$, suppose the local source and spectral support subcategories and restricted fully faithful, exact, colimit-preserving DEG functor are constructed. If the specified source objects have images generating the target, the restriction is an equivalence.

Proof. The first required construction is the actual source generator; a Hida family's scalar algebra alone is not a projective generator of a local block. The second is its spectral object and image map; a formal scheme omits the stack stabilizers. The third is target generation with the required singular support; a Noetherian or Cohen–Macaulay ring does not make its structure sheaf generate an arbitrary ind-coherent support category. With those three hypotheses, the fourth step is Proposition 86.2.4, which proves the asserted equivalence. A global $R = T$ theorem supplies no missing step of this local categorical argument without the specified maps. □

The Serre-Modular Sector

Lemma 86.4.7 *(the residual modularity input).* For the continuous odd irreducible residual representations over $\bar{\mathbb{F}}_p$ considered here, Serre modularity provides a cuspidal modular eigenform realizing the residual representation. The precise minimal weight and conductor, and any asserted range $2 \le k(\bar{\rho}) \le p+1$, require the chosen Serre-weight and twist conventions; they are not used to infer local categorical projectives or support objects.

Residual modularity input. This is the representation-level content of Khare–Wintenberger, *Serre's modularity conjecture*, Parts I and II (2009). Its use here concerns residual modularity; the weight, level and local lifting refinements must retain their exact hypotheses. □

Conjecture 86.4.8 *(modularity lifting and the type-to-cycle comparison).* For a residually modular odd irreducible $\bar{\rho}$ and a lift $\rho : G_{\mathbb{Q}} \to GL_2(\bar{\mathbb{Q}}_p)$, verify the local deformation, p-adic Hodge, ramification and global hypotheses of the applicable Kisin modularity-lifting theorem. The lifting space and type-to-cycle map must also be specified. Residual modularity does not imply that every lift is modular, nor does modularity identify a cycle with a coherent generator.

Kisin's Fontaine–Mazur and modularity-lifting work, together with Gee's prescribed-type lifting problem, supplies the relevant arithmetic context. The fixed-type intersections constructed above are local lifting spaces, not an automorphy theorem.

Theorem 86.4.9 *(conditional Serre-sector DEG comparison).* For $p \ge 5$, a full central character and a chosen parameter in $S^{\text{Serre-res}}$, suppose the actual local block, spectral support category and restricted fully faithful exact colimit-preserving DEG functor are supplied. If chosen projective or compact source objects have images generating the target, that restriction is an equivalence.

Proof. First a modular eigenform realizing $\bar{\rho}$ is not itself an identified compact projective cover; construct the proposed $\widetilde{\pi}_{f,p}$. Second construct the specified type/cycle objects and natural image comparison, including the proposed map $F(\widetilde{\pi}_{f,p}) \simeq \mathcal{O}_{\mathcal{X}^{\mathrm{BM},k(\bar{\rho})}_{p,\chi,\bar{\rho}}}$ when that coherent object is defined. Third prove target generation and singular support for the actual Serre-weight family. Fourth, under these stipulated data, apply Proposition 86.2.4. This retains the arithmetic generator question rather than deducing it from a residual eigenform or cycle multiplicities. □

Assembly on the Union of Non-Taylor–Wiles Sectors

Theorem 86.4.10 *(conditional assembly on the union of sectors).* Fix the common local DEG source and target at $p \ge 5$ and a full central character. Suppose the sector restrictions above are actual full subcategories, their image comparisons hold, and the union of their image objects generates the intended target subcategory under colimits, shifts and cofibres. Then the restriction to their generated source is an equivalence onto that target. This includes the ordinary comparison only with all its own carrier and image hypotheses.

Proof. The ambient fully faithful functor remains fully faithful on the specified generated source. Its image is closed under colimits and cofibres and contains the assumed target generators. Apply the generation criterion. Distinct global sector names do not imply orthogonal local blocks. A direct-sum version would additionally require both cross mapping spectra to vanish; otherwise the extension data must be retained as in Chapter 85. □

The non-solvable comparison and the actual complement

Corollary 86.4.11 *(the complement after specifying the covered set).* The uncovered global parameter set is, by definition,

$$S_{\mathrm{fail}} \setminus (S^{\mathrm{dihedral}} \cup S^{\mathrm{nearly\text{-}ord}} \cup S^{\mathrm{Serre\text{-}res}}).$$

Identifying it with a particular projective-image class, or identifying its local image with a complementary spectral subcategory, requires a further classification and support theorem. No assertion that it consists exactly of A_5 parameters follows from the sector definitions.

Proof. The displayed set is precisely the complement of the stated union. Local restriction need not preserve disjointness, so no categorical complement follows from this set identity. In particular, a large-image parameter is not automatically in a set defined by failure of (TW2). □

Conjecture 86.4.12 *(the non-solvable non-nearly-ordinary comparison).* For the intended non-solvable, non-nearly-ordinary local target, including the projectively A_5 case, construct the actual source objects, spectral images, derived comparison and target generation. An automorphic route must specify the Artin or geometric lift, Taylor's potential-automorphy hypotheses, the applicable Barnet-Lamb–Gee–Geraghty lifting hypotheses, descent, and any Emerton patching data. These arithmetic inputs alone do not supply the categorical generator comparison.

Remark 86.4.13 *(projective images and descent).* The projective-image cases to distinguish include cyclic, dihedral, A_4, S_4, A_5 and the finite-field PSL_2/PGL_2 cases in the appropriate finite-subgroup classification. Their relation to (TW2), local distinguishedness and the actual uncovered set must be proved. Taylor's icosahedral Artin problem and the potential automorphy of Hilbert modular representations have different hypotheses. Descent back to $\mathbb{Q}$ and comparison of local generators remain additional constructions, even when an automorphic lift over an extension has been obtained.

Conventions for the global sector comparisons

Serre's residual modularity, Arthur–Clozel base change, Skinner–Wiles nearly-ordinary deformation theory, Taylor's potential automorphy and Barnet-Lamb–Gee–Geraghty lifting retain their respective hypotheses. Their Hecke eigenvalues require a chosen coefficient field, local-global compatibility and a map to the fixed local problem. The Hodge convention and determinant must be translated as above; weight-space variables and U_p eigenvalues are different data.

The actual local source is a block or a specified full stable subcategory of $D(\mathcal{A}_\zeta)$, and the actual spectral target is a specified support subcategory of $\mathrm{Ind}\, D^b_{\mathrm{coh}}(\mathcal{X}_\delta)$. Identifying the sph-fin and nilpotent-support notation with these carriers requires comparison maps. Modularity, scalar $R = T$, finite subgroup classification and existence of cycles do not replace those maps.

86.5 The Conditional Equivalence for the Local Functor

Union of the strata

Theorem 86.5.1 *(conditional essential image on generated sectors).* For every $p \geq 5$ and full central character, suppose the ordinary, pBT non-ordinary and the three named non-Taylor–Wiles comparisons have their complete carrier, support, restriction and generator data. Suppose their source objects lie in one common stable category and their images generate the chosen target subcategory, retaining all overlap and extension objects. Then the restricted DEG functor is an equivalence onto that

target. The ordinary case retains (TW1)–(TW4), the pBT comparison its stated (TW1)–(TW3), and each global sector its own modularity and local comparison hypotheses.

Proof. The fully faithful exact colimit-preserving restriction has image closed under the generating operations and containing the stipulated generators. Proposition 86.2.4 applies. No pairwise orthogonality of these global sector names is used. □

The remaining essential-image construction

Conjecture 86.5.2 *(the non-ordinary and non-Taylor–Wiles comparison).* The full intended essential-image problem still asks for the supersingular support and generator construction of Conjecture 86.2.12 and the non-solvable non-nearly-ordinary comparison of Conjecture 86.4.12. Showing that these are all remaining sectors requires an actual common carrier, coverage theorem and extension-compatible assembly, as well as all unresolved ordinary and pBT generator comparisons. There is no established reduction to two comparisons alone.

Interaction with the full F1 comparison

Conjecture 86.5.3 *(the complete arithmetic comparison diagram).* The five comparison directions remain the supersingular core, the non-solvable non-nearly-ordinary core, the small-prime wild class map, the Eisenstein adelic comparison and geometric Bernstein-centre gluing. They must be assembled with the actual ordinary, pBT, small-prime and cuspidal functors, their support and mapping-spectrum data, and the global diagram of Conjecture 70.7.1. Proving that this diagram realizes the full essential image requires both coverage and gluing; a list of directions is not an equivalence criterion by itself.

86.6 Consequences

Quadratic induction has an explicit local restriction and irreducibility test, including the characteristic-two nonsplit self-extension and an inert-prime reducible example. Fixed-determinant quotient equations construct the relative ordinary lifting problem. Fixed Hodge and inertial types give actual intersection rings, generic fibres and formal maps retaining determinant identifications. None identifies a framed lifting scheme with the spectral stack or assigns a Hodge type to a residual point. These constructions provide objects and maps for the local categorical questions. Their essential images, arithmetic generators, support comparisons and global sector assembly remain the additional constructions specified above.

Primary conventions for the lifting constructions

Kisin, *The structure of potentially semi-stable deformation rings*, uses the framed representability of Section 1.2 and the fixed-type quotient statements of Theorems 1.2.1–1.2.2, pp. 6–7 of the author manuscript. Page references here use that manuscript. Dotto–Emerton–Gee, arXiv:2603.26887, Theorem 1.1.1 and Remark 1.1.2, p. 3, Section 1.1.6, p. 4, and Section 1.3, p. 8, specify the functor, essential-image limit and central-character convention. Definition C.1.1, p. 265, specifies the determinant-identified stack; Appendix C.2, equations (C.2.1)–(C.2.2), p. 268, and Remark C.2.17, p. 272, specify the coefficient-compatible Galois/étale-module comparison.

Chapter 87

F1.a.2 Class-Match at Wild Primes and Paskunas Block-Centraliser Regularity

At the primes $p = 2, 3$, the intended comparison relates arithmetic block extension classes to a tangent fibre of a specified wild-enhanced Emerton–Gee stack. Its construction requires both a block-to-Galois map and a Galois-to-spectral map, with their coefficient and class normalizations. The finite-algebra examples of Chapter 54 supply neither map. The class-match result below is the conditional composition of these two isomorphisms. Multiplicity and block-centraliser data are separate inputs and do not replace the class-level comparison.

87.1 Objects

The Three Boundary Conditions

The Paskunas comparison has three named boundary conditions:

- **F1.a.2.class-match** Chapter 68.7.3): the class-level identification (not merely dimensional) between the Ext^1-classes α_{01} at $p = 2$ and $(\alpha_{01}, \alpha_{12})$ at $p = 3$ on the automorphic side and the degree-1 tangent fibre of the wild-enhanced Emerton–Gee stack.
- **R.B.1** Chapter 71.4.2(R.B.1)): the very-special ordinary-block Breuil–Mezard multiplicity at $p \geq 5$ on the one sub-stratum where Paskunas 2015 did not give the explicit number.
- **R.B.2** Chapter 71.4.2(R.B.2)): the wild-prime block centraliser regularity result, the analogue of Paskunas' $p \geq 5$ block-centraliser Cohen–Macaulay / regular local dimension result at $p \in \{2, 3\}$.

Inherited Objects

The comparison uses the following objects and proposed data:

- the block decomposition of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$ at $p = 2$ (Chapter 70.5.1) and at $p = 3$ (Chapter 70.5.2);
- the BH type list $\mathbf{T}^{\mathrm{BH}}_{p,\chi}$ (Chapter 68.3.1–68.4.1);
- the wild-enhanced Emerton–Gee stack $\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$ (Chapter 61.5.2);
- the coefficient-compatible arithmetic block realizations asked for in Questions 54.4.8 and 54.4.9; these are additional comparison data, not consequences of the finite examples;
- the Paskunas generic-block regularity statement Chapter 71.3.1(1) at $p \geq 5$.

Additional Inputs

The following inputs are logically separate from the preceding automorphic block computations.

Very-special multiplicity datum. The missing Breuil–Mezard values in the very-special ordinary block at $p \geq 5$.

Wild block-centraliser datum. The Cohen–Macaulay and generic regularity statement for the wild blocks at $p = 2, 3$.

Colmez–Dospinescu–Paskunas 2014, §5. p-adic local Langlands at $p = 3$; contains the block centraliser structure for the three principal-block types.

Bellaïche–Chenevier 2009. *Families of Galois representations and Selmer groups*, Astérisque 324. The residual-gerbe Galois deformation functor at a generic point.

Kisin 2008 J. AMS 21. "Potentially semi-stable deformation rings". The tangent and cotangent-complex structure of local Galois deformation rings at $GL_2(\mathbb{Q}_p)$.

Emerton–Gee arXiv:1908.07185 §9. Wild inertia block structure on the spectral side; the component-level description of the wild-enhanced EG stack at $p \in \{2, 3\}$ with explicit tangent sheaves.

Deformation and Block Comparisons

The very-special datum concerns the Breuil–Mezard multiplicity on the specified sub-stratum. The wild centraliser datum concerns the local ring and its generic fibre. The Galois deformation tangent is computed below; identifying it with the automorphic block deformation problem requires an additional comparison map.

The block-to-Galois comparison and the block-centraliser result are different mathematical inputs. In particular, a centraliser calculation or an equality of dimensions does not construct the class-level map in Hypothesis 87.2.8.

87.2 Fi.a.2 Class-Match at Wild Primes

The Class-Level Target

The class-level compatibility statement is the following: each non-semisimple block's Ext^1-class on the automorphic side must correspond, as a specific k-line, to a specified first-order tangent direction on the wild-enhanced EG stack. We write

$$\mathbb{T}^1_{\mathcal{X}}|_x := H^0\big((\mathbb{L}_{\mathcal{X}}|_x)^\vee\big)$$

for this infinitesimal tangent fibre.

Definition 87.2.1 *(the class-match target, $p = 2$).* At $p = 2$, fix χ and the unique non-semisimple principal block $\mathfrak{B}_2$. The *class-match target* is a k-linear isomorphism

$$\mathsf{c}_2^{\mathrm{class}} \colon \mathrm{Ext}^1_{\mathfrak{B}_2}(S_2, S_2') \xrightarrow{\sim} \mathbb{T}^1_{\mathcal{X}^{\mathrm{EG,wild},2,\chi}_{GL_2}}\Big|_{x_{\tau_2}},$$

where the coefficient category, objects S_2, S_2' and a nonzero class α must be specified as in Question 54.4.8. The target is to carry this class to a specified tangent direction at x_{τ_2}. In characteristic two, trivial and sign characters cannot be used as two distinct objects.

Definition 87.2.2 *(the class-match target, $p = 3$).* At $p = 3$, fix χ and the three principal-block types $\tau_{3,0}$, $\tau_{3,1}$, $\tau_{3,2}$. The class-match target is a k-linear isomorphism

$$\mathsf{c}_3^{\mathrm{class}} \colon \mathrm{Ext}^1(L_0, L_1) \oplus \mathrm{Ext}^1(L_1, L_2) \xrightarrow{\sim} \mathbb{T}^1_{\mathcal{X}^{\mathrm{EG,wild},3,\chi}_{GL_2}}\Big|_{x_{\tau_3}},$$

sending the quiver arrows $\alpha_{01} \mapsto e_1$ and $\alpha_{12} \mapsto e_2$ onto the two tangent directions.

Galois-Deformation Functor on Non-Semisimple Blocks

Definition 87.2.3 *(block deformation functor).* Fix $p \in \{2, 3\}$, χ, and a non-semisimple block $\mathfrak{B}$ with reducible residual $\bar{\rho}_{\mathfrak{B}} \colon G_{\mathbb{Q}_p} \to GL_2(\overline{\mathbb{F}}_p)$. The *block deformation functor* $\mathrm{Def}^{\mathfrak{B}}_{\bar{\rho}_{\mathfrak{B}},\chi} \colon \mathrm{CNL}_{W(k)} \to \mathrm{Set}$ sends a complete Noetherian local $W(k)$-algebra A with residue field k to the set of equivalence classes of liftings $\rho_A \colon G_{\mathbb{Q}_p} \to GL_2(A)$ of $\bar{\rho}_{\mathfrak{B}}$ with central character $\chi \cdot \chi_{\mathrm{cyc}}$ whose reduction is in the block $\mathfrak{B}$. Choose a field k over which the residual representation is defined. The determinant is a specified lift of the residual determinant. Equivalence means conjugation by a matrix reducing to the identity, unless the determinant-one convention is explicitly imposed. Any condition connecting lifts to the arithmetic block is additional data.

Lemma 87.2.4 *(fixed-determinant first-order deformations).* Let $\bar{\rho} : G_{\mathbb{Q}_p} \to GL_2(k)$ be continuous. Write $\mathrm{ad}\,\bar{\rho} = M_2(k)$, with conjugation action, and let $\mathrm{ad}^0\,\bar{\rho}$ be its trace-zero submodule. First-order lifts with fixed determinant, modulo unrestricted strict GL_2-conjugation, form

$$D_{\bar{\rho}} = Z^1_{\mathrm{cts}}(G_{\mathbb{Q}_p}, \mathrm{ad}^0\,\bar{\rho})/d(\mathrm{ad}\,\bar{\rho}).$$

If strict conjugation is restricted to determinant-one matrices, the quotient is $H^1_{\mathrm{cts}}(G_{\mathbb{Q}_p}, \mathrm{ad}^0\,\bar{\rho})$.

Proof. Write a lift as $\rho_\epsilon(g) = (1 + \epsilon c(g))\bar{\rho}(g)$. Multiplication gives $c(gh) = c(g) + g \cdot c(h)$. The identity $\det(1 + \epsilon c) = 1 + \epsilon\,\mathrm{tr}(c)$ shows that fixing the determinant imposes trace zero. Conjugating by $1 + \epsilon X$ changes $c(g)$ by $X - g \cdot X$. This is a coboundary up to sign, and its trace is zero for every $X \in M_2(k)$. Determinant-one conjugations instead require $\mathrm{tr}(X) = 0$, giving the second quotient. □

This calculation supplies no character twist and no pro-representability assertion for a reducible unframed deformation problem. Any additional block condition must first be defined on the lifts and their equivalences.

Hypothesis 87.2.5 *(comparison of formal deformation problems).* Specify the coefficient field, determinant condition, framing and allowed conjugations for the block deformation problem. Assume an equivalence between its formal deformation groupoid and the formal completion of the specified wild Emerton–Gee stack at $x_{\tau_{\mathfrak{B}}}$, preserving automorphism groups. A presentation by $\mathrm{Spf}\, R^{\mathfrak{B}}_{\bar{\rho},\chi}$ requires separate pro-representability and the absence or removal of stabilizers. A formal stack with nontrivial stabilizers is not the formal spectrum of a ring.

Residual Gerbe Comparison

Definition 87.2.6 *(residual gerbe).* For a closed point x of a formal algebraic stack $\mathcal{X}$ with residue field k and automorphism group $\mathrm{Aut}(x)$, the *residual gerbe* $\mathcal{G}_x$ is the closed substack $B\mathrm{Aut}(x) \subset \mathcal{X}$. For $x_{\tau_{\mathfrak{B}}} \in \mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}$ the automorphism group is the centraliser $Z_{GL_2}(\bar{\rho}_{\mathfrak{B}})$.

Hypothesis 87.2.7 *(spectral tangent comparison).* For the specified deformation problem, assume a natural isomorphism

$$\mathbb{T}^1_{\mathcal{X}^{\mathrm{EG,wild},p,\chi}_{GL_2}}\Big|_{x_{\tau_{\mathfrak{B}}}} \xrightarrow{\sim} D_{\bar{\rho}_{\mathfrak{B}}},$$

where D is the first-order quotient in Lemma 87.2.4. Use its determinant-one variant only when that is the chosen equivalence relation. Require compatibility with the specified arithmetic classes. The notation $\mathbb{T}^1$ above denotes H^0 of the tangent complex. It does not identify this space with H^1 of that complex.

Hypothesis 87.2.8 *(the arithmetic block-to-Galois comparison).* For the specified arithmetic block $\mathfrak{B}$, coefficient field, objects and determinant condition at $p \in \{2, 3\}$, suppose there is a natural isomorphism from the relevant block extension space to $D_{\bar{\rho}_{\mathfrak{B}}}$, carrying the selected extension classes to the specified deformation classes. The coefficient convention and this compatibility are part of the hypothesis.

The finite-algebra resolutions in Chapter 54 do not establish this arithmetic isomorphism. One must construct the block functor and verify its induced map on extensions in the stated coefficient category. At three, a comparison with the radical-square-zero three-vertex model also carries a nonzero adjacent Yoneda product in degree two; it cannot be discarded by the algebra's path relation.

Class-Match Theorem

Theorem 87.2.9 *(F1.a.2 class-match, $p \in \{2, 3\}$).* Assume the wild-EG datum of Conjecture 61.5.7, Hypothesis 87.2.8, and the natural Galois-to-tangent isomorphism of Hypothesis 87.2.7, including its class compatibility. Then the class-match isomorphisms $\mathsf{c}_2^{\mathrm{class}}$ and $\mathsf{c}_3^{\mathrm{class}}$ of Definition 87.2.1 and Definition 87.2.2 exist and are natural in the block $\mathfrak{B}$. The automorphic Ext^1-classes α (at $p = 2$) and α_{01}, α_{12} (at $p = 3$) are sent to the tangent directions e_1 (at $p = 2$) and e_1, e_2 (at $p = 3$) respectively.

Proof. Compose the stipulated block-to-deformation map with the inverse of the stipulated spectral-to-deformation map:

$$\mathrm{Ext}^1_{\mathfrak{B}} \xrightarrow{\sim} D_{\bar{\rho}_{\mathfrak{B}}} \xrightarrow{\sim} \mathbb{T}^1_{\chi}|_{x_{\tau_{\mathfrak{B}}}}.$$

Both maps are natural and preserve the specified class labels by hypothesis. Their composite has the same properties. □

Corollary 87.2.10 *(F1.a.2 full essential surjectivity at $p = 2, 3$).* Under all hypotheses of Theorem 87.2.9, and the block-generation and fully-faithfulness hypotheses of Theorem 70.5.4, the block-diagonal functor $\Phi^{\mathrm{BD}}_{p,\chi}$ of Definition 70.5.3 is essentially surjective at $p \in \{2, 3\}$, hence an equivalence.

Proof. Theorem 70.5.4 establishes fully-faithfulness without the wild-EG hypothesis and essential surjectivity on the semisimple blocks. On each non-semisimple block the only obstruction to essential surjectivity was the class-level match, which is now Theorem 87.2.9. Combining gives full essential surjectivity at $p \in \{2, 3\}$, conditional on all the stated class-comparison and generation hypotheses. □

87.3 R.B.1: Very-Special Ordinary-Block Multiplicity

The Paskunas 2015 Residual

Paškunas 2015 Theorem 1.2 computes the block centraliser structure of the ordinary block at $p \geq 5$ in terms of Breuil–Mezard multiplicities $\mu(\sigma, \bar{\rho})$, except on one explicit sub-stratum: the *very-special* locus where the residual $\bar{\rho}|_{G_{\mathbb{Q}_p}}$ is reducible with scalar semisimplification and cyclotomic twist $\bar{\rho} \sim \chi \oplus \chi\omega$ for a specific character χ (Paškunas 2013 Remark 10.5).

Hypothesis 87.3.1 *(very-special multiplicity input). Conjectural statement.* For $p \geq 5$ and the very-special residual $\bar{\rho} \sim \chi \oplus \chi\omega$, let $\mu_{\mathrm{vs}}(\sigma, \bar{\rho})$ denote the Breuil–Mezard multiplicity of the Serre weight σ. The missing very-special input is the finite list of integers $\{\mu_{\mathrm{vs}}(\sigma, \bar{\rho})\}_{\sigma}$, in the numerical normalisation of Paškunas 2015, satisfying the Breuil–Mezard cycle identity for the scalar residual deformation ring.

Remark 87.3.2 *(multiplicity convention).* The hypothesis is not a formula for the very-special multiplicities. It names the exact numerical input required by the Paškunas centraliser argument.

Corollary 87.3.3 *(R.B.1 conditional implication). Conditional on* Hypothesis 87.3.1. If the datum Hypothesis 87.3.1 holds, then residual (R.B.1) of Proposition 71.4.2 follows.

Proof. The datum supplies exactly the very-special Breuil–Mezard multiplicities requested in (R.B.1). It does not compute all ordinary-block extension groups. The actual local algebra calculation is $\mathrm{Ext}^1_A(k,k) = \mathrm{Hom}_k(\mathfrak{m}/\mathfrak{m}^2, k)$, proved by the connecting map and pushout in Proposition 71.3.5. There is no subtraction by the number of relations. Transferring a specified deformation direction to an extension between distinct arithmetic simples still requires the explicit class comparison in that proposition; the multiplicity datum alone does not supply it. □

87.4 R.B.2: Wild-Prime Block Centraliser Regularity

$p = 2$ centraliser datum

Hypothesis 87.4.1 *($p = 2$ wild block-centraliser datum). Conjectural statement.* Let $p = 2$, $\chi \in \mathrm{Hom}(\mathbb{Z}_2^\times, k^\times)$, and $\mathfrak{B}$ a Paškunas block of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_2)}$ with projective cover $P_{\mathfrak{B}}$. The block centraliser algebra $A_{\mathfrak{B}} := \mathrm{End}_{\mathfrak{B}}(P_{\mathfrak{B}})$ is a complete Noetherian local $W(k)$-algebra of Krull dimension 2. Depending on $\mathfrak{B}$:

(i) *Supersingular blocks.* $A_{\mathfrak{B}}$ is a regular local ring of dimension 2.

(ii) *Twisted-Steinberg block.* $A_{\mathfrak{B}}$ is a Cohen–Macaulay complete Noetherian local ring of dimension 2, which is a quotient of a regular local ring of dimension 3 by a single non-zero-divisor.

(iii) *Principal-series blocks.* $A_{\mathfrak{B}}$ is a Cohen–Macaulay complete Noetherian local ring of dimension 2. Regularity requires a separate datum; the existence of an extension class does not decide it. For example, the regular ring $k[[t]]$ has $\mathrm{Ext}^1_{k[[t]]}(k,k) = k$.

Remark 87.4.2 *(centraliser convention).* This is the $p = 2$ centraliser hypothesis in the complete Noetherian $W(k)$-algebra convention of Paškunas blocks.

Colmez–Dospinescu–Paskunas at $p = 3$

Hypothesis 87.4.3 *($p = 3$ wild block-centraliser datum). Conjectural statement.* Let $p = 3$, $\chi \in \mathrm{Hom}(\mathbb{Z}_3^\times, k^\times)$, and $\mathfrak{B}$ a CDP block. The block centraliser $A_{\mathfrak{B}}$ is a complete Noetherian local $W(k)$-algebra satisfying:

(i) Supercuspidal blocks: $A_{\mathfrak{B}}$ is a regular local ring of dimension 2.

(ii) Principal-series non-Steinberg blocks: $A_{\mathfrak{B}}$ is a Cohen–Macaulay complete Noetherian local ring of dimension 3.

(iii) Steinberg / twisted-Steinberg principal block: $A_{\mathfrak{B}}$ is a Cohen–Macaulay complete Noetherian local ring of dimension 3, a quotient of a regular local ring of dimension 4 by a non-zero-divisor.

Remark 87.4.4 *(centraliser convention).* This is the $p = 3$ centraliser hypothesis in the complete Noetherian $W(k)$-algebra convention of Colmez–Dospinescu–Paškunas blocks.

Unified Wild-Prime Block Centraliser Theorem

Theorem 87.4.5 *(R.B.2 conditional implication: wild-prime block centraliser regularity). Conditional on* Hypothesis 87.4.1 and Hypothesis 87.4.3. Let $p \in \{2,3\}$, χ, and $\mathfrak{B}$ a block of $\mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$. The block centraliser $A_{\mathfrak{B}}$ is a complete Noetherian local $W(k)$-algebra of:

- Krull dimension 2 at $p = 2$;

- Krull dimension 3 at $p = 3$ for principal-series blocks, and 2 for supercuspidal blocks.

It is Cohen–Macaulay, and regular on supersingular / supercuspidal blocks. If $A_{\mathfrak{B}}$ is additionally reduced, its total quotient ring is a finite product of fields. Reducedness is a separate hypothesis for the other blocks.

Proof. At $p = 2$ apply Hypothesis 87.4.1: all blocks are Cohen–Macaulay of dimension 2; supersingular blocks are regular; the twisted-Steinberg block is a hypersurface, and the principal-series blocks are Cohen–Macaulay by the stated datum. At $p = 3$, the second datum gives the stated dimensions and Cohen–Macaulay property, and regularity for supercuspidal blocks. Being a hypersurface does not imply generic regularity: the ring $k[[t, u, \epsilon]]/(\epsilon^2)$ remains nonreduced at its minimal prime. If the centraliser is reduced, its localizations at minimal primes are fields, and its total quotient ring is their finite product. This is the additional assertion under reducedness. □

Corollary 87.4.6 *(conditional* Ext^1*-vanishing at wild primes).* Let $p \in \{2, 3\}$, and assume the centraliser datum of Theorem 87.4.5. Assume in addition that $A_{\mathfrak{B}}$ is reduced and that the specified arithmetic generic-fibre category is equivalent, by an exact localization or Morita comparison, to modules over its total quotient ring $Q(A_{\mathfrak{B}})$. Suppose this comparison identifies localized extension groups for the finite modules under consideration. Then

$$\mathrm{Ext}^1_{\mathfrak{B}}(S, S') \otimes_{A_{\mathfrak{B}}} Q(A_{\mathfrak{B}}) = 0.$$

Thus the specified generic-fibre category is semisimple. This does not assert vanishing at regular closed points.

Proof. A reduced Noetherian ring has total quotient ring a finite product of fields. Every short exact sequence of modules over that ring splits. The stipulated comparison therefore identifies the displayed localized extension group with zero, exactly as in Corollary 71.3.9. Neither the hypersurface presentation nor a dimension equality constructs this arithmetic comparison. In contrast, $\mathrm{Ext}^1_{k[[t]]}(k, k) = k$ at the regular closed point. □

87.5 Consequences for F1.a.3

Conditional Boundary

Theorem 87.5.1 *(F1.a.3 boundary after the wild class comparison).* The F1.a.3 conditions of Proposition 71.4.4 have the following form.

- **(R.A)** Per-block BH type-block comparison.
- **(R.B.1)** Very-special ordinary-block Breuil–Mezard: Hypothesis 87.3.1 is the exact multiplicity input.
- **(R.B.2)** Wild-prime block centraliser regularity: the $p = 2, 3$ centraliser data are Hypothesis 87.4.1 and Hypothesis 87.4.3.
- **(R.C)** Wild-EG compact generation (Conjecture 68.7.5).
- **F1.a.2.class-match**: follows from Theorem 87.2.9 (conditional on the wild-EG enhancement and both class-compatible isomorphisms specified in that theorem).

Proof. This is the direct combination of Corollary 87.3.3, Theorem 87.4.5, and Theorem 87.2.9. □

Corollary 87.5.2 *(F1.a.3 remaining conditions).* Without the conditional inputs named above, F1.a.3 consists of:

(i) (R.A) Per-block BH type-block comparison.
(ii) (R.B.1) Very-special ordinary-block Breuil–Mezard datum.
(iii) (R.B.2) Wild-prime block-centraliser datum.
(iv) (R.C) Wild-EG compact generation.
(v) The actual block-to-Galois and spectral class comparisons of Theorem 87.2.9.

Proof. Direct from Theorem 87.5.1. □

87.6 Sources and Conventions

Class-Match Sources and Conventions

The intended comparison passes from extensions in the chosen arithmetic block to determinant-fixed Galois deformation classes and then to the spectral tangent fibre. The block functor, coefficient ring and induced extension isomorphism must be established in Hypothesis 87.2.8. The spectral map must separately identify the actual deformation functor and preserve the selected classes. Once both maps are natural isomorphisms, their composition is natural. Neither equal dimensions nor a block-centraliser theorem alone gives these maps.

R.B.1 Conventions

R.B.1 is the implication from the datum Hypothesis 87.3.1. Its multiplicity convention is the Paškunas 2015 numerical convention for the Breuil–Mezard deformation ring of the scalar residual $\bar{\rho} \sim \chi \oplus \chi\omega$.

R.B.2 Conventions

R.B.2 is the implication from the data Hypothesis 87.4.1 and Hypothesis 87.4.3. These data are stated in the complete Noetherian $W(k)$-algebra convention used for the block centralisers.

87.7 Consequences

(i) F1.a.2.class-match holds at $p \in \{2, 3\}$ as Theorem 87.2.9, conditional on the wild-EG enhancement Conjecture 61.5.7, the actual block-to-Galois isomorphism of Hypothesis 87.2.8, and the class-compatible residual-gerbe identification on the EG side. The class labels α (at $p = 2$) and α_{01}, α_{12} (at $p = 3$) match the tangent directions through the composition residual-gerbe tangent identification $\circ$ block-to-Galois map.
(ii) R.B.1 is the very-special ordinary-block Breuil–Mezard multiplicity input Hypothesis 87.3.1.
(iii) R.B.2 (wild-prime block centraliser regularity at $p \in \{2, 3\}$) is the $p = 2, 3$ centraliser data Hypothesis 87.4.1 and Hypothesis 87.4.3 are supplied.
(iv) F1.a.3 contains (R.A), (R.B.1), (R.B.2), and (R.C) unless the corresponding inputs are imposed.
(v) The source and convention comparison is recorded in Section 87.6.

Thus the wild class-match is a composition theorem conditional on the wild-EG datum and both class-compatible comparison isomorphisms. The very-special multiplicity and wild centraliser statements are separate algebraic inputs.

87.8 References on Local Langlands and Deformation Theory

Primary sources used in this chapter:

- P. Colmez, G. Dospinescu, and V. Paškunas, ''The p-adic local Langlands correspondence for $GL_2(\mathbb{Q}_p)$'', Cambridge J. Math. 2 (2014), 1–47.
- V. Paškunas, ''The image of Colmez's Montreal functor'', Publ. IHES 118 (2013), 1–191.
- V. Paškunas, ''On the Breuil–Mézard conjecture'' (2015).
- J. Bellaïche and G. Chenevier, *Families of Galois representations and Selmer groups*, Astérisque 324, SMF (2009).
- M. Kisin, ''Potentially semi-stable deformation rings'', J. AMS 21 (2008), 513–546.
- M. Emerton and T. Gee, ''Moduli stacks of étale (φ, Γ)-modules and the existence of crystalline lifts'', arXiv:1908.07185 (2019).
- L. Schlessinger, ''Functors of Artin rings'', Trans. AMS 130 (1968), 208–222.
- B. Mazur, ''Deforming Galois representations'', in *Galois Groups over* $\mathbb{Q}$, MSRI Publ. 16 (1989).

Proposition-level separation of sources:

- Class-match (Theorem 87.2.9) requires the actual block-to-Galois map of Hypothesis 87.2.8 and the spectral tangent comparison. The local Langlands and deformation references identify possible inputs; their applicability to these particular coefficients, objects and classes must be proved.
- R.B.1 (Corollary 87.3.3) is conditional on the very-special multiplicity datum Hypothesis 87.3.1.
- R.B.2 (Theorem 87.4.5) is conditional on the $p = 2, 3$ centraliser data Hypothesis 87.4.1 and Hypothesis 87.4.3.

At the proposition level, the class-match theorem keeps its automorphic and spectral sources distinct. The R.B.1 and R.B.2 statements are the conditional inputs displayed above.

Chapter 88

Global Centre Actions and the Arithmetic Comparison

Local central actions generate an algebra of endomorphisms of a global object. Identifying that algebra with a global Bernstein centre requires faithfulness and generation. Identifying it with a derived spectral centre also requires a comparison of higher operations. A complete local determinant ring, an ordinary category centre, and a derived centre are different objects in these problems.

Two calculations constrain a proposed arithmetic construction. The regular nilpotent orbit in $\mathfrak{sl}_2$ has codimension one, not two. Moreover, a complete local ring cannot split as a product of two nonzero Bernstein components, although its generic fibre can split. These calculations leave concrete geometric and algebraic maps to be constructed before a global comparison follows.

88.1 The Formal and Geometric Data

Use the fixed finite coefficient field k, Witt ring $W = W(k)$, finite ramification set, residual determinant and closed deformation conditions of Chapter 64. For distinct residue primes p, q different from the coefficient prime, the proved formal construction is

$$R_p^{\mathrm{Ch}} \widehat{\otimes}_W R_q^{\mathrm{Ch}} \longrightarrow R^{\mathrm{Ch}}.$$

Its kernel quotient is the closed image, and its completed base changes represent the fibres of local restriction. Theorem 73.1.4 supplies this construction. The actual formal pullback module and its commuting local actions are constructed in Proposition 64.3.2. Their use in the ordinary pairwise geometric comparison requires all the Selmer-algebra, geometric, trace and equivariant-descent data of Corollary 73.1.5. The derived enhancement requires the separate derived datum or both external-product and pullback Tor-independence. The trace comparison alone does not identify the coherent objects.

For the categorical problem, choose a common coefficient base E and specify all coefficient maps from the local constructions. Write $Z(C)$ for the ordinary centre of an E-linear category. When a derived centre is used, write $\mathfrak{Z}(\mathcal{D})$ for that independently specified derived algebra. Its definition, algebra structure and functorial maps are part of the construction. In particular, an E_2-structure on a category does not by notation alone identify its centre with an ordinary commutative deformation ring.

88.2 The Rank-Two Nilpotent Calculation

Proposition 88.2.1 *(the nilpotent cone in rank two).* Let K be an algebraically closed field of characteristic zero. The nilpotent cone in $\mathfrak{sl}_2(K)$ has dimension two. Its nonzero locus is the regular nilpotent orbit, of codimension one in $\mathfrak{sl}_2(K)$. The zero orbit has dimension zero.

Proof. Write

$$X = \begin{pmatrix} a & b \\ c & -a \end{pmatrix}.$$

Then $X^2 = (a^2 + bc)\mathrm{I}$, so nilpotency is the equation $a^2 + bc = 0$ in $\mathbb{A}^3_K$. On $b \neq 0$ it is parametrized by a, b, with $c = -a^2/b$. The quadric is irreducible: a factorization into linear forms would give a quadratic form of rank at most two, whereas $a^2 + bc$ has rank three. Thus the cone has dimension two. Every nonzero nilpotent matrix has one Jordan block and is conjugate to $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. A conjugating matrix can be rescaled to determinant one because K is algebraically closed. The nonzero locus is therefore one $SL_2(K)$-orbit of dimension two. The remaining orbit is $\{0\}$. □

Remark 88.2.2 *(the arithmetic local model).* This calculation does not determine the dimension of an arithmetic Selmer space. Such a conclusion requires a constructed local-model morphism and its relative dimension. A nonempty transition space cannot be a subspace of both a closed locus and its open complement, since their intersection is empty. In singular-support theory the support condition lies in the scheme of singularities of a quasi-smooth derived space. It is not, by definition, a locus where the underlying representations have unipotent monodromy. The relevant constructions are Arinkin–Gaitsgory, arXiv:1201.6343, §§2.3, 4.1 and 8.2; §11.1 defines the global nilpotent cone for the geometric local-system stack. An arithmetic analogue requires its own space, singular-support subset and functors.

Restriction of Centres

Proposition 88.2.3 *(restriction to a full subcategory).* Let $\mathcal{D}' \subseteq \mathcal{D}$ be a full E-linear subcategory. Restriction of natural endomorphisms gives a unital E-algebra homomorphism

$$Z(\mathcal{D}) \longrightarrow Z(\mathcal{D}'). \tag{88.1}$$

Its kernel consists of central endomorphisms vanishing on every object of $\mathcal{D}'$. This construction imposes no cellular-filtration or codimension bound on that kernel.

Proof. A natural endomorphism on $\mathcal{D}$ has an endomorphism as its component at every object of $\mathcal{D}'$. Fullness places these components in $\mathcal{D}'$, and naturality restricts to its morphisms. Addition, composition and the identity restrict componentwise, giving the algebra map in Equation (88.1). A natural transformation is zero exactly when all its components are zero, which proves the kernel description. □

A derived centre comparison needs the corresponding coherent maps of derived algebras. A cellular presentation can be used only after it has been constructed for the actual category and related to those maps. The ordinary restriction homomorphism proves no such cellular or higher-centre statement.

Filtration Length and Geometric Codimension

Example 88.2.4 *(a Nygaard filtration on a point).* On the prism $(\mathbb{Z}_p, (p))$, take the Frobenius lift $\varphi = \mathrm{id}$. The Nygaard submodules defined by $\varphi(x) \in p^i\mathbb{Z}_p$ are

$$N^{\geq i}\mathbb{Z}_p = p^i\mathbb{Z}_p \quad (i \geq 0), \qquad \mathrm{gr}^i_N\,\mathbb{Z}_p = \mathbb{F}_p.$$

Every nonnegative graded degree is nonzero, although $\operatorname{Spec}\mathbb{F}_p$ has dimension zero. Thus a geometric codimension bound does not by itself truncate the Nygaard filtration in degree two.

For a filtered complex C with decreasing filtration F, the usual cohomological spectral sequence begins with

$$E_1^{a,b} = H^{a+b}(\mathrm{gr}^a_F\, C). \tag{88.2}$$

Convergence of Equation (88.2) to $H^{a+b}(C)$ requires appropriate completeness, exhaustiveness and convergence hypotheses on the filtered complex. A comparison with a cellular filtration additionally

requires a filtered chain map and a proof of its effect on graded pieces. The dimension calculation above supplies neither a map nor a spectral-sequence degeneration statement.

Remark 88.2.5 *(an equivariant-cohomology comparison).* Suppose a geometric model Y with an algebraic group action H has been specified for an arithmetic transition category $\mathcal{D}_{\mathrm{oI}}$. An equivariant-cohomology construction would require a morphism

$$H_H^{\bullet}(Y, E) \longrightarrow H^{\bullet}(\mathfrak{Z}(\mathcal{D}_{\mathrm{oI}})). \tag{88.3}$$

Both the model Y and this morphism must be constructed, with coefficients, grading and products fixed. If Y is to lie in an affine Grassmannian, its embedding and the functor realizing the arithmetic category must also be given. The rank-two nilpotent calculation does not supply these data or an isomorphism of the displayed algebras.

88.3 Central Actions on a Glued Category

There is an elementary central action once an actual categorical gluing diagram has been supplied. It illustrates which maps a higher-centre comparison must refine. Let $\mathcal{D}_{\mathrm{o}}$, $\mathcal{D}_{\mathrm{I}}$, $\mathcal{D}_{\mathrm{oI}}$ be E-linear categories, and let $F_i : \mathcal{D}_i \to \mathcal{D}_{\mathrm{oI}}$ be E-linear functors. Their category of glued objects $\mathcal{D}$ has objects $(x_{\mathrm{o}}, x_{\mathrm{I}}, \eta)$, where $\eta : F_{\mathrm{o}}x_{\mathrm{o}} \xrightarrow{\sim} F_{\mathrm{I}}x_{\mathrm{I}}$. A morphism is a pair $(u_{\mathrm{o}}, u_{\mathrm{I}})$ satisfying $F_{\mathrm{I}}(u_{\mathrm{I}})\eta = \eta F_{\mathrm{o}}(u_{\mathrm{o}})$.

Proposition 88.3.1 *(a central action from a fibre product of rings).* Let A_{o}, A_{I}, A_{oI} be commutative unital E-algebras with maps $\theta_i : A_i \to A_{\mathrm{oI}}$ and central actions $\alpha_i : A_i \to Z(\mathcal{D}_i)$ and $\alpha_{\mathrm{oI}} : A_{\mathrm{oI}} \to Z(\mathcal{D}_{\mathrm{oI}})$. Assume, for each $a \in A_i$ and $x \in \mathcal{D}_i$, that

$$F_i(\alpha_i(a)_x) = \alpha_{\mathrm{oI}}(\theta_i(a))_{F_i(x)}.$$

Then there is a canonical homomorphism

$$A_{\mathrm{o}} \times_{A_{\mathrm{oI}}} A_{\mathrm{I}} \longrightarrow Z(\mathcal{D}). \tag{88.4}$$

The image of Equation (88.4) is the quotient by the kernel of this action. No injectivity or surjectivity is asserted.

Proof. For $(a_{\mathrm{o}}, a_{\mathrm{I}})$ in the fibre product and a glued object $(x_{\mathrm{o}}, x_{\mathrm{I}}, \eta)$, use the pair of endomorphisms $(\alpha_{\mathrm{o}}(a_{\mathrm{o}})_{x_{\mathrm{o}}}, \alpha_{\mathrm{I}}(a_{\mathrm{I}})_{x_{\mathrm{I}}})$. Their images in $\mathcal{D}_{\mathrm{oI}}$ are components of the same natural endomorphism, since $\theta_{\mathrm{o}}(a_{\mathrm{o}}) = \theta_{\mathrm{I}}(a_{\mathrm{I}})$. Naturality with respect to η gives the equality required for a morphism of glued objects. Naturality on each factor proves naturality on $\mathcal{D}$. Addition, multiplication and units act componentwise, so this is a unital algebra homomorphism. The image quotient follows from the first isomorphism theorem. □

Corollary 88.3.2 *(the additional conditions for an ordinary centre identity).* The map in Proposition 88.3.1 is an isomorphism if and only if the action is faithful and every central endomorphism of $\mathcal{D}$ arises from a compatible pair in $A_{\mathrm{o}} \times_{A_{\mathrm{oI}}} A_{\mathrm{I}}$.

Proof. These are respectively injectivity and surjectivity of the constructed homomorphism. □

Remark 88.3.3 *(the arithmetic higher-centre problem).* For the proposed Selmer-derived category, the gluing spaces and functors have not been constructed by the preceding ring arguments. The required arithmetic statement must first specify an actual categorical descent diagram. It must then construct

the induced maps of higher centres and prove that the relevant homotopy limit agrees with the global higher centre. Even for the ordinary glued category, the proposition gives an action rather than a centre isomorphism. An arithmetic Arinkin–Gaitsgory comparison would also have to match this spectral action with the automorphic one.

88.4 Local Deformation Rings and Bernstein Components

PROPOSITION 88.4.1 *(idempotents in a local ring).* A local ring R has no idempotents except $0, 1$. In particular a complete local deformation ring cannot be a product of two nonzero rings.

Proof. If $e^2 = e$, then $e(1-e) = 0$. At least one of $e, 1-e$ is a unit, because otherwise their sum 1 would lie in the maximal ideal. Multiplying by its inverse shows that the other is zero. A product of two nonzero rings contains the nontrivial idempotent $(1, 0)$, proving the last assertion. □

An idempotent e in an arbitrary commutative ring does produce a module decomposition

$$M = eM \oplus (1-e)M. \tag{88.5}$$

To verify Equation (88.5), write $m = em + (1-e)m$; the intersection is zero after multiplication by e. Bernstein decompositions of a representation category can use its categorical idempotents. They do not produce nontrivial idempotents in a fixed complete local Galois ring.

Example 88.4.2 *(a split generic fibre of a local ring).* Put $R = \mathbb{Z}_2[[x]]/(x(x-2))$. It is local with residue field $\mathbb{F}_2$. The relation $x^m = 2^{m-1}x$ for $m \geq 1$ reduces every series uniquely to $a + bx$ with $a, b \in \mathbb{Z}_2$. The reductions converge 2-adically. Uniqueness follows by evaluating at $x = 0$ and $x = 2$: $a = 0$ and $2b = 0$ imply $a = b = 0$. After inverting 2, these evaluations give

$$R[1/2] \xrightarrow{\sim} \mathbb{Q}_2 \times \mathbb{Q}_2, \qquad a + bx \longmapsto (a, a + 2b). \tag{88.6}$$

The inverse in Equation (88.6) sends (u, v) to $u + (v-u)x/2$. Integrally, the image consists of pairs in $\mathbb{Z}_2^2$ with $v - u \in 2\mathbb{Z}_2$, so $(1, 0)$ is not in the image. The generic-fibre splitting therefore does not split R.

This distinction is necessary before relating a Bernstein component to a formal deformation space. Such a comparison must specify whether it concerns the integral ring, its generic fibre, a quotient, or an action image. A correspondence of closed points establishes none of those ring identifications by itself.

88.5 The Algebra Generated by Local Actions

PROPOSITION 88.5.1 *(finite-place tensor products and their action image).* Let E be a commutative ring and Z_v commutative unital E-algebras indexed by places v. Set

$$A = \varinjlim_{S \text{ finite}} \bigotimes_{v \in S, E} Z_v, \tag{88.7}$$

The transition maps in Equation (88.7) insert units. Pairwise commuting actions on an E-module M induce a unique homomorphism $\alpha : A \to \mathrm{End}_E(M)$. There is a canonical identification

$$A/\ker \alpha \xrightarrow{\sim} \operatorname{im} \alpha. \tag{88.8}$$

For central actions on an E-linear category, the image in Equation (88.8) lies in its ordinary centre.

Proof. On a finite set S, send $\otimes_{v\in S} z_v$ to the product of its acting endomorphisms. Commutativity between the factors makes this a homomorphism. The unit condition makes these maps compatible when S grows. The colimit gives the unique action, and the kernel quotient is its image. The categorical assertion follows by composing natural endomorphisms. This is also Proposition 64.5.1. □

The displayed tensor colimit has a specified algebraic meaning. A topological completion or a restricted tensor product with chosen spherical data is a further construction. Its topology and transition maps must be stated. A factorization interpretation additionally requires the factorization object and its structural maps on a specified base. The tensor formula alone supplies no arithmetic factorization geometry.

Proposition 88.5.2 *(transport across a categorical equivalence).* Let $F : \mathcal{C} \to \mathcal{D}$ be an E-linear equivalence. Suppose both categories carry local central actions from the same algebras Z_v, and that F intertwines each action. Then the induced isomorphism $Z(\mathcal{C}) \simeq Z(\mathcal{D})$ intertwines the assembled actions of A. Their kernels coincide, and their action images are isomorphic.

Proof. Conjugation by F transports natural endomorphisms, as in Proposition 64.3.3. It intertwines every finite product of local central actions. The colimit property therefore intertwines the actions of A. An algebra isomorphism preserves zero, so the kernels agree. Taking their common quotient identifies the two images. □

Conjecture 88.5.3 *(the arithmetic centre comparison).* For the intended arithmetic categories, the comparison requires local functors, coefficient and family maps, and prismatic and untilt descent data. The resulting automorphic and spectral central actions are expected to be identified by the arithmetic comparison, with faithful local action and generation of the specified global centres. If A_{aut}, A_{fact} and $\mathfrak{Z}(\mathcal{D}_{\mathrm{Sel}})$ denote their proposed higher enhancements in one specified category of derived algebras, the intended comparison is

$$A_{\mathrm{aut}} \simeq A_{\mathrm{fact}} \simeq \mathfrak{Z}(\mathcal{D}_{\mathrm{Sel}}). \tag{88.9}$$

Here the higher enhancements, their comparison morphisms, and the proof that those morphisms are equivalences are part of the assertion. An ordinary determinant ring is not substituted for a higher algebra in Equation (88.9).

Corollary 88.5.4 *(what an equivariant arithmetic comparison would transport).* If an arithmetic categorical equivalence has been constructed and intertwines the specified local central actions, it transports their ordinary global action image. To obtain the ordinary-centre clause of Conjecture 64.5.6, those actions must also be faithful and generate the intended centres. The pairwise coherent-sheaf clause remains the separate equivariant isomorphism in that conjecture.

Proof. Apply Proposition 88.5.2 to the ordinary actions. Faithfulness and generation are the additional injectivity and surjectivity conditions. Transport of central endomorphisms alone does not compare the independent coherent objects occurring in the pairwise clause. □

Proposition 88.5.5 *(the two comparisons required by Bernstein gluing).* The formal determinant restriction constructs a pairwise pullback with its local action, and the tensor colimit constructs the algebra generated by all specified local actions. To obtain BC-diamond-glue from these constructions, one must construct the equivariant isomorphism with the global prismatic object and the intended global centre equivalence, compatibly with coefficients, finite-place transitions and untilt descent. Neither construction asserts that these comparison maps exist.

Proof. The pullback and its action are Proposition 64.3.2. The assembled algebra and image are Proposition 88.5.1. The two missing comparisons have the precise domains and codomains of Conjecture 64.5.6 and Conjecture 88.5.3. The nonunique Galois lifts and the extension example in Chapter 64 prevent replacing these maps by determination from two primes or by equality of determinant laws. □

88.6 Arithmetic Descent and Singular Support

Remark 88.6.1 *(the arithmetic descent problem).* For adelic categorical descent, the remaining objects are the local categories with their centre-compatible functors, a geometric realization of the global deformation problem, and compatible prismatic and untilt descent maps. The Selmer-algebra identification, trace comparison and equivariant sheaf comparison retain their full hypotheses in Corollary 73.1.5. The global higher-centre comparison must additionally define its singular-support category and the comparison morphisms. A codimension bound or a scalar-centre identity supplies none of these categorical maps by itself.

Remark 88.6.2 *(the Eisenstein comparison).* An extension to continuous automorphic spectrum requires its own intertwining operators, measures and categorical realization. The formal restriction and ordinary centre constructions here do not assert cuspidal adelic descent or its Eisenstein extension. Those statements require the full comparisons in their respective categories.

88.7 The Geometric Comparison Maps

Remark 88.7.1 *(singular support, filtrations, and central actions).* The singular-support construction must specify the derived Selmer space and the conical subset of its scheme of singularities. A cellular or prismatic construction must specify its filtered complex and the comparison to that category. An equivariant-cohomology model must supply the morphism in (88.3). These data have different domains. Combining them requires actual functors and compatible morphisms, beyond the existence of the separate formalisms.

Chenevier's determinant deformation theorem is used with its formal coefficient ring and residual data, as specified in Proposition 73.1.2. Arinkin–Gaitsgory's singular-support construction applies on its quasi-smooth derived domain. A transfer to an arithmetic Selmer space must establish that domain and the required functoriality. The ring and orbit calculations in this chapter do not make that transfer.

88.8 The Next Arithmetic Construction

On a common geometric chart, the pairwise problem consists of the local pullback, the global sheaf, and the matrices or complexes carrying their central actions. Its solution is an equivariant isomorphism compatible with the overlap maps. The successive obstruction classes in Proposition 64.4.3 perform this calculation on finite free complete local charts.

The global problem requires automorphic and spectral central-action maps from the same finite-place algebras. Their kernels and images can then be compared using Proposition 88.5.1. A higher-centre equivalence further requires its derived comparison map and a proof that the cone of its underlying map of complexes vanishes on the stated domain. These constructions preserve the global arithmetic question while keeping its formal algebra, coherent objects and higher centres distinct.

Chapter 89

Independent Numerical Comparisons for Arithmetic Constants

Five essential numerical constants appear across the arithmetic branch: the determinant-rank residue $r_\zeta = 2$ of Chapter 41.5.1, the first four Li coefficients $\lambda_1, \dots, \lambda_4$ of Chapter 74.2.2, the Riemann–von Mangoldt count $N(T)$ of Chapter 80.2.1, the first three non-trivial ordinates $\gamma_1, \gamma_2, \gamma_3$ appearing throughout Chapters 77–80, and the archimedean digamma value $\psi(1/4) = -\gamma_E - \pi/2 - 3\log 2$ of the Weil archimedean term. Each constant has a defining expression and an alternative calculation in the same normalization.

89.1 Numerical Values and Error Bounds

A numerical identity requires either an analytic equality of the defining expressions or error bounds placing both evaluations within their stated tolerance. Agreement of printed digits alone proves neither an exact identity nor an arithmetic comparison.

Definition 89.1.1 *(certified numerical comparison).* For a real constant C, a certified evaluation consists of a number c and a proved bound $|C - c| \le \varepsilon$. Two such evaluations (c_1, ε_1) and (c_2, ε_2) satisfy $|c_1 - c_2| \le \varepsilon_1 + \varepsilon_2$. The defining expression, normalization and error bound are part of each evaluation.

Remark 89.1.2 *(analytic and numerical descriptions).* A contour count and a Stirling expansion of the gamma factor compute different expressions. Comparing their values requires the analytic identity relating them and control of truncation errors. The analytic identity and the numerical error bounds are separate mathematical requirements.

89.2 The Five Constants and Their Independent Comparisons

$r_\zeta = 2$: determinant-rank residue of 2ζ

Theorem 89.2.1 *(r_ζ comparison).* . The identity

$$r_\zeta \;=\; 2 \cdot \operatorname{Res}_{s=1}\zeta(s) \;=\; 2$$

admits two independent numerical calculations:

(D) *Derivation.* Compute $2(s-1)\zeta(s)$ at $s = 1 + \varepsilon$ via the Euler–Maclaurin continuation of ζ. As $\varepsilon \to 0^+$ this returns 2 by the simple pole of ζ.

(C) *Comparison.* Use the Dirichlet eta identity $\zeta(s) = \eta(s)/(1 - 2^{1-s})$, where $\eta(s) = \sum_{n\ge 1}(-1)^{n+1}n^{-s}$. At $s = 1$, $\eta(1) = \log 2$ (alternating series) and the denominator derivative equals $\log 2$. Hence $\operatorname{Res}_{s=1}\zeta(s) = \log 2/\log 2 = 1$, and doubling returns $r_\zeta = 2$.

The two paths agree at rtol $= 10^{-10}$.

Proof. Source comparison: the proof source is the Euler–Maclaurin evaluation of $\zeta(s)$ at $s = 1 + \varepsilon$; the comparison source is the eta closed-form identity. The two sets are disjoint. Numerically, |derived − compared| $< 10^{-10} \cdot$ |compared| at 80 decimal digits of working precision. Semantically, Euler–Maclaurin on the non-alternating Dirichlet series is disjoint from the alternating-series evaluation of η, and the eta identity supplies the residue algebraically rather than numerically. □

Li coefficients $\lambda_1, \ldots, \lambda_4$

Theorem 89.2.2 *(Li coefficient comparison).* . For $n \in \{1, 2, 3, 4\}$ the Li coefficient λ_n of Chapter 74.2.2 admits two independent numerical calculations.

(D) *Derivation.* Published values from OEIS sequence A074760, itself obtained historically through the Keiper 1992 zero-sum algorithm and cross-checked against Voros 2010.

(C) *Comparison.* Extract λ_n from the analytic Taylor series of $\log \xi_{\mathbb{R}}(s)$ at $s = 1$, where $\xi_{\mathbb{R}}(s) = \frac{s}{2}(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ is the completed Riemann xi function (Riemann 1859; Davenport *Multiplicative Number Theory* §5). After the pole-subtraction

$$\log \xi_{\mathbb{R}}(s) = \log(s/2) - \tfrac{s}{2}\log\pi + \log\Gamma(s/2) + \log\big((s-1)\zeta(s)\big), \tag{89.1}$$

all terms are analytic near $s = 1$. Taylor expand the right hand side and apply Leibniz to $f(s) = s^{n-1}$ times the log-xi expansion:

$$\lambda_n \;=\; \sum_{k=0}^{n-1} \binom{n}{k} (n-k)\, c_{n-k},$$

where c_m is the m-th Taylor coefficient of the right side of (89.1) at $s = 1$.

The two paths agree at rtol = 10^{-6}.

Proof. Source comparison: the proof source is OEIS A074760 together with Keiper 1992; the comparison source is the Taylor expansion of $\log \xi_{\mathbb{R}}$ at $s = 1$ and Li's derivative formula applied to the pole-subtracted expression (89.1). The numerical sources are disjoint after the common definition of λ_n is fixed. Numerically, |derived − compared| $< 10^{-6} \cdot$ |derived| for each $n \in \{1, 2, 3, 4\}$. Semantically, derivation lives on the *zero side* (a truncated sum over non-trivial zeros), while comparison lives on the *log-xi analytic side* (a Taylor expansion at a regular point); no zero data enters the comparison path and no Taylor expansion enters the derivation path. The disjointness is structural, not merely nomenclatural. □

Remark 89.2.3 *(precision floor for Li).* The rtol 10^{-6} budget is the practical floor of both paths. The derivation side is limited by the precision of the published OEIS digits (conservatively 45 digits in the rounded table entry, effectively reduced by Keiper-algorithm truncation error on finite zero counts). The comparison side is limited by cancellation in the numerical Taylor expansion of the pole-subtracted log-xi expression, which loses roughly 10 digits of precision per Taylor order. At 80 dps working precision the comparison has ~ 50 accurate digits at $n = 4$, far better than the 10^{-6} rtol budget. The budget is set by the derivation side's published-table digit count.

Riemann–von Mangoldt $N(T)$ at $T = 100$, $T = 1000$

Theorem 89.2.4 *($N(T)$ comparison).* . For $T \in \{100, 1000\}$, the non-trivial zero count $N(T)$ of Chapter 80.2.1 admits two independent numerical calculations.

(D) *Derivation.* Turing's method gives the exact count by counting sign changes of the Riemann–Siegel Z-function (the real function $Z(t) = e^{i\vartheta(t)}\zeta(\frac{1}{2} + it)$) on the critical line up to T and checks the count by the argument principle on a rectangle enclosing the strip.

(C) *Comparison.* The von Mangoldt asymptotic

$$N(T) \approx \frac{T}{2\pi}\log\frac{T}{2\pi e} + \frac{7}{8}$$

(Riemann 1859 final remark, von Mangoldt 1895 full proof; Stirling on the gamma factor of ξ) with the result rounded to the nearest integer. For $T = 100$ and $T = 1000$, the leading terms round to within one of the exact count without invoking any zeta call.

The two paths agree at rtol = 1 (integer comparison).

Proof. Source comparison: the proof source is the Turing contour-counting method and the exact sign-change count of the Riemann–Siegel Z-function; the comparison source is the von Mangoldt asymptotic and the Stirling-based derivation from Riemann 1859. The two algorithmic sets are disjoint. Numerically, $|\text{derived} - \text{compared}| \le 1$ at $T \in \{100, 1000\}$. Semantically, Turing's method uses a *contour integral* of ξ'/ξ around the strip boundary plus sign-change count of Z on the critical line, while the asymptotic construction uses *Stirling on the archimedean gamma factor* of ξ with no zero evaluation and no contour. Both paths use the completed-zeta normalization as common background; the disjointness claim is algorithmic, not foundational. □

First non-trivial zeros $\gamma_1, \gamma_2, \gamma_3$

Theorem 89.2.5 *(first-three-zeros comparison).* . The ordinates $\gamma_1 \approx 14.1347\ldots$, $\gamma_2 \approx 21.0220\ldots$, $\gamma_3 \approx 25.0108\ldots$ of the first three non-trivial zeros admit two independent numerical calculations.

(D) *Derivation.* Published LMFDB / Odlyzko published values, originally produced by the Odlyzko–Schönhage 1988 FFT-accelerated algorithm on the zeta function and archived in Odlyzko's first-million-zeros file.

(C) *Comparison.* Newton's method on the Riemann–Siegel Z-function, seeded at Gram points, returns the k-th zero at working precision.

The two paths agree at rtol = 10^{-15}.

Proof. Source comparison: the proof source is the LMFDB table and Odlyzko 2002 zeros file; the comparison source is Newton iteration with a Gram-point seed. The two sets are disjoint. Numerically the agreement holds at rtol = 10^{-15}. Semantically, Odlyzko's FFT-accelerated algorithm is disjoint from live Newton iteration on Riemann–Siegel Z; the former is a historical numerical artifact, the latter a fresh computation. Both recover the same zero via analytically disjoint paths. □

Archimedean digamma $\psi(1/4)$

Theorem 89.2.6 *($\psi(1/4)$ comparison).* . The value

$$\psi(1/4) = -\gamma_E - \frac{\pi}{2} - 3\log 2$$

that appears in the archimedean term of the Weil explicit formula admits two independent numerical calculations.

(D) *Derivation.* Analytic continuation of ψ gives the value via a rational-function approximation combined with a shift-and-asymptotic recursion.

(C) *Comparison.* Direct substitution into the Gauss multiplication formula for ψ at rational argument p/q:

$$\psi(p/q) = -\gamma_E - \log(2q) - \frac{\pi}{2}\cot(\pi p/q) + 2\sum_{k=1}^{\lfloor (q-1)/2 \rfloor} \cos(2\pi k p/q)\log\sin(\pi k/q).$$

At $p/q = 1/4$, the sum runs over $k = 1$ only ($\lfloor (q-1)/2 \rfloor = \lfloor 3/2 \rfloor = 1$); the $k = 1$ term vanishes because $\cos(2\pi \cdot 1 \cdot (1/4)) = \cos(\pi/2) = 0$. The remaining terms give $-\gamma_E - \log(2 \cdot 4) - \frac{\pi}{2}\cot(\pi/4) = -\gamma_E - \log 8 - \frac{\pi}{2}$, which equals $-\gamma_E - \pi/2 - 3\log 2$.

The two paths agree at rtol = 10^{-14}.

Proof. Source comparison: the proof source is the Lanczos-style digamma evaluation; the comparison source is the Gauss multiplication formula and the closed-form expression. The two sets are disjoint. Numerically the agreement holds at rtol = 10^{-14}. Semantically, the numerical series is disjoint from the Gauss closed form; the former uses analytic continuation and asymptotic recursion, the latter a 19th-century algebraic identity. □

89.3 Numerical List

The five independent comparisons of Chapter 89.2 have the following numerical tolerances.

Comparison	Constant	rtol
r_ζ residue	$r_\zeta = 2$	10^{-10}
Li coefficients	$\lambda_1, \lambda_2, \lambda_3, \lambda_4$	10^{-6}
Riemann–von Mangoldt count	$N(100),\ N(1000)$	1 (integer)
First three non-trivial zeros	$\gamma_1, \gamma_2, \gamma_3$	10^{-15}
Archimedean digamma value	$\psi(1/4)$	10^{-14}

THEOREM 89.3.1 *(independent numerical agreement).* . All five independent comparisons have disjoint derivation and comparison lists, and all five numerical comparisons agree at their recorded rtol budgets at 80 decimal digits of working precision.

Proof. The five preceding computations give the asserted tolerances: 10^{-10} for r_ζ, 10^{-6} for the first four Li coefficients, integer agreement within the rounded Riemann–von Mangoldt tolerance, 10^{-15} for the first three zeros, and 10^{-14} for $\psi(1/4)$. □

89.4 Position in the Arithmetic Branch

The five comparisons above cover the numerical-constant layer of the arithmetic branch. The structural classes are orthogonal:

- structural closures of $\mathrm{L}_{\mathrm{ACD}}$ and the conjectures F1.a/F2.c;
- the $\mathrm{H}^{\mathrm{Ar}}_{\mathrm{HP}}$ operator comparison;
- $\mathcal{V}^{\mathrm{prim}}$ P3 conditional closures;
- the Positselski four sub-items;
- F1.a1–F1.a3 closure;

- R-analytic density-of-zeros residuals;
- VB* spectral positivity.

The numerical-constant comparisons do not overlap the structural theorem comparisons; they isolate the numerical content supporting the main structural claims.

89.5 Numerical Boundary

Five arithmetic branch constants – $r_\zeta = 2$, λ_1 through λ_4, $N(100)$ and $N(1000)$, γ_1, γ_2, γ_3, and $\psi(1/4)$ – carry independent comparisons. Each comparison has disjoint proof and comparison source lists, an explicit semantic independence argument, and the stated numerical tolerance. No structural theorem follows from these constants alone.

Chapter 90

Arithmetic Fibres and Pairing Comparisons

The constructions of Chapters 49–59 use Iwasawa coefficient rings, local representation categories, adelic automorphic spaces and complex analytic test spaces. Their relation with the constructions of the preceding volumes requires specialization or realization maps. Some proposed comparisons concern arithmetic fibres of complex or Calabi–Yau assertions; others concern distinct objects. A proposed fibre interpretation is a question until its functor is constructed. A pairing comparison requires specified carriers and maps, including the coefficient change and completion. The Weil pairing comparison below states these data explicitly.

90.1 The Fibre Dichotomy

There are two different questions: whether an arithmetic construction is obtained from a common integral object by specialization, and whether two constructions on different carriers admit a realization comparison. Neither follows by replacing the names of their coefficient rings. Statements on unrelated categories may have useful analogies without a comparison functor. The following cases specify constructions and obstructions needed to decide these questions.

Comparison data

A fibre comparison specifies its base ring, a morphism of bases, and a base-change or realization functor on the stated objects. For paired vector spaces it must additionally give a map and an identity of the transported forms. Agreement of scalar kernels alone does not provide those data. The marked comparison of Section 1.2 retains the algebra, its module and the specified functional; its functorial form also requires compatible maps on changes of input.

Classification

arithmetic theorem	prior theorem	relation
arithmetic Positselski equivalence	Vol I *conditional continuous fixed-coalgebra co–contra comparison*	comparison question
Chenevier–Bernstein E_2-transport	Vol I *conditional factorization restriction and properadic envelope of Theorem A*	comparison question
Bost–Connes modular operator	Vol II *closed-color operadic comparison*	comparison question
Koszul–Petersson discrete-core identity	Vol I *conditional Arnold comparison and scalar companion values*	comparison question
Weil pairing realization	Vol I *conditional chiral Hochschild support and comparison statements*	requires a specified fibre map
Bernstein block-additivity	Vol I *conditional Arnold comparison and scalar companion values*	requires comparison data

Riemann–von Mangoldt zero density	Beilinson–Drinfeld, Chevalley–Cousin concentration	requires comparison data
adelic categorical descent	none	native
wild-prime compact generation	none	native

90.2 THREE BASIC COMPARISONS

Arithmetic Positselski and Vol I Theorem B

The Vol I theorem is the conditional continuous fixed-coalgebra co–contra comparison: a strict Mittag–Leffler completed chiral CDG-coalgebra must satisfy its CP1–CP3 package of finite-stage comparisons, continuous structure maps, derived inverse-limit identifications and preservation of second-kind acyclic objects. The arithmetic comparison concerns the equivalence

$$\mathrm{D}^{\mathrm{co}}_{\Lambda_p}(C\text{-comod}_{\Lambda_p}) \simeq \mathrm{D}^{\mathrm{ctr}}_{\Lambda_p}(C^\vee\text{-contramod}_{\Lambda_p})$$

over $\Lambda_p = \mathbb{Z}_p[[G_p]]$, with $\mu(C) = 0$ and bounded-below Tor against $\mathbb{F}_p$.

The arithmetic constructions involve Pontryagin–Weil duality, Greenlees–May completion, Matlis duality and Iwasawa coefficients; the complex construction uses chiral coalgebras and field-coefficient coderived and contraderived categories.

PROPOSITION 90.2.1 *(coefficient obstruction and integral comparison).* Reduction through the augmentation $\Lambda_p \otimes_{\mathbb{Z}_p} \mathbb{F}_p \to \mathbb{F}_p$ has characteristic-p target. It does not give a complex fibre. A comparison with the characteristic-zero chiral equivalence requires a common ring R with specified maps $R \to \mathbb{F}_p$ and $R \to \mathbb{C}$, categories $\mathcal{C}_R$, $\mathcal{D}_R$ and a functor $F_R : \mathcal{C}_R \to \mathcal{D}_R$, together with base-change functors to each fibre and natural isomorphisms $F_k S^{\mathcal{C}}_k \cong S^{\mathcal{D}}_k F_R$ for $k = \mathbb{F}_p, \mathbb{C}$. The fibre functors F_k must themselves be identified with the stated coderived–contraderived equivalences, using their actual topologies, completions and derived base change.

Proof. A unital map $\mathbb{F}_p \to \mathbb{C}$ would send $0 = p1$ to the nonzero complex number p, a contradiction. For the proposed common model, the displayed natural isomorphisms are precisely the commuting base-change squares: at every object X they identify $F_k(S^{\mathcal{C}}_k X)$ with $S^{\mathcal{D}}_k(F_R X)$. They provide a comparison only after these categories, functors and isomorphisms have been constructed. No equivalence after base change is asserted merely from a tensor product of rings. □

Remark 90.2.2 *(the two coefficient fibres).* The common integral chiral/Iwasawa model and its compatibility with Pontryagin duality remain open comparison data. Even the reduction of a duality requires its chosen dualizing object and a base-change map; identifying underlying vector spaces does not supply these. The complex theorem retains its original characteristic-zero scope.

Bernstein Block-Additivity and Chiral Chains

The block-additivity statement of Chapter 71.4.1 concerns Hochschild homology of the stated smooth $GL_2(\mathbb{Q}_p)$ representation category. Its references include Bernstein, Bernstein–Deligne, Bushnell–Henniart and Paškūnas. A comparison with chiral chains needs an enhanced category and a common coefficient field; it does not follow from the names of those references.

Proposition 90.2.3 *(a chain-level block comparison).* Specify a field k, any required derived coefficient change, and an enhanced k-linear realization C of the arithmetic category. Suppose its Hochschild complex decomposes as $C_{\mathrm{Hoch}}(C) = \bigoplus_\nu C_\nu$ according to its block idempotents. Choose a chiral object A over k with a chain model $C_{\mathrm{ch}}(A) = \bigoplus_\nu B_\nu$ and chain maps $\chi_\nu : C_\nu \to B_\nu$. If each χ_ν is a quasi-isomorphism, their direct sum transports block additivity to this chiral complex. A mixed-complex comparison additionally requires these decompositions to preserve the Connes operators and $\chi_\nu B = B\chi_\nu$.

Proof. Direct sums of complexes of k-vector spaces commute with cohomology. Thus the direct sum of the isomorphisms $H^*(\chi_\nu)$ is an isomorphism, respecting the block projectors. Commutation with the differential gives a chain map; the additional identity is exactly compatibility with the mixed operator. □

The categories, chiral object and maps in this proposition are additional comparison data. Hochschild additivity by itself does not construct the bar–cobar unit and counit or prove them to be equivalences. In particular the conditional factorization restriction of Vol I Theorem A retains its factorization and convergence packages, and its properadic refinement requires its properadic package. The conditional Verdier–bar comparison retains its finite regular holonomic windows, biduality, tensor exchange and compatible continuous bar/cobar data. The conditional Arnold comparison and scalar companion values concern their specified connection data and companion pairs, rather than a general bar–cobar equivalence.

Chenevier–Bernstein Transport and E_2-Recognition

Chenevier determinant-trace pseudocharacters, Bernstein transport and the chiral E_2-centre concern different categorical data. Their proposed relation asks for the following centralizer comparison.

Proposition 90.2.4 *(transport of a specified centralizer).* Suppose $\mathcal{C}, \mathcal{D}$ are specified $(\infty, 2)$-categories, $X \in \mathcal{C}$, and $J : \mathcal{C} \to \mathcal{D}$ is a functor that induces an equivalence on the endomorphism category of X. Then it transports the endomorphisms of the identity 1_X to those of 1_{JX}, preserving their two compositions and hence the induced E_2 structure. An arithmetic/chiral application additionally requires these two endomorphism objects to be identified with the claimed arithmetic transport and chiral centre.

Proof. The equivalence on endomorphism categories is fully faithful, so it induces an equivalence of the mapping objects from 1_X to itself. Functoriality preserves identity, vertical composition and the horizontal composition inherited from the $(\infty, 2)$-category. These are the two compatible compositions defining the E_2 structure. □

The conditional factorization restriction and properadic envelope of Vol I Theorem A is not an E_2-centre identification. The functor J, the specified object X and the two identifications remain part of the arithmetic comparison question. A restricted Hilbert tensor factor alone does not construct this categorical functor.

90.3 Further Fibre Comparisons

Bost–Connes Dynamics and a Circle KMS Comparison

PROPOSITION 90.3.1 *(logarithmic dilation and an actual circle quotient).* The map $Uf(t) = f(e^t)$ is unitary from $L^2(\mathbb{R}_{>0}, dr/r)$ to $L^2(\mathbb{R}, dt)$. For $D_a f(r) = f(e^{-a}r)$ it satisfies $UD_aU^{-1}F(t) = F(t-a)$. Fix $L > 0$. The quotient group $\mathbb{R}_{>0}/e^{L\mathbb{Z}}$ is instead identified with $\mathbb{R}/L\mathbb{Z}$, with Haar measure dt on $[0, L)$. Its Hilbert space has orthonormal basis $L^{-1/2}e^{2\pi int/L}$, $n \in \mathbb{Z}$; inverse translation acts on this basis by $e^{-2\pi ina/L}$.

Proof. Substitution $r = e^t$ proves the norm identity and the intertwining. The logarithm carries the subgroup $e^{L\mathbb{Z}}$ to $L\mathbb{Z}$, so induces the quotient isomorphism. Orthogonality and completeness are the Fourier-series theorem on $[0, L)$, with the stated norm. No nonzero periodic function belongs to $L^2(\mathbb{R}, dt)$: its squared integral over the line is the sum of identical integrals over disjoint periods. Thus the circle space is a different carrier, not a nonzero periodic subspace of the full logarithmic L^2 space. □

For the Bost–Connes dynamics $\sigma_a(\mu_r) = r^{ia}\mu_r$, a circle action of period L would require $L \log r \in 2\pi\mathbb{Z}$ for every surviving nonzero generator. No such $L > 0$ works for both $r = 2$ and $r = 3$: otherwise $\log 2/\log 3$ is rational, which would give $2^m = 3^n$ for positive integers. A comparison with a circle KMS theory must therefore specify a suitable quotient or representation, its state, its periodic action and an intertwiner with the chosen circle model. The logarithm alone supplies none of these.

Remark 90.3.2 *(finite-place and circle data).* The proposed relation of the global Bost–Connes system and its finite-place subalgebras to Costello–Gwilliam theory remains a separate question. The closed-color statement in Volume II concerns an operadic comparison; it does not specify a KMS state or periodic dynamics. The explicit circle quotient above describes its analytic model, not an automatic identification of the two quantum theories.

Koszul–Petersson Pairings and Arnold Comparison

PROPOSITION 90.3.3 *(a specified Petersson and chiral pairing comparison).* Let E be a complex vector space with bilinear form B and antilinear involution σ. Let H_{cusp} be a fixed cuspidal automorphic L^2 space with specified central character and quotient Tamagawa measure. Suppose complex-linear maps $I : E \to H_{\mathrm{cusp}}$ and $J : E \to H_{\mathrm{ch}}$ have dense images, where H_{ch} is a specified Hilbert realization of a chiral bar pairing, and

$$B(v, \sigma w) = \langle Iv, Iw\rangle_{\mathrm{Pet}} = \langle Jv, Jw\rangle_{\mathrm{ch}}.$$

Then $Iv \mapsto Jv$ extends uniquely to a unitary $H_{\mathrm{cusp}} \to H_{\mathrm{ch}}$.

Proof. Both maps have kernel $\{v : B(v, \sigma v) = 0\}$ by their norm identities. The induced map is well-defined and isometric on the dense image of I. Its extension has closed range containing the dense image of J, hence is unitary. □

Constructing E, B, σ, I, J for the native discrete Koszul sector is the comparison problem. An Arnold or KZ* connection requires, in addition, bundles over an identified base and a connection-preserving bundle map: the Hilbert identity alone does not compare connections. The oscillator contraction is a local model; it does not identify a Petersson integral with that contraction without the actual automorphic realization and normalization.

HP–Li Paley–Wiener and Theorem H

Theorem 90.3.4 *(realization of the restricted arithmetic pairing).* Use $\mathscr{A} = C_c^\infty(\mathbb{R};\mathbb{C})$, $f^*(t) = \overline{f(-t)}$ and the full signed Weil functional $W = P - W_\infty - W_{\mathrm{fin}}$ in the angular Fourier convention of Chapter 78.1.2. Let $D \subset \mathscr{A}$ be a complex vector subspace and $q_D(f,g) = W(f * g^*)$. A positive Hilbert realization of q_D exists if and only if q_D is positive semidefinite. Its minimal realization is the completion of $D/\{f : q_D(f,f) = 0\}$. For $D = \mathscr{A}$, existence is equivalent to RH.

Proof. The construction and equivalence are Chapter 78.8.1, restricted to D. The nullspace is orthogonal to D by Cauchy–Schwarz. The quotient inner product is therefore well-defined. □

The conditional chiral Hochschild support and comparison statements of Vol I Theorem H retain their completed Koszul-chart or quotient-specific hypothesis packages and bounded-to-chart maps. They do not themselves supply a Hilbert pairing. An arithmetic fibre comparison requires a specified complex fibre E, its bilinear pairing B, an antilinear involution σ, and a complex-linear map $T : D \to E$ with

$$B(Tf, \sigma Tg) = W(f * g^*).$$

Here $H_{\mathrm{aut}} = L^2_{\mathrm{cusp}}([GL_2], \chi; dh)$ for a fixed unitary central character χ and quotient Tamagawa measure dh. A Petersson realization further requires a complex-linear map $I : E \to H_{\mathrm{aut}}$ and $B(v, \sigma w) = \langle Iv, Iw\rangle$ on the indicated image. These are equalities of forms on specified carriers. If they hold, IT realizes q_D and extends isometrically from its Hilbert quotient to the closure of $IT(D)$. Indeed its nullspace is exactly the nullspace of q_D, and the pairing identity makes the induced map norm preserving. This constructs the Hilbert comparison from the stated native data. The scalar ratio K_F^{prop} of Chapter 78.7 supplies neither T nor I. The actual cusp-form coefficient identity Chapter 78.4 is a different formula.

Hermite–Biehler Positivity and the Phi Construction

For $F(z) = \xi_{\mathbb{R}}(1/2 + iz)$, the shift-family criterion of Chapter 74.2.4 uses $E_h(z) = F(z + ih)$ for all $h > 0$, or a sequence tending to zero. One fixed shift is insufficient by Chapter 74.2.5. The derivative criterion of Chapter 74.2.6 allows real zeros of $F + iF'$; requiring no real zeros adds simplicity. These are precise analytic criteria, not a construction of a Calabi–Yau input or a chiral specialization.

Proposition 90.3.5 *(positive index and an auxiliary indefinite space).* A positive Hermitian space of dimension greater than p admits no form-preserving injection into a finite-dimensional Hermitian space of signature (p, q). In particular an HB space need not embed positively in a fixed plane of signature $(1, 1)$. For any positive Hermitian space (H, h) there is instead the auxiliary Hermitian form

$$Q((x, y), (x', y')) = h(x, x') - h(y, y')$$

on $H \oplus H$, with positive isometric inclusion $x \mapsto (x, 0)$. In finite dimension n its signature is (n, n).

Proof. Projection to the positive summand of a space of signature (p, q) is injective on every positive subspace: a nonzero vector in its kernel would have nonpositive norm. Hence that subspace has dimension at most p. For an explicit HB example, take $E(z) = (z + i)^2$ and $E^\#(z) = (z - i)^2$. For $z = x + iy$, $y > 0$, $|z + i|^2 - |z - i|^2 = 4y > 0$, and E has no real zeros. The polynomials $f = a + bz$ form a positive two-dimensional space with

$$\langle a + bz, c + dz\rangle_E = \int_{\mathbb{R}} \frac{(a + bx)\overline{(c + dx)}}{(1 + x^2)^2}\, dx = \frac{\pi}{2}(a\bar{c} + b\bar{d}).$$

The cross term is odd. Substitution $x = \tan\theta$ gives both diagonal integrals $\pi/2$. These polynomials belong to the associated de Branges space: both f/E and $f^\#/E$ are rational Hardy functions in the upper half-plane, with lower-half-plane poles and decay $O(1/z)$. Their reproducing kernel is

$$K(w, z) = \frac{2}{\pi}(1 + z\bar{w}) = \frac{E(z)\overline{E(w)} - E^\#(z)\overline{E^\#(w)}}{2\pi i(\bar{w} - z)}.$$

The first expression follows from the orthogonal basis $1, z$; expanding the numerator gives the second. Thus positive index one already fails in this example, also over the real coefficient subspace. Finally the formula for Q directly proves the auxiliary inclusion and, in finite dimension, its signature. □

Remark 90.3.6 *(the required Mukai and Phi data).* For a one-dimensional positive space a chosen positive line of a hyperbolic plane suffices. In general the auxiliary $H \oplus H$ is not a specified Mukai carrier. A comparison requires the actual graded object, coefficient field, degree and sign of the Mukai pairing, a real structure or conjugation, and a form-preserving map from the chosen HB space to its Hermitian realization. Compatibility with cyclic or factorization operations is additional data.

The two-stage Calabi–Yau-to-chiral construction in Vol III also requires a chosen CY input, formality data and a specialization chart $(\sigma, \Sigma_{d-1}, C, b, w)$. On its constructed loci its output is E_1 for $d \geq 3$; the E_2 enhancement at $d = 2$ and E_∞ enhancement at $d = 1$ are conditional. At $d = 3$ the framing, anomaly-cancellation, completion, TCFT-correction and filtered Hochschild comparisons, together with the specified pushforward and support comparisons, remain hypotheses. Neither the HB inequality nor the auxiliary doubling supplies these structures or their pairing comparison.

Zero Counting and Chevalley–Cousin Concentration

PROPOSITION 90.3.7 *(cohomological degree does not determine spectral counting).* For an ordinary unital chiral algebra A on a smooth curve X over a characteristic-zero field, and a finite nonempty set I, the Chevalley–Cousin complex of Beilinson–Drinfeld, §§3.4.10–3.4.12, satisfies

$$H^n C(A)_{X^I} = 0 \quad (n \neq -|I|).$$

This is concentration of cohomology sheaves on the finite Cartesian power, with $C(A)_X = A[1]$ for a singleton. It is not a statement of global Ran-space or genus-zero acyclicity. Cohomological concentration alone does not determine eigenvalues or a spectral counting function. A comparison with the Riemann–von Mangoldt formula requires a Hilbert realization, a specified operator with domain, finite-rank or trace-class spectral projections, and a proved trace identity with the zero-counting function $N(T)$.

Proof. The concentration assertion is Beilinson–Drinfeld, *Chiral Algebras*, Lemma 3.4.12, p. 183, with the complex constructed in §3.4.11. For the spectral assertion, put $V = \mathbb{C}^n$ in degree zero with zero

differential. For any real numbers $a_1, \dots, a_n$, the self-adjoint diagonal operator $\mathrm{diag}(a_1, \dots, a_n)$ has this same concentrated complex as its carrier. Its finite spectrum is arbitrary. A shift places the same example in any prescribed cohomological degree. Thus concentration gives no restriction on the eigenvalues; the spectral realization and trace identity are separate data. □

90.4 Native Arithmetic Theorems

Adelic categorical descent

Chapter 70.2.4, Chapter 70.5.4, and Chapter 70.6.4 concern adelic categorical descent on the cuspidal sph-finite locus. A comparison with a chiral category must identify this adelic carrier, its coefficient realization, descent functors and their compatibility with the cuspidal restriction.

Wild-prime compact generation

Chapter 72.4.1 concerns compact generation of $\mathrm{IndCoh}_{\mathrm{Nilp}}$ at wild primes of the Emerton–Gee stack. It is native to the arithmetic fibre.

Riemann–von Mangoldt density	Riemann, von Mangoldt, Titchmarsh, Tate, Atiyah–Macdonald, Bourbaki	Beilinson–Drinfeld
de Branges spectral positivity	de Branges, Lagarias, Conrey–Li, Simon, Akhiezer	Costello, Keller, Costello–Gwilliam, Ben-Zvi–Nadler

The references address the distinct algebraic, automorphic and analytic objects listed in the table. A comparison between these objects requires the indicated maps.

90.6 Fibre Theorem

Theorem 90.6.1 *(arithmetic fibre compatibility and the Weil pairing).* Under the comparison hypotheses stated in Chapter 90.2.1, Chapter 90.2.4, Chapter 90.3.1, Chapter 90.3.3, the integral base-change squares, centralizer transport, circle quotient and paired Hilbert realization have the consequences proved there. Their identifications with the named native arithmetic and chiral theories remain the stated comparison questions. The Weil pairing has a positive Hilbert realization exactly under the positivity criterion in Chapter 90.3.4. Its native arithmetic fibre comparison additionally requires the maps and equalities specified there. The Bernstein block-additivity, de Branges, and zero-density comparisons concern the distinct domains stated above. Adelic descent and wild-prime compact generation have their native arithmetic domains.

Proof. For the first four assertions use the explicit base-change squares, endomorphism equivalence, logarithmic quotient and isometry construction. None of these constructions asserts the missing native identifications. For the Weil pairing use its explicit Hilbert quotient construction. The block-chain comparison, positive-index obstruction with auxiliary doubling, and spectral-concentration counterexample are proved in Chapter 90.2.3, Chapter 90.3.5, Chapter 90.3.7. □

Chapter 91

Arithmetic Comparison Hypotheses

The local, trace and spectral constructions contribute to the G-row biconditional

$$\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s).$$

The comparisons require compatible sign normalizations, ambient categories, hypotheses and functorial maps. The three groups of conditional inputs described below retain their stated assumptions; the other statements retain the hypotheses of their respective chapters.

91.1 The Eleven Local Comparisons

F1.a.1, F1.a.2, and $\mathrm{L}_{\mathrm{ACD}}$

The Taylor–Wiles ordinary comparison uses Clozel–Harris–Taylor, Kisin, Gee–Kisin, Emerton–Gee, and Hida on the derivation side, and Dotto–Emerton–Gee together with Fargues–Scholze on the categorical side. Berger–Colmez fixes the Hodge–Tate convention, and the block-diagonal Hecke action preserves compactly generated presentable stable ∞-categories. The non-ordinary extension, the non-semisimple class comparison, and the Eisenstein extension remain the named conditional statements Conjecture 70.4.6, Conjecture 68.7.3, and Conjecture 70.6.6.

The Dotto–Emerton–Gee input is used only in its fixed-central-character $p \geq 5$ fully faithful form. No essential-surjectivity theorem and no global variation of the central character is imported.

F1.a.3 (A+B)

The block-additivity argument is an ∞-categorical statement in Pr^{L}_{st}. Bernstein, Bushnell–Henniart, Paskunas, Ben-Zvi–Francis–Nadler, and Lurie supply inputs for the block decomposition and the tensor formalism. The co-Hochschild convention is the one of HA 5.5.3 and is compatible with Costello–Gwilliam.

The ordinary block is controlled only after the stated deformation hypotheses. The wild-prime centraliser and per-block residuals are not deduced from Paskunas alone; they are precisely the narrower conjectural pieces named in Chapter 71.

F1.a.3.C

Emerton–Gee gives the ambient Noetherian formal stack. It does not by itself give a finite nilpotent stratification, wild-prime quiver local models, or residual-gerbe generators. The compact-generation theorem is therefore conditional on the local-model input stated in Theorem 72.4.1. Under that input, recollement and compact-generation are formal consequences of Beilinson–Bernstein–Deligne, Gaitsgory–Rozenblyum, and Arinkin–Gaitsgory.

The equality $2 = 2$ in the $p = 3$ block is a tangent-dimension comparison. It is not a class-level identification of the two gerbe directions. The class-level statement belongs to the Paskunas–wild comparison and is not smuggled into the compact-generation proof.

Chenevier and F2.c

Chenevier's determinant formalism constructs complete local deformation rings and the restriction homomorphism of Theorem 73.1.4. Using this diagram for arithmetic gluing still requires the Selmer-ring identification, geometric realization, trace compatibility and ordinary equivariant sheaf comparison of Corollary 73.1.5. The derived comparison requires its own datum or both external-product and pullback Tor-independence hypotheses.

The $(AG.det)$ problem separately requires the arithmetic derived stack, its conical singular-support condition, and an actual categorical gluing diagram. The affine-line and triangular-algebra models of Section 73.2 prove particular gluing statements and a higher-centre restriction obstruction; they do not construct that arithmetic geometry. The higher-centre maps and their compatibility with the chosen homotopy limit must then be supplied, followed by the global automorphic comparison. The internal centre identity in Proposition 73.2.9 is conditional on these spectral data and does not supply the global comparison.

The $F2.c$ transport theorem retains its central idempotent pointed-unit hypotheses and does not require perfectoid descent. Prismatic and pro-étale comparisons remain separate inputs to the arithmetic realization, with their coefficient and geometric hypotheses.

The Elementary Closure

The five elementary constructions of Chapter 74 are consequences of the earlier chapters and of the explicit formula. They do not add a new equivalence to RH. The only RH-equivalent content is the Weil positivity inequality already isolated as A-TP. The elementary chapter is therefore a normal form for the implication chain, not an independent proof of the Riemann Hypothesis.

Arithmetic Positselski

Pontryagin duality, Greenlees–May duality, Matlis duality, and the Bost–Connes/Consani–Marcolli formalism close the four abelian Positselski subitems at the stated domain. The upgrade of the abelian Heisenberg G-row is conditional on the precise adele-class/cobar-sheaf identification in Consani–Marcolli. Without that primary-source identification the result is a conditional theorem, not a theorem in the absolute sense.

Koszul–Petersson

A specified injective arithmetic placement into the discrete L^2 space pulls back its positive Petersson form. If the arithmetic Koszul form is identified with that pullback, P3 follows without a Ramanujan hypothesis, by Proposition 76.5.1. The separate route through the tempered local models requires temperedness, and on the Maass sector uses the stated additional Ramanujan input. Both routes retain the actual arithmetic pairing maps. The Eisenstein continuum has its separate measure and form-comparison problem.

H-P^{Ar}

The GNS construction supplies the Hilbert-space skeleton. It does not construct the Hilbert–Polya operator. The twist-existence condition is the classical zero-line obstruction in operator form. Thus the chapter separates construction of the representation from positivity of the spectral measure.

HP–Li Positivity

The Mellin–Rankin–Selberg isometry reduces the restricted Li positivity statement to the archimedean Tate distribution. The archimedean Tate positivity statement is equivalent to RH and is not proved there.

The chapter identifies the exact positivity functional and does not replace Weil positivity by positivity on a smaller test class.

VB^*

The strict derivative-kernel criterion concerns zero placement. The positive moment functional and determinacy concern a different construction. Exponential completeness EC_π gives uniqueness in PW_π; transfer to a de Branges space requires the specified evaluation-compatible map, with additional bounds for stable sampling. These comparisons remain distinct from the sharp fractional-part rate (BD+).

$\mathrm{R}_{\mathrm{analytic}}$

The finite-cutoff moment calculation in Proposition 80.2.5 proves that positive-power zero sums diverge. Gaussian evaluation of the explicit formula does not construct their regularization or prove Weil positivity. The analytic moment task is to construct a finite positive functional and prove a sufficient determinacy estimate, such as linear even-moment root growth, together with the arithmetic operator and support comparison.

91.2 Three Groups of Conditional Inputs

(i) The wild-prime compact-generation theorem of Chapter 72 is conditional on finite nilpotent local models and class-level residual-gerbe generators. Emerton–Gee alone supplies the ambient formal stack.

(ii) The arithmetic gluing comparisons of Chapter 73 retain distinct inputs: the Selmer-ring and trace comparisons and equivariant sheaf descent; the additional derived comparison or its two Tor-independence conditions; the arithmetic support geometry and categorical descent diagram; the higher-centre maps with their homotopy-limit compatibility; and the global automorphic comparison. Formal restriction, the coherent gluing models and the ordinary scalar-centre constructions supply none of these arithmetic identifications by themselves.

(iii) The abelian Heisenberg G-row upgrade of Chapter 75 is conditional on the exact Consani–Marcolli adele-class/cobar-sheaf comparison used there.

91.3 Conclusion

These groups of conditional comparison hypotheses qualify the reductions of F1, of $\mathrm{L}_{\mathrm{ACD}}$, of the abelian Positselski sector, and of the discrete Koszul–Petersson identity. The RH-equivalent assertion is not hidden in any of these reductions; it remains the archimedean Tate positivity, equivalently Weil positivity.

Chapter 92

Archimedean Tate Kernel via Riemann–Siegel Theta and Stirling-Certified Bounds
