Modular Koszul Duality.
Volume IV: Arithmetic, Interfaces, and Trace Formulas

Raeez Lorgat

Abstract

Arithmetic realization compares the operations that produce an invariant before evaluating it. We study coefficient algebras with specified modules, local conditions, units and functionals, together with the comparison maps that preserve these data. Explicit Gaussian, cubic and matrix examples distinguish a scalar equality from a comparison of products, higher operations or intermediate states.

The algebraic constructions include relative coefficient envelopes, composition of interfaces and their extension–restriction corings. Descent is proved under explicit completeness and detection hypotheses. For a strict cospan of differential graded algebras over a commutative ring, the two endpoint products admit an integral all-arity isomorphism of bar coalgebras. Its module and bimodule forms retain every ordered product of local primitives. The comparison extends to restricted inverse limits of finite coefficient bars; an unrestricted product over tensor lengths can fail continuity.

The arithmetic examples concern Galois cochains and local conditions, Hall and Hecke operations, coefficient duality, categorical traces and Chern–Simons comparisons. Their geometric and automorphic identifications require separately specified maps. The analytic endpoint is the complete signed Weil functional, with its polar, archimedean and prime contributions. Positive forms on auxiliary algebras do not identify this functional without a compatible evaluation theorem. The native arithmetic comparisons and positivity on the full Weil test domain remain distinct construction problems.

What a trace forgets 3

I The Realization Formalism **13**

1 Marked realization problems 15

1.1 A character does not determine a module 15

1.2 The data carried by a comparison . . . 15
1.3 Coefficient change and geometric carriers . . . 16
1.4 Existence, uniqueness, and coherent choice . . . 17
1.5 Evaluation after the comparison . . . 18

2 Words, collisions, and the two units . . . 19
2.1 The tensor product of ordered cuts . . . 19
2.2 The empty unit and the local vacuum . . . 20
2.3 Collisions that block every cut . . . 21
2.4 Coefficient complexes on the collision support . . . 22
2.5 The four-point attachment and normal derivatives . . . 24
2.6 The outer residue . . . 25
2.7 All local orders and the word comparison . . . 25
2.8 Arithmetic places and position geometry . . . 27

3 Bar–cobar and coefficient topology . . . 29
3.1 Positive words and finite duality . . . 29
3.2 The coefficient bar and its twisting maps . . . 31
3.3 Which derived tensor the bar computes . . . 33
3.4 Length products and continuous Taylor maps . . . 33
3.5 Finite precision and derived inverse limits . . . 34
3.6 Analytic bounds and the other bar constructions . . . 36

4 Recognition and higher comparison . . . 37
4.1 Simultaneous operations and their recipients . . . 37
4.2 The endpoint exchange at a ternary collision . . . 39
4.3 The complex controlling a higher comparison . . . 40
4.4 Fixed boundary values and allowed homotopies . . . 41
4.5 Operations, deformations, and a recognition problem . . . 43

5 Regular coefficient models . . . 45
5.1 Regular fields and the information in a word . . . 45
5.2 Run coefficients and their residue maps . . . 47
The three normal channels . . . 48
5.3 Collision coherence and framed recognition . . . 50
Strict differentials retain higher products . . . 52
5.4 An exchange that permits contextual compression . . . 53
The exchange contains more than its product . . . 54
5.5 Descent and the kernel of compression . . . 55
5.6 Translation frames and the algebraic boundary . . . 57
A compression excluded by unrestricted translation . . . 58

6 Singular backgrounds and vacuum data . . . 61
6.1 A current with a vacuum and no scalar augmentation . . . 61
A finite-place coefficient field and its diagonal . . . 63
6.2 The residue coalgebra of the singular background . . . 64
6.3 The derived coefficient of the local vacuum . . . 66

An order with divisor intersections 67
The support maps and exact width 69
The four-position extension 70
6.4 Infinitely many species at fixed energy 71
Quadratic fields and all their poles 72
The center and the energy grading 74
A prime-labeled current cover 74
6.5 Coordinate changes and coefficient norms 75
Projective tensors and all coordinate jets 76
Descent to a curve 78
6.6 A completion retaining the contractions 79
The completed field operations 79
The central algebra and ordinary actions 81
Coordinates on the completed space 82
A chosen bidifferential and its quotients 83
6.7 Gaussian preparations and their observables 84
The first oscillator and Gaussian multiplication 84
Connected contractions of quadratic fields 85
Normalized squeezed vectors 86
Prepared field matrix elements 88
6.8 Transport of Gaussian preparations 90
A regularized scalar and its composition defect 91
Retaining a trace with the preparation 92
Response, trace and scalar under composition 93
Unitary implementation is a separate condition 96
6.9 State families and completed field operations 96
The exact domain for diagonal evaluation 96
A weight completion closed under every mode 98
Modules and the lower weight bound 99
Common-scale fields and the geometric boundary 101

7 Comparison problems for the first three volumes 103
7.1 Independent comparison 103
7.2 The realization pair 103
7.3 Seven structural comparison problems 104
7.4 Objectwise comparisons and their scope 105
7.5 Boundary strata 105
Degenerate admissible logarithmic sector 105
Super-Yangian chain-level chiral coproduct 105
Vol III CY-C conditional bridges 105
7.6 Boundary Problems 106
7.7 Structural Consequences Inherited from Vols I–III 106
The four-conductor split and the Koszul-self-dual trinity 107
Universal chain-homotopy normalisation 107
Shadow-tower exact closed forms 107

Shadow-Galois Chenevier determinant at $p = 691$ . . . 108
Drinfeld double global obstruction class . . . 108
Eight-form Gritsenko–Cléry spread and cover assignment . . . 108
Three-factor universal trace identity with ζ-regularisation . . . 108
Two-stage factorisation of the Calabi–Yau-to-chiral functor . . . 109
K3 Hall–Drinfeld chiral-bialgebra equivalence . . . 109
CoHA-to-$W_{1+\infty}$ triangle with two λ-parameters . . . 109
Three-tier topologisation discipline . . . 109
Khan–Zeng finite-jet BV/PVA sector . . . 110
Joyce–KPS compact Calabi–Yau threefold sector . . . 110
Post-Tate Hadamard support and the M_t-graph dual . . . 110
Boundary frontiers F1–F10 . . . 111

8 Relative coefficient envelopes . . . 113
8.1 Coefficients in a monoidal category . . . 113
8.2 The comparison of the two bars . . . 114
8.3 Recovery at the empty configuration . . . 116
8.4 Endomorphisms and the orientation of composition . . . 116
8.5 Scalar change . . . 117

9 Connected descent and seam corings . . . 119
9.1 The coring of an algebra map . . . 119
9.2 Composition after restriction . . . 120
9.3 The empty coefficient and noncommutative differentials . . . 121
9.4 A matrix obstruction to strong connected transport . . . 122
9.5 Reconstruction along an arity filtration . . . 124
9.6 Effective coring descent . . . 125

10 Arithmetic coefficients and local conditions . . . 129
10.1 The arithmetic curve and its coefficients . . . 129
10.2 Continuous cochains with their multiplication . . . 130
10.3 Local conditions and retained primitives . . . 131
10.4 Completion before rationalization . . . 132
10.5 Restriction, transfer, and tensor support . . . 134
10.6 Deformation functors on one coefficient category . . . 134
10.7 The Selmer pullback and its tangent . . . 136
10.8 Real places and the range of cohomology . . . 137
10.9 Tame symbols and their recipients . . . 137
10.10 Iwasawa coefficients and coalgebra length . . . 139

11 Relative products and all-arity gluing . . . 141
11.1 The two endpoint products . . . 141
11.2 The integral bar comparison . . . 143
11.3 Transporting all module operations . . . 145
11.4 Relative bimodules . . . 146
11.5 The homological meaning of the bar . . . 147

11.6 Homotopy-commuting coefficient maps . . . 148
11.7 Finite precision and continuous gluing . . . 148

12 Hall correspondences and primitive kernels . . . 151
12.1 Extension counts and the tensor crossing . . . 151
12.2 The local primitive and its Green norm . . . 153
12.3 Flag convolution and a nonacyclic primitive class . . . 154
12.4 A Fourier kernel on the extension space . . . 155
12.5 Every cut of a flag . . . 156
Comparison with the scalar Hall primitive . . . 158
12.6 The attaching maps and their contractions . . . 158
The omitted outer covector locus . . . 160
12.7 Descent after forgetting the flag . . . 160
12.8 Cohomology of the extension correspondence . . . 162
12.9 Primitive fields for a symmetric quiver . . . 163
12.10 A potential and the perverse filtration . . . 165
12.11 An ordinary coproduct obstruction on a shuffle algebra . . . 167
12.12 The arithmetic Hall comparison . . . 169

13 Hecke, Adams, and Witt operations . . . 171
13.1 Three operations on mode indices . . . 171
13.2 Composition and the boundary of a prime chain . . . 172
13.3 The algebra of linear divisor operators . . . 174
13.4 The linear Hecke law and its determinant . . . 175
13.5 Satake parameters and the radial state . . . 176
The integral cyclic module of a tree . . . 177
Finite sets of primes . . . 180
13.6 The integral symmetric-function lattice . . . 180
Special lambda operations . . . 181
13.7 Big Witt coordinates and the cofree construction . . . 183
Plethysm and the full comonad . . . 184
13.8 Products, gradings, and algebraic completions . . . 186
13.9 Oscillator intertwiners and vertex products . . . 187
13.10 Hilbert closures and a weighted threshold . . . 188
The kernel created by completion . . . 189
The exact weighted boundary . . . 190
13.11 Operations and states in the arithmetic comparison . . . 192

14 Hall fields on curves . . . 195
14.1 Closed points and Green adjunction . . . 195
14.2 Three normalizations of the exchange . . . 197
An elementary modification . . . 198
14.3 Local fields on every polynomial Hall state . . . 199
Finite power covers . . . 200
Fields, quasi-modules and residue maps . . . 200

14.4 Collective counting fields . . . 201
Reciprocal normalization . . . 202
A finite-dimensional trace comparison . . . 203
14.5 Gain equations and their derived intersections . . . 203
The divided exponential chart . . . 204
Scalar operations on the pole ring . . . 205
14.6 Supported coefficients with excess . . . 205
Normal derivatives and the ordinary module . . . 206

Scalar actions and the full categorical center . . . 508
Gluing central actions . . . 509
20.23 The marked arithmetic comparison . . . 510
21 Enhanced traces and sewing . . . 513
21.1 A trace and the class it evaluates . . . 513
21.2 Chains, cyclic rotation, and completion . . . 514
Categorical trace and Morita comparison . . . 516
21.3 A functional that supplies sewing . . . 516
21.4 Spherical traces and marked closures . . . 518
The scalar unit of a Leavitt algebra . . . 519
21.5 Extensions and regular Hochschild traces . . . 520
The dual numbers . . . 520
A directed algebra and cyclic endpoint matching . . . 521
21.6 Tensoring local trace complexes . . . 522
21.7 Orthogonal blocks and cyclic decomposition . . . 524
Filtered continuity on a specified trace carrier . . . 525
21.8 Arithmetic shifts, phases, and occupation traces . . . 526
Normalized creation and higher modes . . . 527
The Gibbs trace and its domain . . . 528
21.9 Gauge classes in Hochschild cohomology . . . 528
Finite cycles detecting every exterior degree . . . 529
21.10 Smooth algebras and the time generator . . . 531
Closed differentiation in physical time . . . 532
Logarithmic dilation and an actual circle quotient . . . 533
21.11 Explicit positive local pairings . . . 533
The Segal form and an archimedean line . . . 534
Weighted occupations and two isometries . . . 535
The spherical norm depends on the representation . . . 535
21.12 The prime Gibbs state and its modular conjugation . . . 536
21.13 Restricted tensor pairings and arithmetic placement . . . 538
Meromorphic comparison . . . 540
21.14 Instanton sums, Fock traces, and their comparison . . . 541
The hook-weighted specialization . . . 542
The all-charge Fock trace . . . 542
The arithmetic instanton comparison . . . 542
21.15 Geometric transfer operators and Liouville scaling . . . 543
The semiclassical Liouville equation . . . 544
21.16 Tate integrals and meromorphic lines . . . 544
The functional equation and its normalization . . . 545
A scattering phase and a positive measure . . . 546
Discriminants and residues . . . 548
21.17 The maps required for sewing . . . 548

Intermediate labels and coends 549
A finite analytic sewing construction 549
21.18 Genus, rank, and coefficient data 550
Weights and the zero-rank case 551
21.19 Naturality and stabilization 551
Changing the rank 552
Three different diagonal constructions 553
Evaluating a duality defect 553
21.20 The level-dependent Hecke trace 554
21.21 Trace functionals and their analytic domains 555
A common compact test class 556
A finite trace difference with a negative value 556
21.22 The enhanced arithmetic comparisons 557

22 Arithmetic Chern–Simons and boundary realization 559
22.1 Finite gauge fields and their integration 559
Integration over homotopy fibers 560
Boundary lines and adjoints 560
Circle and surface counts 561
22.2 Three-cocycles and finite topological gluing 561
The degree of transgression 562
22.3 The arithmetic action and its boundary torsor 563
An explicit gauge homotopy 563
Local torsors and the global section 564
The decomposition formula 565
Compact p-adic coefficients 565
22.4 Abelian linking and Wilson correlations 566
Local boundary conditions for linking 568
22.5 Wilson values and Frobenius 568
The unramified quotient 569
Coefficient fields and congruences 569
Power traces and Euler factors 570
An elliptic curve at five 571
22.6 Congruence towers and Hilbert limits 571
The lifting measure 571
A positive profinite Hilbert construction 572
The bounded part of an inverse system 573
22.7 Twisted traces and a finite modular example 574
The double of C_2 575
22.8 Ordered incidence and local current algebras 575
An actual tensor construction of vertex algebras 576
22.9 An explicit physical boundary model 577
Regular observables and the ending line 577
All jets with corrected transition maps 578
The boundary period map 579

The Gaussian cap . . . 581
Rigidity in the regular polynomial class . . . 582
22.10 Sewing states and evaluating the formal comparison . . . 583
The jet twist . . . 584
An exact evaluation criterion . . . 585
Coincidence and nested regions . . . 586
22.11 Arithmetic bulk and boundary comparisons . . . 586
Finite towers . . . 587
Modular categories . . . 587
Factorization from fields . . . 587
Fully dualizable objects . . . 588
A six-functor trace . . . 588
Comparing Hilbert realizations . . . 589
22.12 Other physical realizations and the remaining maps . . . 589

23 The Weil algebra and its domain . . . 591
23.1 Compact tests and Mellin reflection . . . 591
23.2 Prime powers and exponential weights . . . 593
23.3 Theta continuation and the zero divisor . . . 594
The argument term in zero counting . . . 596
23.4 The complete arithmetic functional . . . 597
23.5 Exponential extensions and their topology . . . 599
23.6 The polar and finite-prime forms . . . 600
23.7 The gamma kernel and its auxiliary form . . . 602
A second gamma density . . . 603
23.8 Gaussian normalization and cross terms . . . 604
The heat normalization . . . 606
Changing the Fourier scale . . . 606
The auxiliary Gaussian cone . . . 607
23.9 The complete positivity criterion . . . 608
23.10 Moment equations and the topology of approximation . . . 610
23.11 The maximal positive convolution ideal . . . 613
23.12 The independent arithmetic comparison . . . 616

II The Arithmetic Realization Branch 617

24 The Arithmetic Realization Branch . . . 619
24.1 Identity . . . 619
24.2 Form Discipline . . . 619
24.3 Local-to-Global Form . . . 620
24.4 Realization over $\overline{\mathrm{Spec}\,\mathbb{Z}}$ . . . 621
24.5 Source Decomposition . . . 621
24.6 Conventions . . . 621
24.7 Imports and Assembly . . . 621

24.8 Arithmetic-Modular Extension: All-Genus Axis . . . 622
24.9 Arithmetic Gravity and the E_1 Ordered Bar . . . 623

25 The Arithmetic Curve and the Heisenberg Cover . . . 625
25.1 The Arithmetic Curve . . . 625
25.2 Λ-Ring Input . . . 625
25.3 The Finite Heisenberg Cover . . . 626
25.4 The Divisor-Substitution Obstruction to GL_2-Hecke . . . 626
25.5 Polynomial Averaging and the Arithmetic Comparison . . . 627
25.6 The Depth Analogy . . . 627
25.7 Boundary Conditions for the Five Arithmetic Analogues . . . 628
25.8 Boundary Conditions . . . 628

26 Finite-place fields and arithmetic comparison . . . 631
26.1 The formal algebra over a finite-place field . . . 631
26.2 Conformal normalization and logarithmic energy . . . 632
26.3 Common coefficients and restricted tensors . . . 632
26.4 Completion in the prime and completion at the diagonal . . . 633
26.5 Choosing a local coefficient model . . . 633
26.6 The adelic and automorphic comparison . . . 634
26.7 Formal loop spaces and the arithmetic problem . . . 634
26.8 The local and global maps still required . . . 635

27 Divisor Substitutions and Satake Parameters . . . 637
27.1 The Satake Pair and Why It Matters . . . 637
27.2 Adams operations and Hecke representations . . . 637
27.3 Explicit Computation: The Recursion Fails . . . 638
27.4 Diagonalisation onto the Satake Pair . . . 639
27.5 The Angle θ_p as Unramified Langlands Parameter . . . 639
27.6 A radial Hecke comparison . . . 640
27.7 Hecke operations and the distinguished state . . . 642
27.8 Finite sets of primes and the arithmetic comparison . . . 643
27.9 The Chiral Framework over $\overline{\mathrm{Spec}\,\mathbb{Z}}$ . . . 643
27.10 The Corrected Local Model and Its Consequences . . . 644

28 Divisor sums and Adams operations on polynomial Fock space . . . 645
28.1 The two substitutions . . . 645
First-mode calculations . . . 645
28.2 Composition on a prime chain . . . 646
28.3 An explicit presentation of the prime-chain algebra . . . 648
28.4 Integral Adams operations and the Hall lattice . . . 649
The two integral lattices . . . 650
28.5 Products, coproducts, and gradings . . . 650
28.6 Oscillators and vertex operations . . . 651
28.7 Hilbert completion and arithmetic energy . . . 652
28.8 The Common Algebraic Image and the Hilbert Kernel . . . 654

A Weighted Hilbert Threshold . . . 656
28.9 The arithmetic comparison problem . . . 658
28.10 Curve zeta functions in Hall operator exchange . . . 658
Local Hall operators and their normalization . . . 659
The global exchange . . . 660
Torsion acting on a line bundle . . . 661

29 Bost–Connes Operators and Hochschild Trace Classes . . . 663
29.1 The Bost–Connes C^*-Algebra . . . 663
29.2 Prime occupations and oscillator operators . . . 664
29.3 Arithmetic phases and the comparison carrier . . . 664
29.4 The tensor decomposition by current modes . . . 665
29.5 Kesten–McKay = Plancherel of Unramified $GL_2(\mathbb{Q}_p)$ . . . 666
29.6 The Soibelman Cohomological Hall Algebra Reading . . . 667
29.7 Gauge Derivations and Smooth Domains . . . 667
Higher Gauge Cup Products . . . 669
Finite-Prime and All-Prime Gauge Smoothness . . . 671
29.8 Vertex-Algebraic Invariants of the Heisenberg Covers . . . 674
29.9 The Fock representation and the trace comparison . . . 674
29.10 Structural Conclusions . . . 674

30 Adelic Factorization Axioms . . . 677
30.1 The Ran Space of $\overline{\mathrm{Spec}\,\mathbb{Z}}$ . . . 677
30.2 Factorization for Disjoint Place Labels . . . 677
30.3 The Diagonal and $\mathbb{Z}_p \mathbin{\widehat{\otimes}} \mathbb{Z}_p$ . . . 678
30.4 Pointed Data at Each Finite Place . . . 678
30.5 The Holomorphic-Topological Structure . . . 678
30.6 Five Axioms (F1)–(F5) for the Minimal Adelic Factorization . . . 679
(F1) Archimedean factorization. . . . 679
(F2) Coefficient category. . . . 679
(F3) Hecke-eigen decomposition. . . . 679
(F4) Archimedean–finite compatibility. . . . 679
(F5) Regular p-adic product. . . . 679
30.7 Classical Factorization at Finite Places: Absence of a BV Action Functional . . . 680
30.8 Factorization Boundary . . . 680

31 The Arithmetic Instanton Partition Function . . . 683
31.1 Nekrasov's Z_{inst} on $\mathbb{C}^2$ . . . 683
31.2 The Arithmetic Curve as a One-Dimensional Object: No Instanton Sector . . . 683
31.3 The Self-Product $\overline{C} \times_{\mathbb{F}_1} \overline{C}$ as Arithmetic Surface . . . 683
31.4 Rank Analysis: $U(1)^\infty$ per Prime . . . 684
31.5 The $\epsilon_2 \to \infty$ Degeneration . . . 684
31.6 Arakelov Coulomb Modulus . . . 685
31.7 Nekrasov–Shatashvili Limit: $\log \zeta(s) = \sum_p \mathcal{W}_p^{\mathrm{NS}}(s)$ . . . 685
31.8 AGT: Semiclassical Liouville Degenerates to Free Boson . . . 685

31.9 Maulik–Okounkov and the Bethe-Hecke Shadow . . . 686
31.10 The Topological-Sector Reading (Compatible with Nekrasov) . . . 686
31.11 The ($\epsilon_2 \to \infty$, $b \to 0$) Degenerate Limit: Structure of $L(s)$ . . . 686

32 The Arithmetic Modular Functor . . . 689
32.1 Axioms and Their Translation . . . 689
32.2 Arakelov Discriminant as Lattice Volume . . . 689
32.3 Weil–Deligne Sewing . . . 690
32.4 Arithmetic Symmetries . . . 690
32.5 Verlinde Scalar and the Class Number Formula . . . 691
32.6 Explicit Computation: Conformal Blocks via Tate Integrals . . . 691
32.7 Functional Equation as Sewing Axiom . . . 691
32.8 Five-Axiom Arithmetic Modular Functor . . . 692
(A1) Finiteness. . . . 692
(A2) Factorization. . . . 692
(A3) Weil–Deligne sewing. . . . 692
(A4) Modular invariance. . . . 692
(A5) Functional equation. . . . 692

33 Arithmetic bar constructions and residue comparisons . . . 693
33.1 Incidence of finite places . . . 693
33.2 Steinberg symbols and reciprocity . . . 693
33.3 The coefficient tensor coalgebra . . . 694
33.4 Graded Koszulness and arithmetic purity . . . 695
33.5 The primary Mellin character . . . 696
33.6 Complementarity and the functional equation . . . 696
33.7 Coalgebra duality with Iwasawa coefficients . . . 697
33.8 A concrete arithmetic coefficient bar . . . 697
33.9 The arithmetic comparison to be constructed . . . 698

34 The Automorphic Vertex of the Langlands–TQFT Triangle . . . 699
34.1 The Kapustin–Witten Obstruction: Absence of Complex Structure . . . 699
34.2 The BLLPRvR Obstruction: Infinite Flavour Rank . . . 699
34.3 The Chern–Simons Obstruction: Irrational Levels . . . 700
34.4 The Belinski–Khalatnikov–Lifshitz Billiard: Thermodynamic Coarse-Graining 700
34.5 The Automorphic Vertex . . . 700
34.6 Asymptotic Symmetries at the BKL End-of-Time Boundary . . . 700
34.7 The Vol III Φ_d Functor: Arithmetic Domain Boundary . . . 701
34.8 Automorphic Placement . . . 701
34.9 The Automorphic Vertex: Structural Consolidation . . . 701

35 Local central charge and global residue . . . 703
35.1 Rescaling and the conformal vector . . . 703
35.2 The sum over primes . . . 703
35.3 The prime zeta function and analytic continuation . . . 704
35.4 Pole order and logarithmic residue . . . 705

35.5 The surviving Witt modes . . . 705
35.6 Mellin reflection and a modular comparison . . . 705
35.7 Arithmetic degree and a possible anomaly comparison . . . 706
35.8 The comparison data . . . 707

36 Integral Relative Galois Cochains and Their Bar Coalgebras . . . 709
36.1 The relative arithmetic problem . . . 709
36.2 Continuous cochains and the path fiber . . . 710
36.3 The bar coalgebra and its universal map . . . 712
36.4 Changing the endpoint in every arity . . . 713
The endpoint isomorphism . . . 715
Strict naturality . . . 717
36.5 The derived tensor interpretation and its hypothesis . . . 718
36.6 Coefficient maps and completion . . . 718
36.7 Corestriction and arithmetic comparison . . . 721

37 Arithmetic Chern–Simons Holography . . . 723
37.1 Class $\mathcal{S}$ Fails Arithmetically . . . 723
37.2 The Hitchin Base Has No Class-$\mathcal{S}$ Arithmetic Specialization . . . 723
37.3 Kim's Arithmetic Chern–Simons . . . 724
37.4 $\mathcal{V}^{\mathrm{prim}}$ and the ACS Boundary Shadow . . . 724
37.5 Wilson Lines Are Labeled by Ramified Hecke Characters . . . 725
37.6 Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees as Adelic Character . . . 725
37.7 Arithmetic CS as the Generating Principle . . . 725

38 The Hochschild Trace of the Iwahori Hecke Category . . . 727
38.1 The Naive $\mathrm{Bun}_{GL_2}(\mathrm{Spec}\,\mathbb{Z})$ Has Only One Coarse Point . . . 727
38.2 The Spherical Hecke Category Collapses the OPE . . . 727
38.3 The Iwahori Hecke Category Carries Convolution Data . . . 728
38.4 The Emerton–Gee Spectral Side . . . 728
38.5 The Hochschild Trace Placement . . . 729
38.6 Connection to Gaiotto's 3D Chern–Simons Presentation . . . 729
38.7 Hecke Trace = Eichler–Selberg . . . 730
38.8 The Arithmetic Langlands Diamond for $\mathcal{V}^{\mathrm{prim}}$ . . . 730

39 Arithmetic E_n Formality and CoHA . . . 731
39.1 Chains on Little Intervals and Rectification . . . 731
39.2 E_2-Formality Fails Integrally . . . 731
39.3 A Specified Strict Associative Model . . . 732
39.4 The Chiral Bracket via Adelic Residue . . . 732
39.5 The arithmetic Hall comparison . . . 733
39.6 Euler series and cyclic classes . . . 733
39.7 Arithmetic Formality Stratification . . . 733

40 The Arithmetic Yangian Collapses to Its Bethe Subalgebra . . . 735
40.1 The Four Obstructions to a Naive Arithmetic Yangian . . . 735
40.2 The Bethe-Algebra Collapse . . . 735

40.3 Primes Are Lattice Sites, Not Spectral Parameters . . . 736
40.4 Automorphic Closure as Bethe Heuristic . . . 737
40.5 Explicit Computation: $\mathfrak{gl}_1$ and $\mathfrak{gl}_2$ . . . 737
$\mathfrak{gl}_1$ (Dirichlet characters) . . . 737
$\mathfrak{gl}_2$ (Hecke eigenforms) . . . 737
40.6 Local r-Matrix per Prime . . . 737
40.7 Yangian → Hecke = Langlands as Arithmetic Bethe Ansatz . . . 738

41 Synthesis: Six Conditional Windows . . . 739
41.1 The Synthesis . . . 739
41.2 The Essential Theorem . . . 740
41.3 Five Arithmetic Comparison Problems . . . 740
41.4 Segal Axioms as Tate's Thesis . . . 741
41.5 Rank Residue . . . 741
41.6 The Coherent Arithmetic Structure . . . 741
(B) Base. . . . 742
(V) Chiral algebra. . . . 742
(M) Module category. . . . 742
(W) Wilson-line defects. . . . 742
(F) Modular functor. . . . 742
(Z) Partition function. . . . 743
(R) Rank residue. . . . 743
(K) Koszul complementarity. . . . 743
41.7 Langlands as Arithmetic Bethe Ansatz . . . 744
41.8 Source-Family Convergence . . . 745
41.9 The Three Open Conjectures . . . 745
41.10 Structural Rigidity of $\mathcal{V}^{\mathrm{prim}}$ . . . 746
41.11 Logical Form of the Arithmetic Branch . . . 746

42 Boundary Conjectures for the Six-Window Trace . . . 749
42.1 F1: Global Arithmetic Arinkin–Gaitsgory . . . 749
42.2 F2: E_2-Enhancement via Scholze Diamonds . . . 749
42.3 F3: Arithmetic Ben-Zvi–Nadler . . . 750
42.4 Further Boundary Conditions F4–F11 . . . 750
F4: B-Row Arithmetic Realisation . . . 750
F5: Arithmetic Chain Homotopy h_A^{Ar} . . . 751
F6: Chenevier Determinant at $p = 691$ . . . 751
F7–F10: Additional Boundary Conditions . . . 751
F11: All-Genus Arithmetic Koszul Duality . . . 751
42.5 Dependency Lattice . . . 752
42.6 Implication to the Trace Statement . . . 752
42.7 Boundary Index . . . 752

43 Closure of F1–F3 and Resolution of the Three Pillars . . . 755
43.1 Conditions for an Arithmetic Comparison . . . 755
43.2 F1: Structural Closure . . . 755

Statement . . . 755
Mathematical Inputs and Comparison Conditions . . . 756
Local geometric inputs. . . . 756
Obstruction 2 (conventions). . . . 756
Obstruction 3 (ambient categories). . . . 756
Obstruction 4 (missing hypothesis). . . . 756
Obstruction 5 (false functoriality). . . . 756
Obstruction 6 (unproved equivalence). . . . 756
Obstruction 7 (numerical comparison). . . . 756
Structured Reduction . . . 756
43.3 F2: Structural Closure . . . 758
Statement . . . 758
Mathematical Inputs and Comparison Conditions . . . 758
Local geometric inputs. . . . 758
Local geometric comparison. . . . 758
Ambient categories. . . . 759
Pointing maps. . . . 759
Cross-place coherence. . . . 759
Formal assembly and geometric comparison. . . . 759
Scope. . . . 759
Structured Reduction . . . 759
43.4 F3: Conditional Closure . . . 760
Statement . . . 760
Mathematical Inputs and Comparison Conditions . . . 760
Carriers and conventions. . . . 760
Obstruction 5 (false functoriality). . . . 760
Obstruction 6. . . . 760
Scope. . . . 760
Conditional Closure . . . 760
43.5 P1: G-Row Complementarity and the Functional Equation . . . 761
The Arithmetic Comparison . . . 761
The Character and Its Missing Identifications . . . 761
A Criterion That Detects Complementarity . . . 762
Mellin Reflection and the Forward Direction . . . 763
43.6 P2: Tate Functional Equation and Explicit Formula . . . 763
Statement . . . 763
Mathematical Inputs and Comparison Conditions . . . 763
Analytic normalization. . . . 763
Theorem . . . 764
43.7 P3: Unitarity of $\mathcal{V}^{\mathrm{prim}}$ . . . 765
Statement . . . 765
Local Positivity and Pairing Compatibility . . . 765
Theorem . . . 765
43.8 Logical Form Table . . . 766

43.9 Closure Boundary . . . 767
44 The Riemann Hypothesis Reformulation . . . 769
44.1 The Conjecture F-RH . . . 769
44.2 Three-Pillar Implication Structure . . . 769
44.3 Li-Positivity as Arithmetic Virasoro Unitarity . . . 770
Li's Criterion . . . 770
Hilbert–Pólya Transform Computation . . . 770
44.4 Comparison to Existing RH Mechanisms . . . 773
44.5 Residual Conditions . . . 774
44.6 A Sufficient Path to RH . . . 774
44.7 Relation to the Arithmetic Branch Essential Theorem . . . 775
44.8 The F-RH Reduction . . . 775
45 Arithmetic Virasoro Positivity Bootstrap . . . 777
45.1 Statement Recalled . . . 777
The Operator Sequence . . . 777
Conditional Chain: VB* $\Rightarrow$ Li Positivity $\Leftrightarrow$ RH . . . 777
45.2 Obstructions . . . 778
Virasoro levels . . . 778
Moment problem . . . 778
Kac determinant . . . 778
Fock combinatorics . . . 779
Weil trace . . . 779
de Branges datum . . . 779
45.3 Level-by-Level Positivity . . . 779
Level $n = 1$: Unconditional . . . 779
Level $n = 2$: Formal Threshold . . . 780
Levels $n = 3, 4$: Bombieri-Lagarias Upper Bound . . . 780
45.4 Moment Problem Reformulation . . . 781
The Shifted Zero Measure . . . 781
Li-Stieltjes Moment Formulation . . . 781
Hamburger Moment Determinacy . . . 781
45.5 Local Kac Determinant at $c = 2$ . . . 782
The Kac Formula . . . 782
The Arithmetic $c = 2$ Regime . . . 782
Unitarity Gap at Special Weights . . . 783
45.6 Fock-Combinatorial Identity . . . 783
Explicit Action on Number States . . . 783
The Symmetric-Function Identity . . . 784
45.7 Reduction to the Irreducible Core Obstruction . . . 784
The Core Statement . . . 784
The Named Obstruction . . . 785
45.8 Comparison to Classical RH Equivalents . . . 785
45.9 Zero-Divisor Condition . . . 786

The Precise Condition . . . 786
Virasoro Boundary . . . 786
45.10 Arithmetic Zhu Finiteness Test . . . 787
45.11 Zero-Measure Conjecture . . . 788
45.12 Operator Boundary . . . 788
46 Arithmetic Co–Contra Comparison . . . 791
46.1 Statement and Motivation . . . 791
Review: Classical Positselski . . . 791
The Λ-Coefficient Target . . . 792
46.2 Obstruction Analysis Table . . . 794
Obstruction 1: Base-Change Lift . . . 794
Obstruction 2: Exact Structures and Derived Recipients . . . 794
Obstruction 3: μ-Invariant Vanishing for the Heisenberg Bar . . . 794
Obstruction 4: Weight Compatibility Under Bar–Cobar . . . 795
Weight comparison. . . . 795
Weight calculation. . . . 795

What a trace forgets

A trace assigns a number to an operation. To recover the operation from that number, one must know what the trace has forgotten. Four elementary calculations will guide the arithmetic constructions in this volume. They retain, respectively, a primitive of a relation, a higher product, an intermediate module state, and a geometric condition on an arithmetic operator. Each calculation identifies data that a comparison must retain.

Gaussian reduction and multiplication

Fix a real number $\hbar > 0$. The normalized Gaussian functional on polynomials is

$$\mathbb{E}_\hbar[p] = \frac{1}{\sqrt{2\pi\hbar}} \int_{\mathbb{R}} p(x) e^{-x^2/(2\hbar)}\, dx.$$

Integration by parts has no boundary term and gives

$$\mathbb{E}_\hbar[xp - \hbar p'] = 0. \tag{1}$$

This relation defines a two-term cochain complex

$$C^{-1} = \mathbb{R}[x]\varepsilon, \qquad C^0 = \mathbb{R}[x], \qquad d(p\varepsilon) = xp - \hbar p'.$$

There are no other degrees. Its differential is injective: if p has degree n and nonzero leading coefficient, then $xp - \hbar p'$ has degree $n+1$ with the same leading coefficient. The relations

$$[x] = 0, \qquad [x^{n+1}] = \hbar n [x^{n-1}], \qquad n \geq 1,$$

show that $H^0(C)$ is spanned by $[1]$. Equation (1) and $\mathbb{E}_\hbar[1] = 1$ show that $[1] \neq 0$, so

$$H^{-1}(C) = 0, \qquad H^0(C) \cong \mathbb{R}.$$

Under this identification,

$$\mathbb{E}_\hbar[x^{2r+1}] = 0, \qquad \mathbb{E}_\hbar[x^{2r}] = \hbar^r \frac{(2r)!}{2^r r!}.$$

The recurrence proves the formula without evaluating another integral.

Polynomial multiplication does not descend to this quotient. Indeed,

$$d\varepsilon = x, \qquad d(x\varepsilon) = x^2 - \hbar,$$

so $[x] = 0$ but $[x^2] = \hbar[1] \neq 0$. Equivalently, $\mathbb{E}_\hbar[x]^2 = 0$ and $\mathbb{E}_\hbar[x^2] = \hbar$. The differential is not a derivation for the graded product on $\mathbb{R}[x] \otimes \Lambda(\varepsilon)$, where $|\varepsilon| = -1$ and $\varepsilon^2 = 0$: the Leibniz rule applied to $x\varepsilon$ would omit the term $-\hbar$. Thus a valid reduction of complexes need not be a reduction of algebras.

The specified primitives $p\varepsilon$ record which relations have been imposed and how products encounter them.

Even when integration produces an effective quadratic action, that action does not determine the normalization. Let $x \in \mathbb{R}^n$, $y \in \mathbb{R}^m$, and let

$$Q = \begin{pmatrix} A & B \\ B^t & C \end{pmatrix}$$

be real symmetric and positive definite. Here C is invertible. Completing the square gives

$$\int_{\mathbb{R}^m} \exp\left[-\frac{x^t A x + 2x^t B y + y^t C y}{2\hbar}\right] dy \\ = (2\pi\hbar)^{m/2} (\det C)^{-1/2} \exp\left[-\frac{x^t (A - BC^{-1}B^t) x}{2\hbar}\right].$$

To verify both factors, substitute $y + C^{-1}B^t x$ for y and diagonalize the positive matrix C. Each resulting one-dimensional integral contributes $\sqrt{2\pi\hbar/c_i}$, where c_i is an eigenvalue of C. Already with $B = 0$, varying C leaves the effective action $x^t A x/2$ unchanged and changes its amplitude. A comparison of prepared states must therefore preserve both the quadratic response and the determinant factor.

A cubic relation in a strict differential graded algebra

Let k be a field of characteristic zero and $A = k[x]/(x^3)$, with augmentation $x \mapsto 0$. A free resolution of the augmentation module k, in nonpositive cohomological degrees, is

$$\cdots \xrightarrow{x} A \xrightarrow{x^2} A \xrightarrow{x} A \longrightarrow k \longrightarrow 0.$$

Write $P^{-n} = Ae_n$ for $n \geq 0$, and

$$d_P e_n = \begin{cases} x e_{n-1}, & n \text{ odd}, \\ x^2 e_{n-1}, & n > 0 \text{ even}. \end{cases}$$

Exactness follows from $\ker(x : A \to A) = (x^2)$ and $\ker(x^2 : A \to A) = (x)$.

The graded endomorphisms of P form an associative differential graded algebra E, with composition as product and differential

$$D(T) = d_P T - (-1)^{|T|} T d_P.$$

Define maps U, H of degree one and V of degree two by

	n odd	$n > 0$ even
Ue_n	e_{n-1}	$-xe_{n-1}$
He_n	0	$-e_{n-1}$

$$Ve_n = e_{n-2} \quad (n \geq 2).$$

Each map is zero when the indicated output degree is absent. The two parities give the identities

$$DU = DV = 0, \qquad U^2 = -xV = DH, \qquad UH + HU = -V. \tag{2}$$

For example, on e_2, both U^2 and DH give $-xe_0$, while $(UH + HU)e_2 = -e_0$. The same computations repeat every two degrees.

Applying $\mathrm{Hom}_A(-,k)$ to P gives one copy of k in each nonnegative degree and zero differential. Hence $\mathrm{Ext}^n_A(k,k) \cong k$ for every $n \geq 0$. The augmentation $P \to k$ identifies $H^*(E)$ with these groups. Here one uses the elementary property that a bounded-above complex of projective modules maps every acyclic complex to an acyclic Hom complex: a cocycle is made null-homotopic successively from the highest nonzero degree down, lifting at each step through the surjection onto cycles. This applies to the cone of $P \to k$.

Write $u = [U]$ and $v = [V]$. The maps V^r and UV^r map to nonzero elements of $\mathrm{Hom}_A(P^{-2r}, k)$ and $\mathrm{Hom}_A(P^{-(2r+1)}, k)$, respectively. Also $UV = VU$, since their coefficients have the same parity. Together with $U^2 = DH$, this proves

$$H^*(E) = \Lambda_k(u) \otimes_k k[v], \qquad |u| = 1, \quad |v| = 2.$$

There is more information in E than in this binary product. For a degree-one cocycle U with $U^2 = DH$, the cohomology class of $UH + HU$ is its triple Massey product, with this sign convention. It is closed because

$$D(UH + HU) = -U(DH) + (DH)U = 0.$$

Changing either primitive changes its class by an element of $uH^1(E) + H^1(E)u$. This indeterminacy is zero here, because $H^1(E) = ku$ and $u^2 = 0$. Thus

$$\langle u, u, u \rangle = \{-v\} \neq \{0\}. \tag{3}$$

In the graded algebra $H^*(E)$ with zero differential, the same triple product is $\{0\}$, by choosing both primitives zero. Maps of differential graded algebras preserve the displayed construction and its indeterminacy. A quasi-isomorphism therefore preserves this single-valued product under its cohomology identification. Consequently E cannot be joined to $H^*(E)$ with zero differential by a chain of quasi-isomorphisms. Its multiplication was strictly associative from the start. Strict associativity has retained the cubic information in a differential and its primitives; it has not removed it.

An intermediate state in an ordered product

Let e_1, e_2 be the standard basis of k^2, and let E_{ij} send e_j to e_i and the other basis vector to zero. Put $a = E_{12}$, $b = E_{21}$. Then

$$aba = a, \qquad aab = 0. \tag{4}$$

The first word carries e_2 to e_1, then to e_2, then to e_1, reading actions from right to left. The reordered word kills every vector. The order of the intermediate states is part of the operation.

The normalized trace $\tau(M) = \mathrm{Tr}(M)/2$ gives $\tau(ab) = \tau(ba) = 1/2$, and both words in (4) have trace zero. A later input distinguishes them:

$$\tau(abab) = \tfrac{1}{2}, \qquad \tau(aabb) = 0.$$

Even replacing a two-factor product by the scalar operator with the same trace changes subsequent composition. The linear projection $p(M) = \tau(M)I$ satisfies

$$p(ab)a = \tfrac{1}{2}a \neq aba.$$

Thus tracing a collision before composing it with the remaining inputs can discard a coefficient that those inputs still use.

POSITIVE COUNTING DATA WITHOUT THE REQUIRED ABSOLUTE VALUES

Consider the integral matrix

$$M = \begin{pmatrix} 2 & 1 \\ 1 & 3 \end{pmatrix}, \qquad N_n = 5^n + 1 - \operatorname{Tr}(M^n), \qquad n \geq 1.$$

For a positive integer d, let $\mu(d)$ be the Möbius function: it is zero if a prime square divides d, and is $(-1)^r$ if d is the product of r distinct primes. Define

$$a_d = \frac{1}{d} \sum_{e \mid d} \mu(d/e) N_e. \tag{5}$$

Every a_d is a positive integer. For integrality, regard M as the adjacency matrix of a finite directed multigraph. The number $\operatorname{Tr}(M^n)$ counts closed walks of length n with a marked starting point. Grouping them by their least period gives

$$\operatorname{Tr}(M^n) = \sum_{d \mid n} d\, b_d(M),$$

where $b_d(M)$ is the number of primitive cyclic walks of length d. The same statement holds for the one-vertex matrices (5) and (1). Möbius inversion therefore expresses a_d as the difference of three integers.

To prove positivity, write $\lambda = (5 + \sqrt{5})/2$ and $\lambda' = (5 - \sqrt{5})/2$. Both are positive, their sum is 5, and $\operatorname{Tr}(M^n) = \lambda^n + (\lambda')^n$. Consequently $0 < N_n \leq 5^n + 1$ and $N_n \geq 5^n - 2\lambda^n$. Every proper divisor of d is at most $d/2$, so

$$\sum_{\substack{e \mid d \\ e < d}} N_e \leq 2 \sum_{e=1}^{\lfloor d/2 \rfloor} 5^e < 5 \cdot 5^{d/2}.$$

Since $\lambda/5 < 3/4$, equation (5) gives, for $d \geq 4$,

$$d a_d > 5^d \left(1 - 2(3/4)^d - 5^{1-d/2}\right) > 0.$$

The bracket increases with d, and its value at $d = 4$ is $107/640$. Direct calculation gives

$$a_1 = 1, \quad a_2 = 5, \quad a_3 = 25, \quad a_4 = 110, \quad a_5 = 500.$$

Take a_d formal closed points of degree d. Their zeta series, defined by a formal Euler product, is

$$\begin{aligned} Z(t) &= \prod_{d \geq 1} (1 - t^d)^{-a_d} = \exp\left(\sum_{n \geq 1} \frac{N_n}{n} t^n \right) \\ &= \frac{1 - 5t + 5t^2}{(1 - t)(1 - 5t)}. \end{aligned}$$

Each coefficient uses only finitely many factors. The middle identity follows from $N_n = \sum_{d \mid n} d a_d$. The last follows by diagonalizing M, or by the formal identity $-\log\det(I - tM) = \sum_{n \geq 1} \operatorname{Tr}(M^n) t^n / n$.

These counting data admit positive forms of the usual Hall type. At a point of degree d, take finite-dimensional nilpotent $\mathbb{F}_{5^d}[u]$-modules. An object L is a finite direct sum of such local modules over

the formal points. Each automorphism group is finite. On the complex vector space with basis their isomorphism classes, the form

$$\left\langle \sum_L z_L [L], \sum_L w_L [L] \right\rangle = \sum_L \frac{\overline{z_L} w_L}{|\operatorname{Aut}(L)|}$$

is positive definite on finite sums. Extensions and subobjects are finite counting problems at each point; no algebraic curve has been used to supply them.

There is also a reciprocal polynomial and an alternating form:

$$P(t) = 1 - 5t + 5t^2 = 5t^2 P(1/(5t)), \qquad M^t J M = 5J, \qquad J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

Nevertheless the reciprocal roots λ, λ' of P do not have absolute value $\sqrt{5}$. Positive extension-counting forms and these two identities thus do not imply the weight-one absolute-value condition. They have not supplied a geometric Frobenius realization with that property.

The arithmetic comparisons that follow must retain the data exposed by these calculations. A relation has a specified primitive; a product can have a nonzero higher operation; a collision can leave an intermediate state; and a positive auxiliary form need not be the arithmetic functional to be realized. The comparison maps, their coefficient domains, and the operations they preserve are therefore part of the mathematical object studied in this volume.

Preface

Arithmetic operations produce quantities that can also appear as characters, partition functions or spectral traces. The subject of this volume is the comparison before evaluation: the coefficient algebras, modules, relative conditions and geometric operations that could explain such an equality. Its source and target must be constructed, and the map between them must preserve the structures consumed by later operations. Equality of the final numbers is then a consequence with a specified mathematical domain.

The prologue gives four reasons for retaining this information. Gaussian integration preserves a relation complex while changing both products and normalization. The cubic algebra has a strict differential graded model with a nonzero triple product. A matrix coefficient lost by an early trace changes a subsequent four-input evaluation. Positive extension-counting forms and a reciprocal polynomial can coexist with the wrong absolute values for a geometric weight-one operator. These are calculations on explicit carriers; each identifies data that the corresponding scalar has omitted.

Chapter 1 defines comparisons preserving an algebra, a module, a selected vector and a functional. It separates objectwise existence, uniqueness and coherent choice. The coefficient ring and its topology enter the definition: a finite torsion ring admits no unital map to a characteristic-zero field, and taking an inverse limit before rationalization is a different construction.

The algebraic core then retains intermediate coefficient states through relative interfaces. Chapter 8 constructs their composition under the stated central-action and derived tensor hypotheses. Chapter 9 identifies the coring introduced by restriction of coefficients and proves descent under explicit completeness and detection hypotheses. An empty coefficient and a local unit have different carriers; an adjunction counit need not identify a restricted composite with its original interface.

Relative arithmetic classes also retain primitives. For a restriction map $f : A \to B$, a relative cocycle (a, y) satisfies $da = 0$ and $f(a) = dy$. Multiplying two such classes can use one or the other local primitive. Chapter 11 constructs the two products and their integral comparison in every arity, including the induced module and bimodule operations. No division is needed. A restricted inverse limit over finite coefficient rings preserves the comparison; an unrestricted product over word lengths need not do so. Its interpretation as a derived tensor has its own flatness hypothesis.

The comparison questions from the first three volumes retain their specific invariants. For an automorphic product with seed constant coefficient $c_N(0)$, the weight identity

$$w_N = \frac{c_N(0)}{2}$$

is one possible numerical comparison. Interpreting this weight as a Borcherds–Kac–Moody invariant, written κ_{BKM}, requires the actual denominator construction and its normalization. Reading the same seed coefficient twice is not a second construction. Likewise the affine expression

$$\kappa = \frac{\dim(\mathfrak{g})(k + h^\vee)}{2h^\vee},$$

for a simple Lie algebra $\mathfrak{g}$, level k and dual Coxeter number $h^\vee$, is an invariant to compare in its stated normalization. It is not, by itself, a screening-cohomology comparison.

For the Virasoro shadow model, the proposed comparisons involve the rational functions

$$c_S = -\frac{218}{45}, \qquad |\omega|^2(c) = \frac{c^2(5c+22)}{4(45c+218)}, \qquad S_5(c) = -\frac{48}{c^2(5c+22)}.$$

The pole and denominators specify excluded parameter values for these formulas. If an actual function H satisfies $H^2 = t^4 Q_c$, then, on a domain where the quotients are defined,

$$U = (\log H)' - \frac{2}{t} = \frac{Q_c'}{2Q_c}, \qquad U' + 2U^2 = \frac{Q_c''}{2Q_c}.$$

The second identity follows by differentiating the first. Identifying these functions with a shadow tower, a Borel invariant or an operator-product coefficient requires the respective construction. The four quantities (K, K^κ, K_c, K_g), the conductor, complementarity, central-charge and ghost-number invariants, likewise have different definitions. Their comparisons, the determinant at $p = 691$, and the eight-form Gritsenko–Cléry family enter with the source hypotheses stated for each object.

For the finite-type, freely generated finite-jet Khan–Zeng Poisson vertex models, the shifted-cotangent Batalin–Vilkovisky construction compares the classical master equation with the Hamiltonian condition. The quantum master equation, reflected weights, boundary vertex algebra and higher operadic lift require additional analytic and geometric constructions. The spectral-decomposition retract, Fulton–MacPherson boundary terms, reflection conventions and the lift map belong to those hypotheses; the classical calculation does not supply them. The holomorphic–topological comparison also concerns the seven presentations of the two-coloured chiral–topological Swiss-cheese datum $\mathsf{SC}^{\mathrm{ch,top}}$. The operadic, Koszul-dual, factorization, BV/BRST and convolution descriptions require their actual comparison maps. The Drinfeld-centre and derived-geometric descriptions further require the specified enrichment and representability hypotheses.

On the Calabi–Yau side, a specified two-stage construction has the form

$$\Phi_d = \mathrm{Sp}^{\mathrm{ch}}_{\Sigma_{d-1},C} \circ \Phi_d^{\mathrm{FA}}.$$

The first map produces the declared factorization object; the second uses the chosen cycle Σ_{d-1}, curve C and its specialization data. Comparisons with a K3 Hall–Drinfeld object $\mathbf{H}_{\Delta_5}$, Joyce's vertex algebra and Kontsevich–Pandharipande–Soibelman orientation data, the Maulik–Nekrasov–Okounkov–Pandharipande invariants, or a framed Lagrangian theory each require their own maps. The proposed K3 representation targets are the full rank-24 Mukai module, a Heisenberg–Mukai quotient, and an intermediate quantum vertex W-algebra. Identifying any of these targets requires the evaluation map, its preserved form and the specified $\mathfrak{so}(4,20)$ action. An S^3-framing likewise belongs to the Lagrangian data. A proved specialization does not identify all the other constructions with it.

The analytic arithmetic endpoint is the full signed Weil functional, with both polar evaluations, the archimedean term and every prime power. A positive state on an auxiliary algebra gives a realization of that functional only after a product- and involution-preserving comparison and its evaluation identity have been proved on the full test domain. Chapter 119 separates the stated arithmetic comparisons from the remaining Weil positivity condition; its list is not an exhaustion theorem for every possible realization problem.

The topology of a proposed spectral recipient can already exclude a comparison. The graph norm of multiplication by t on $L^2(\mathbb{R}, dt)$ is

$$\|f\|^2_{\mathrm{gr}} = \int_{\mathbb{R}} (1+t^2)|f(t)|^2\, dt.$$

Every continuous functional is integration against a measurable function q with $\int |q(t)|^2/(1+t^2)\,dt < \infty$. Such a function is locally integrable. If its distribution is supported on a locally finite set, it must vanish, since that set has Lebesgue measure zero. Put $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$, where ζ is the Riemann zeta function. In particular the graph dual cannot carry nonzero point or finite-jet residues on

$$\Gamma_{\xi}^{\mathrm{crit}} = \{\gamma \in \mathbb{R} : \xi(\tfrac{1}{2} + i\gamma) = 0\}.$$

A spectral-flow construction using these residues needs a stronger specified domain, such as a suitable rigged, Paley–Wiener, de Branges or reproducing-kernel space, or a boundary theory with continuous trace and jet maps. It must also retain multiplicities, the full Hadamard divisor where needed, and compatibility with the post-Tate quotient. The choice of recipient is therefore part of the arithmetic comparison itself.

Part I

The Realization Formalism

Chapter 1

Marked realization problems

An arithmetic construction can determine an algebra, a module, and a trace without determining a geometric realization of them. A comparison must specify which of these data it preserves. It must also specify the maps used when the inputs vary. These requirements are already distinct for two-dimensional modules over the dual numbers.

1.1 A character does not determine a module

Let k be a field of characteristic zero, and put $A = k[\epsilon]/(\epsilon^2)$. On the vector space k^2, with basis e_1, e_2, consider the representations

$$\rho_0(a + b\epsilon) = aI, \qquad \rho_1(a + b\epsilon) = aI + bN, \qquad N = \begin{pmatrix} 0 & 1 \\ 0 & 0 \end{pmatrix}.$$

Both are unital algebra maps, since $N^2 = 0$. Their characters, the functions obtained by taking the matrix trace, agree on every element of A:

$$\operatorname{Tr} \rho_0(a + b\epsilon) = \operatorname{Tr} \rho_1(a + b\epsilon) = 2a. \tag{1.1}$$

They are nevertheless nonisomorphic as A-modules. An intertwining isomorphism g would satisfy $g\rho_0(\epsilon) = \rho_1(\epsilon)g$, hence $Ng = 0$, contradicting invertibility. This remains impossible if one permits an automorphism of A: such an automorphism sends ϵ to $c\epsilon$ for some $c \in k^\times$, so its nonzero nilpotent action remains nonzero.

The vector e_2 gives a further useful mark. It generates the whole module under ρ_1, since $Ne_2 = e_1$; under ρ_0 it generates only ke_2. The common character has forgotten an extension and a cyclic-vector condition. Even equality of all these scalar evaluations does not provide the module comparison.

1.2 The data carried by a comparison

Fix a commutative ring R. Complexes are cohomological and all tensor products in this section are over R. A *marked algebra with module and functional* is a tuple

$$\mathcal{A} = (A, M, v, \tau),$$

where A is a unital associative differential graded algebra, M is a left differential graded A-module, $v : R \to M$ is a chain map, and $\tau : A \to R$ is a chain map of degree zero. The chosen vector $v(1)$ is therefore closed. If the functional is required to be cyclic, this means

$$\tau(ab) = (-1)^{|a||b|}\tau(ba)$$

for homogeneous inputs. Cyclicity is an extra hypothesis; it is not part of the meaning of an arbitrary functional.

A comparison $(f, g) : \mathcal{A} \to \mathcal{A}'$ consists of a unital differential graded algebra map $f : A \to A'$ and a chain map $g : M \to M'$ such that

$$g(am) = f(a)g(m), \qquad g \circ v = v', \qquad \tau' \circ f = \tau. \tag{1.2}$$

An isomorphism requires both maps to be invertible. A comparison need not be an isomorphism: its image and the operations lost in its kernel can be part of the question.

The two distinguished maps in this tuple have different types. The algebra unit is a map $R \to A$. The selected vector is a map $R \to M$. Unitality of the action says $1_A m = m$; it does not choose v. In geometric constructions an empty coefficient and a local vacuum likewise need their own maps on their respective carriers.

Additional operations enlarge the tuple and the equations (1.2). For example, an endomorphism $F_A : A \to A$ is preserved when $f F_A = F_{A'} f$; an operator F_M on the module requires $g F_M = F_{M'} g$. An involution requires its own compatibility. If a multiplication is associative only through specified higher homotopies, the comparison contains components compatible with those homotopies. Keeping only its first component is then a different comparison problem.

PROPOSITION 1.2.1. The displayed marked objects and their comparisons form a category. Every comparison preserves an ordered module operation and its final evaluation whenever the latter is defined by the retained maps. In particular,

$$g(a_1 \cdots a_r v(1)) = f(a_1) \cdots f(a_r) v'(1), \qquad \tau'(f(a_1) \cdots f(a_r)) = \tau(a_1 \cdots a_r).$$

Proof. Compose the algebra maps and the module maps separately. Substitution in each equation of (1.2) verifies it for the composite; identity maps satisfy the same equations. Ordinary composition of chain maps gives associativity. The first displayed identity follows by induction using the module equation. The second uses multiplicativity of f and then $\tau' f = \tau$. No factors have been interchanged, so no new Koszul sign occurs. □

The converse is false if only scalar identities are retained. Equation (1.1) gives characters agreeing on every input while the modules are not isomorphic. The ordered matrix calculation in the prologue shows why even a scalar identity at one arity may fail to survive insertion into a larger operation.

1.3 Coefficient change and geometric carriers

A change of coefficient ring begins with an actual unital map $R \to S$ of commutative rings. Ordinary extension gives

$$A_S = S \otimes_R A, \qquad M_S = S \otimes_R M, \qquad v_S = 1 \otimes v, \qquad \tau_S = 1 \otimes \tau,$$

using $S \otimes_R R \cong S$. Its algebra product and action are the induced ones. Tensoring the equations (1.2) gives a comparison over S. This algebraic construction does not require flatness. Extension depending only on quasi-isomorphism classes uses derived tensor products, with compatible algebra and module resolutions when needed.

For a prime ℓ and $r \geq 1$, there is no unital ring map $\mathbb{Z}/\ell^r \to K$ to a field K of characteristic zero: the relation $\ell^r 1 = 0$ would have to hold in K. More generally, if an abelian group V is annihilated by ℓ^r, then

$$V \otimes_{\mathbb{Z}} K = 0,$$

because $v \otimes c = \ell^r v \otimes (c/\ell^r) = 0$. Thus direct rationalization of finite-torsion cochains loses their coefficients.

The inverse-limit construction is different. With the usual reduction maps,

$$\mathbb{Z}_\ell = \varprojlim_r \mathbb{Z}/\ell^r, \qquad \mathbb{Q}_\ell = \mathbb{Z}_\ell[1/\ell].$$

Every term of the inverse system tensors to zero over $\mathbb{Z}$ with $\mathbb{Q}$, whereas $\mathbb{Z}_\ell \otimes_{\mathbb{Z}} \mathbb{Q} \cong \mathbb{Q}_\ell \neq 0$: an integer prime to ℓ is already a unit in $\mathbb{Z}_\ell$. Tensoring with $\mathbb{Q}$ has therefore not commuted with this inverse limit. There is also no continuous unital field map $\mathbb{Q}_\ell \to \mathbb{C}$ with their usual topologies. Such a map fixes the rational numbers, but the sequence ℓ^n tends to zero in $\mathbb{Q}_\ell$ and has unbounded complex absolute value. This argument concerns continuity, not the existence of an abstract field embedding.

Geometry introduces another change of carrier. If an arithmetic input is defined over R and the position curve X is defined over a field k, the coefficient functor and its interaction with the operations must be specified. Even after a scalar map $R \to k$ has been chosen, a coefficient algebra alone gives no sheaves on the Cartesian powers X^I, for finite ordered sets I, no restrictions to collision strata, and no maps for inserting one configuration into another.

For a chosen family of sheaves A_I, write $\boldsymbol{Q}_n(A_{I_1}, \dots, A_{I_n}; A_J)$ for its declared complex of allowed operations. The definition of $\boldsymbol{Q}_n$ must specify supports, pole or growth bounds, tensor products and completions, as appropriate to the example. A geometric comparison is then a system of maps on these actual complexes preserving their differentials, substitutions and specified units. A primitive in a larger Hom complex need not belong to $\boldsymbol{Q}_n$. Consequently an obstruction being exact after forgetting support or continuity does not provide a comparison in the chosen category.

1.4 Existence, uniqueness, and coherent choice

Suppose that a category of realizations and a category of retained data have been constructed, together with a forgetful functor. A groupoid is a category in which every arrow is invertible. To ask for realizations up to isomorphism, retain all objects and only invertible arrows. Denote the resulting groupoids by $\mathscr{R}$ and $\mathscr{D}$, and the functor between them by $U : \mathscr{R} \to \mathscr{D}$. For $d \in \mathscr{D}$, its *realization groupoid* has objects

$$\operatorname{Ob} \operatorname{Real}_U(d) = \{(r, \alpha) : r \in \mathscr{R},\ \alpha : U(r) \xrightarrow{\sim} d\}.$$

An arrow from (r, α) to (r', α') is an arrow $h : r \to r'$ satisfying $\alpha' U(h) = \alpha$. This description is the homotopy fibre of the map of classifying spaces of the two groupoids.

Existence means that this groupoid has an object. Uniqueness up to isomorphism means that it is connected. Uniqueness with a unique compatible isomorphism means that it is equivalent to the one-object groupoid with only its identity arrow; its classifying space is then contractible. Automorphisms of a realization can prevent this last condition even when every realization is isomorphic to it.

In a setting with higher morphisms the analogous definition is

$$\operatorname{Real}_U(d) = \operatorname{hofib}_d(U^{\simeq} : \mathscr{R}^{\simeq} \to \mathscr{D}^{\simeq}),$$

where the superscript denotes the space retaining objects and all equivalences. That formula presupposes the categories and U; it does not construct them. A comparison required to be noninvertible belongs to the relevant category of arrows, with its prescribed source and target, rather than to the displayed space of identifications.

A functor is fully faithful when its maps on all sets of arrows are bijections. It is essentially surjective when every target object is isomorphic to an image object.

PROPOSITION 1.4.1. For a functor between groupoids, every realization groupoid is equivalent to a point if and only if the functor is fully faithful and essentially surjective.

Proof. Essential surjectivity supplies an object (r, α) in each fibre. Full faithfulness supplies the unique arrow between any two such objects, namely the lift of $(\alpha')^{-1}\alpha$. This makes each fibre equivalent to a point.

Conversely, nonemptiness of the fibres gives essential surjectivity. Given $\beta : U(r) \to U(r')$, consider the two objects (r, β) and $(r', 1)$ in the fibre over $U(r')$. Its equivalence to a point supplies exactly one arrow between them. By its defining equation, this is exactly one lift of β. Thus U is fully faithful. □

Objectwise existence alone does not give coherent choices. For an explicit example, let $C_n = \mathbb{Z}/n\mathbb{Z}$, written additively, and let BC_n be the groupoid with one object and automorphism group C_n. Reduction modulo two gives

$$U : BC_4 \longrightarrow BC_2.$$

Its realization groupoid has two objects, corresponding to the two identifications in C_2. Reduction $C_4 \to C_2$ is surjective, so they are isomorphic. The automorphism group of either is the kernel $\{0, 2\} \cong C_2$. Thus the fibre is equivalent to BC_2; in particular it is nonempty.

A functorial section, even one whose composite with U is only naturally isomorphic to the identity, would give a group homomorphism $s : C_2 \to C_4$ splitting reduction. The natural isomorphism changes the composite by conjugation, which is trivial in C_2. But the image of the nonzero element would have to have order dividing two, so it is 0 or 2; both reduce to zero. No such section exists. The missing compatibility is on arrows, although the objectwise existence problem has been solved.

1.5 EVALUATION AFTER THE COMPARISON

The functional equation in (1.2) is a commutative triangle on a common domain. If the two functionals are defined independently, its proof identifies their evaluations. If instead τ is defined to be $\tau' f$, the same triangle holds by definition and gives a transported functional. It has not identified an independently prescribed arithmetic one. Both constructions are legitimate, with different conclusions.

For positivity the algebraic structure being preserved is decisive. Let A, B be complex algebras with conjugate-linear involutions $*$ satisfying $(ab)^* = b^*a^*$, and let $f : A \to B$ preserve the product and involution. Suppose that τ_B is linear on a subspace containing every $f(a)^*f(a)$, and $\tau_B(f(a)^*f(a)) \geq 0$ for all $a \in A$. If $\tau_A(a^*a) = \tau_B(f(a^*a))$ on the same inputs, then

$$\tau_A(a^*a) = \tau_B(f(a)^*f(a)) \geq 0.$$

This implication uses the actual product and involution identities. For an unbounded weight, the displayed expressions must lie in its domain; no value at the unit is inferred. A proposed positive trace realization of the Weil functional must supply this map and this evaluation identity on its full test domain.

The construction of each side is part of the comparison problem. Two arguments may use the same homological algebra without being circular; disjoint lists of references can still conceal a target defined from the desired answer. Independence here requires the arithmetic input and the comparison object to be specified without defining one by the invariant that the comparison is meant to explain. The remaining task is to construct the operation-preserving maps and their coherent behavior under change of inputs.

Chapter 2

Words, collisions, and the two units

Consider three ordered positions (x, y, x), with $x \neq y$. Neither cut 1|23 nor cut 12|3 separates the positions on its two sides. The obstruction is the equality of the first and last positions. A construction based on consecutive cuts must therefore retain a nonconsecutive collision. At four positions, the resulting support has two components, and their coefficients meet in a nonsplit extension. These examples determine the geometric data needed before a bar construction can be compared with fields.

We first construct the tensor product associated with ordered cuts. Its unit is supported at the empty configuration. The local vacuum is a different object, present at every number of positions. We then compute the collision supports and their coefficient complexes, and compare a fixed word with the space of all local orders. Finally, we separate these position spaces from the discrete set of arithmetic places.

2.1 The tensor product of ordered cuts

Let k be a field of characteristic zero and X a nonempty smooth separated curve of finite type over k. Write $\mathcal{D}(Y)$ for the unbounded derived category of right algebraic differential modules on a smooth scheme Y, with its stable enhancement; $\mathcal{D}(k) = \mathcal{D}(\operatorname{Spec} k)$ is the derived category of k-vector spaces. All inverse images, direct images and tensor products below are derived. We use the coherent differential-module formalism of external products, extraordinary inverse images $f^!$, direct images f_*, and localization for an open immersion. Thus base-change isomorphisms include their compatibility with composition. This is the formalism used in chiral Koszul duality.[1] Our cohomological convention is $H^q(M[s]) = H^{q+s}(M)$.

Put $[n] = \{1, \dots, n\}$. A monotone surjection $\alpha : [n] \twoheadrightarrow [m]$ defines a diagonal map

$$d_\alpha : X^m \longrightarrow X^n, \qquad (y_1, \dots, y_m) \longmapsto (y_{\alpha(1)}, \dots, y_{\alpha(n)}).$$

A *word coefficient system* consists of $F_0 \in \mathcal{D}(k)$, objects $F_n \in \mathcal{D}(X^n)$ for $n > 0$, and coherent equivalences $d_\alpha^! F_n \simeq F_m$. Coherent means that these equivalences and all their composition homotopies are part of the datum. Its category is

$$\mathcal{W}_X = \mathcal{D}(k) \times \varprojlim_{\substack{[n]\neq\varnothing \\ \text{monotone surjections}}} \mathcal{D}(X^n),$$

where a surjection acts by $d_\alpha^!$. The empty configuration is a separate factor.

For nonnegative p, q with $p + q = n$, let $U_{p,q} \subset X^n$ be the open locus $x_i \neq x_j$ whenever $i \leq p < j$, and write $j_{p,q} : U_{p,q} \hookrightarrow X^n$. If $p = 0$ or $q = 0$, this is the identity open immersion. Define the *cut product* by

$$(F \star_{\mathrm{cut}} G)_n = \bigoplus_{p+q=n} j_{p,q,*} j_{p,q}^!(F_p \boxtimes G_q). \tag{2.1}$$

[1] J. Francis and D. Gaitsgory, *Chiral Koszul duality*, Selecta Mathematica **18** (2012), 27–87, §1.4; arXiv:1103.5803.

Here $X^0 = \operatorname{Spec} k$, so for $n > 0$ the empty terms are the ordinary coefficient tensors $F_0 \otimes_k G_n$ and $F_n \otimes_k G_0$.

PROPOSITION 2.1.1 *(Cut product).* Formula (2.1) defines an associative monoidal structure on $\mathcal{W}_X$. Its unit is

$$K_0 = k, \qquad K_n = 0 \quad (n > 0).$$

For $r \geq 1$ systems $F^{(1)}, \dots, F^{(r)}$, its iterated product in arity n is the sum over consecutive ordered decompositions of $[n]$ into r blocks, localized where positions in different blocks are distinct.

Proof. Let $j : U \hookrightarrow Y$ be an open immersion with closed complement $i : Z \hookrightarrow Y$. Localization gives $i_* i^! M \to M \to j_* j^! M$, and $i^! j_* = 0$. For $N \in \mathcal{D}(U)$ and $f : Y' \to Y$, transitivity of extraordinary inverse images therefore shows that $f^! j_* N$ has zero extraordinary restriction to $f^{-1}Z$. Its restriction to $f^{-1}U$ is the pullback of N. Localization and the full faithfulness of extension from an open set identify it with $j'_* f_U^! N$, where $j' : f^{-1}U \hookrightarrow Y'$. These identifications are coherent under composition.

Apply this to $f = d_\alpha$ and $U = U_{p,q}$. If the cut separates two labels in the same fibre of α, its inverse image is empty. Otherwise it is the inverse image of a unique cut of $[m]$, and the coefficient equivalences for F and G give the corresponding summand in arity m. Thus the displayed sum is a word coefficient system.

In an iterated product, successive localizations require exactly that positions in distinct final blocks be disjoint. Each parenthesization therefore gives the same sum, with the same coefficient and open immersion in every summand. The coherent base-change maps identify these sums; their further compositions agree on the same final open set. This proves every associativity coherence. If one input is K, only its empty block survives, and the remaining summand is the other input. These identifications give the unit coherences. □

Call F *positive* if $F_0 = 0$. For positive inputs, all blocks in the proposition are nonempty. There are $\binom{n-1}{r-1}$ such decompositions when $1 \leq r \leq n$, and none when $r > n$: choose their $r - 1$ cuts among the $n - 1$ gaps. This finiteness concerns the number of geometric blocks. It places no bound on an auxiliary bar length in a coefficient algebra at the empty configuration.

2.2 The empty unit and the local vacuum

There is also a pointwise tensor product of differential modules, using the diagonal $\Delta_{X^n} : X^n \hookrightarrow X^n \times X^n$:

$$(F \otimes^! G)_n = \Delta_{X^n}^! (F_n \boxtimes G_n).$$

Its unit is the dualizing system

$$J_0 = k, \qquad J_n = p_n^! k = \omega_{X^n}[n] \quad (n > 0), \tag{2.2}$$

where $p_n : X^n \to \operatorname{Spec} k$. Transitivity gives $d_\alpha^! J_n = J_m$. The shift in (2.2) is part of the right differential-module convention; J_n is not the unshifted canonical bundle.

A counital coassociative cut coalgebra is an object with a coproduct $C \to C \star_{\mathrm{cut}} C$ and a counit $C \to K$, satisfying their coherent identities. A coaugmentation is a coalgebra map $K \to C$. We call it connected when $C_0 = k$ and the empty components of counit and coaugmentation are identities.

Proposition 2.2.1 *(Vacuum coalgebra).* The system J is a connected cut coalgebra. Its component at a cut is the localization map

$$J_n \longrightarrow j_{p,q,*}J_{U_{p,q}} = j_{p,q,*}j_{p,q}^{!}(J_p \boxtimes J_q).$$

The maps $K \to J \to K$ are identity at the empty configuration and zero in positive arity.

Proof. The adjunction for $j_{p,q}$ gives the displayed map. Two successive coproducts localize on the locus where three consecutive blocks are pairwise disjoint. Both orders of localization give its adjunction map. The same argument works for every number of blocks, proving the coherent coalgebra identities. The cuts with an empty block are identities. They prove the counit and coaugmentation identities. □

A *local vacuum marking* of a connected cut coalgebra is a specified coalgebra map $u : J \to C$. The coaugmentation $K \to C$ determines only its empty value. Even if a nonzero unary vacuum is specified, extending it to such a marking can fail.

Example 2.2.2 *(A unary vacuum that does not extend).* Let $\Delta_n : X \hookrightarrow X^n$ be the small diagonal and put

$$P_0 = k, \qquad P_n = \Delta_{n,*}J_1 \quad (n > 0).$$

Closed base change and Kashiwara equivalence give $d_\alpha^{!}P_n = P_m$. Every positive cut has empty intersection with the small diagonal. Give P zero coproduct at these cuts and identity coproduct at each cut with an empty block. This is a connected cut coalgebra: an iterated coproduct with two or more nonempty output blocks is zero in every parenthesization.

There is no coalgebra map $u : J \to P$ with $u_1 = \mathrm{id}_{J_1}$. Indeed, restrict its binary coproduct identity to $U = X^2 \setminus \Delta_2$. The path through P_2 is zero, whereas the path through $J_1 \boxtimes J_1$ is the identity of J_U. This object is nonzero, since a smooth nonempty curve has two distinct geometric points. The contradiction concerns the specified unary identity. The map $J \to K \to P$, whose positive components vanish, still exists.

2.3 Collisions that block every cut

Write $\Delta_{ij} \subset X^n$ for the equality $x_i = x_j$. For $n \geq 2$, define the reduced closed subscheme

$$Z_n = \left(\bigcap_{p=1}^{n-1} \bigcup_{i \leq p < j} \Delta_{ij} \right)_{\mathrm{red}}. \tag{2.3}$$

Thus a tuple lies in Z_n exactly when every consecutive cut is crossed by an equality. Put $Z_1 = X$. The first cases are

$$Z_2 = \Delta_{12}, \qquad Z_3 = \Delta_{13}, \qquad Z_4 = \Delta_{14} \cup (\Delta_{13} \cap \Delta_{24}). \tag{2.4}$$

For the last equality, a tuple with $x_1 \neq x_4$ must still cross its first and last gaps. If it does not have both $x_1 = x_3$ and $x_2 = x_4$, these two requirements force $x_1 = x_2$ and $x_3 = x_4$. The middle cut then forces all four coordinates equal, contrary to $x_1 \neq x_4$. The converse inclusions follow by checking the three gaps.

There is an equally explicit description in every arity. A matching on $[n]$ is a set of disjoint pairs (a, b), with $a < b$. Associate to it the closed subscheme $\Delta_M = \bigcap_{(a,b)\in M} \Delta_{ab}$. The pair (a, b) crosses the gaps $a, a+1, \ldots, b-1$. Call M spanning if its pairs cross every gap, and irredundant if deleting any pair destroys this property.

THEOREM 2.3.1 *(Components of the cut support).* Assume X is geometrically integral and $n \geq 2$. The irreducible components of Z_n are the Δ_M for irredundant spanning matchings M. A matching with r pairs has codimension r, and there are

$$\binom{n-2}{2r-2}, \qquad 1 \leq r \leq \lfloor n/2 \rfloor,$$

such components. For $n \geq 3$ their total number is 2^{n-3}.

Proof. The equalities of a geometric tuple partition $[n]$ into blocks. In a block with at least two labels, replace all its equalities by the equality of its smallest and largest labels. This retains exactly the gaps crossed by that block. The resulting pairs are disjoint. If the tuple lies in Z_n, they form a spanning matching; remove redundant pairs to obtain M. Consequently Z_n is the union of the Δ_M in the statement.

Order the pairs by their left endpoints, $a_1 < \cdots < a_r$. An interval contained in another is redundant, so their right endpoints also increase. Spanning gives $a_1 = 1$, $b_r = n$, and $a_{i+1} < b_i$: equality of these endpoints is excluded because this is a matching. A pair has a gap not crossed by its neighbours exactly when $b_{i-1} < a_{i+1}$, for $1 < i < r$. Thus, for $r > 1$, the endpoints occur in precisely the order

$$1 = a_1 < a_2 < b_1 < a_3 < b_2 < \cdots < a_r < b_{r-1} < b_r = n.$$

Conversely this order makes the matching spanning and gives every pair a private gap. Choosing its $2r-2$ interior endpoints therefore gives the binomial coefficient above. For $r = 1$, the unique pair is $(1, n)$.

Each Δ_M is isomorphic to X^{n-r}, hence is irreducible of codimension r. Containment between two such diagonals would make the partition into pairs for one refine that for the other. Since a pair has no nontrivial proper refinement except deletion, irredundancy excludes a strict containment. They are therefore exactly the components. Summing the even binomial coefficients of order $n-2$ gives 2^{n-3} when $n \geq 3$. □

2.4 COEFFICIENT COMPLEXES ON THE COLLISION SUPPORT

A support records where a coefficient can live. It does not record the coefficient or its maps along intersections. We make those maps explicit for $X = \mathbb{A}^1_k$. Let $R = k[z_1, \ldots, z_n]$. For this calculation we use complexes of R-modules. Their localizations have natural left differential-module actions. Tensoring with $\omega_{X^n}[n]$ gives the corresponding supported right-module coefficients of J_n; the scalar complexes below carry no such shift. For $f \in R$, put

$$L_f = [\, R \longrightarrow R[f^{-1}] \,],$$

in cohomological degrees 0, 1, with the localization differential. The augmentation $\epsilon_f : L_f \to R$ is identity in degree zero and zero in degree one. This flat complex represents $R\Gamma_{V(f)}R$, the derived functor of sections supported on $V(f)$. For a general coefficient complex Q, $L_f \otimes_R Q$ represents $R\Gamma_{V(f)}Q$.

Define

$$g_p = \prod_{i \leq p < j} (z_i - z_j), \qquad C_n = \bigotimes_{p=1}^{n-1} L_{g_p}.$$

This is a bounded complex of flat modules, with 2^{n-1} localization summands. Iterated local cohomology gives $C_n \simeq R\Gamma_{Z_n}R$. Local cohomology depends on the reduced support. The ideal generated by the g_p need not be radical: at $n = 3$, with $x = z_1 - z_2$ and $y = z_2 - z_3$, it is

$$(x(x+y),\, y(x+y)) = (x+y)(x,\, y),$$

whose radical is $(x + y)$.

The component description gives another model that displays the attachments. Choose a total order on the finite set $\mathcal{M}_n$ of irredundant spanning matchings. For $M \in \mathcal{M}_n$, let

$$K_M = \bigotimes_{(a,b)\in M} L_{z_a - z_b},$$

with pairs ordered by their left endpoints. For a nonempty subset $A = \{M_0 < \cdots < M_p\}$, put $K_A = K_{M_0} \otimes_R \cdots \otimes_R K_{M_p}$. Repeated equations remain repeated tensor factors in this formula.

Proposition 2.4.1 *(Component model).* The complex

$$S_n = \bigoplus_{\varnothing \neq A \subseteq \mathcal{M}_n} K_A[|A| - 1] \tag{2.5}$$

represents $R\Gamma_{Z_n} R$. On $K_A[p]$, its internal differential is $(-1)^p d_{K_A}$; its other differential is $\sum_{j=0}^{p} (-1)^j \partial_j$, where ∂_j applies the augmentation of K_{M_j} and deletes that factor. The latter differential is zero when $p = 0$. The augmentations give a natural span of quasi-isomorphisms

$$C_n \longleftarrow C_n \otimes_R S_n \longrightarrow S_n. \tag{2.6}$$

The same assertions hold after tensoring with any complex Q.

Proof. The tensor of the L_f's computes local cohomology supported on the intersection of their zero sets. Thus K_A represents $R\Gamma_{\cap_{M\in A}\Delta_M} R$. The augmentation of a factor induces the inclusion of sections supported on this intersection into sections supported on the intersection with that factor omitted. These are the maps ∂_j.

Two deletions commute before their alternating signs, so the horizontal differential squares to zero. It commutes with each unshifted internal differential; the factor $(-1)^p$ makes the two total differentials anticommute. For two closed sets, the resulting complex is the local-cohomology Mayer–Vietoris triangle

$$R\Gamma_{Z\cap Z'} R \longrightarrow R\Gamma_Z R \oplus R\Gamma_{Z'} R \longrightarrow R\Gamma_{Z\cup Z'} R.$$

Iterate this triangle over the finite component set. At each step the new intersections are exactly the summands containing the new component, with the displayed deletion maps. This proves (2.5).

Local cohomology supported on Z_n is idempotent. Indeed, its localization triangle becomes the identity triangle on an object whose restriction to the complement of Z_n vanishes. Apply this to C_n and S_n. The two counits are exactly the arrows of (2.6), so both are quasi-isomorphisms. Every term used is flat and the complexes are bounded. Tensoring the construction with an arbitrary complex therefore computes its derived tensor and preserves these quasi-isomorphisms. □

At the generic point of a component with r pairs, invert the equations that exclude the other components and choose independent normal coordinates $u_1, \ldots, u_r$ for the pairs. Its local cohomology is concentrated in degree r, represented by negative powers of all the u_i. In particular it contains $1/(u_1 \cdots u_r)$; the iterated residue of $du_1 \cdots du_r/(u_1 \cdots u_r)$, in that order, is one. This follows directly by tensoring the r two-term localization complexes, or by their Laurent monomial basis.

The idempotence just used is a property of local cohomology. It must be distinguished from derived intersection. For example, over $k[u]$, the free resolution $[\, k[u] \xrightarrow{u} k[u] \,]$ of k, in degrees -1, 0, gives

$$k \otimes^{\mathbf{L}}_{k[u]} k \simeq k \oplus k[1], \qquad L_u \otimes_{k[u]} L_u \simeq L_u.$$

The first complex retains a normal Tor class. The second retains all principal parts along the same closed support.

2.5 THE FOUR-POINT ATTACHMENT AND NORMAL DERIVATIVES

At four positions choose $a = z_1 - z_4, b = z_1 - z_3, c = z_2 - z_4$, and the spectator coordinate z_4. Suppress the spectator polynomial factor and put $R = k[a, b, c]$. Formula (2.4) becomes

$$Z_4 = V(a) \cup V(b, c) = V(ab, ac).$$

Its coefficient complex is

$$R \xrightarrow{f \mapsto (f,f)} R[(ab)^{-1}] \oplus R[(ac)^{-1}] \xrightarrow{(f,g) \mapsto g - f} R[(abc)^{-1}]. \tag{2.7}$$

Its terms have cohomological degrees 0, 1, 2.

PROPOSITION 2.5.1 *(Nonsplit attachment).* Let

$$M = R[b^{-1}, c^{-1}] / \big(R[b^{-1}] + R[c^{-1}]\big).$$

The only nonzero cohomology of (2.7) is

$$H^1_{Z_4}(R) = R[a^{-1}]/R, \qquad H^2_{Z_4}(R) = M[a^{-1}].$$

The attachment of $V(b, c)$ to the union is the nonsplit exact sequence of R-modules

$$0 \longrightarrow M \longrightarrow M[a^{-1}] \longrightarrow H^3_{(a,b,c)}(R) \longrightarrow 0.$$

Proof. Inside $R[(abc)^{-1}]$, the two middle localizations intersect in $R[a^{-1}]$. This computes H^1. Their quotient in the last term has basis $a^i b^{-j} c^{-l}$, with $i \in \mathbb{Z}$ and $j, l > 0$, which gives $M[a^{-1}]$. There is no degree-zero kernel because localization of the polynomial ring is injective.

The module M is free over $k[a]$, with basis $b^{-j} c^{-l}$ for $j, l > 0$. Its quotient after inverting a has basis with all three exponents negative. This is the top local cohomology at (a, b, c), proving exactness. Every element of this quotient is killed by a power of a, whereas multiplication by a is invertible on $M[a^{-1}]$. Every R-linear map from the quotient back to the middle term is consequently zero. The quotient contains the nonzero class $1/(abc)$, so the surjection has no section. □

The intersection $V(a, b, c)$ cannot therefore be replaced by an independent direct summand while preserving the coefficient action. Even at one normal coordinate, a scalar residue loses this action. To see it in the right differential-module convention, set

$$P = k[u, u^{-1}]\, du / k[u]\, du, \qquad e_r = [u^{-r-1} du] \quad (r \geq 0).$$

The right Weyl action is

$$e_0 u = 0, \qquad e_r u = e_{r-1}\ (r > 0), \qquad e_r \partial_u = (r + 1) e_{r+1}.$$

Indeed, right differentiation of a density $f\, du$ is $-f'\, du$. The formulas satisfy $\partial_u u - u \partial_u = 1$ and give $e_0 \partial_u^r = r! e_r$. All normal derivatives are present. The scalar residue sends e_0 to one and e_r to zero for $r > 0$, but its kernel is not stable under u: $\operatorname{Res}(e_1 u) = 1$. It is therefore insufficient as a replacement for this coefficient module.

2.6 The outer residue

The nonconsecutive support already changes a three-position calculation. Put $x = z_1 - z_2$, $y = z_2 - z_3$, and consider

$$f(x, y) = \frac{1}{x(x + y)}.$$

Let L be the coefficient of $x^{-1}y^{-1}$ in the expansion for $|x| < |y|$, and R the same iterated coefficient for $|y| < |x|$. These inequalities specify formal Laurent expansions; no analytic limiting operation is required. For the outer collision use $u = x + y = z_1 - z_3$. Let N be the coefficient of $u^{-1}y^{-1}$ in the expansion for $|u| < |y|$. The volume form is unchanged: $dx \wedge dy = du \wedge dy$.

Proposition 2.6.1. With these coordinates and orientations,

$$L = 1, \qquad R = 0, \qquad N = -1, \qquad L - R + N = 0.$$

Proof. The three expansions are respectively

$$\sum_{r \geq 0} (-1)^r x^{r-1} y^{-r-1}, \qquad \sum_{r \geq 0} (-1)^r y^r x^{-r-2}, \qquad -\sum_{r \geq 0} u^{r-1} y^{-r-1}.$$

Their indicated coefficients are 1, 0, −1. □

This residue identity does not by itself construct an associativity homotopy. In a specified operation complex Q, closed degree-zero operations L, R, N satisfying $L - R + N = 0$ admit $h \in Q^{-1}$ with $dh = L - R = -N$ exactly when $[N] = 0$ in $H^0(Q)$. For $Q = k$ in degree zero, the three scalars just computed satisfy the identity and admit no such h. A field comparison must specify the operation complex, its supported coefficients and the primitive there.

2.7 All local orders and the word comparison

A fixed word has consecutive cuts. To retain every local ordering at a collision, let I be a nonempty finite set and take a copy X^I_σ of X^I for each total order σ on I. For two orders define

$$V_{\sigma,\rho} = X^I \setminus \bigcup_{\substack{i,j \in I \\ \sigma \text{ and } \rho \text{ order } i,j \text{ differently}}} \Delta_{ij}.$$

Glue the two copies by the identity on this open subset, and denote the resulting scheme by $\mathscr{R}_I$. The chart coordinates induce $q_I : \mathscr{R}_I \to X^I$. For $X = \mathbb{A}^1_{\mathbb{C}}$, this is the configuration space used for raviolo vertex algebras.[2]

Proposition 2.7.1 *(Ordered configuration atlas).* These identifications satisfy the gluing cocycle. The map $q_I : \mathscr{R}_I \to X^I$ is a local isomorphism, and $\mathscr{R}_I$ is smooth and quasi-compact with quasi-compact intersections of affine opens. Over a geometric tuple whose equality blocks are B, its fibre has

$$\prod_B |B|!$$

points. In particular the fibre at a threefold collision has six points.

[2] L. Alfonsi, H. Kim and C. A. S. Young, *Raviolo vertex algebras, cochains and conformal blocks*, §4.1; arXiv:2401.11917.

Proof. On a triple overlap, if two orders disagree on a pair, at least one of their comparisons with the third order disagrees on that pair. Thus $V_{\sigma,\rho} \cap V_{\rho,\tau} \subseteq V_{\sigma,\tau}$. All transition maps are identities, which proves the cocycle. The charts give smoothness and the local-isomorphism assertion. There are finitely many charts; their intersections are complements of finitely many diagonals in the noetherian scheme X^I, so the asserted quasi-compactness follows.

Over a fixed tuple, two charts are identified exactly when they give the same order within each equality block. Every choice of orders on these blocks extends to a total order on I. The choices on different blocks are independent, proving the fibre formula. □

A surjection $\alpha : I \twoheadrightarrow J$ with an order on each fibre defines $\delta_\alpha : \mathscr{R}_J \to \mathscr{R}_I$. On a chart ordered by τ on J, expand each label to its ordered fibre and use the usual diagonal map of coordinates. The inverse image of an overlap is precisely the overlap for the two orders on J, so these chart maps glue. Composing such surjections concatenates the ordered fibres and gives the same diagonal map. These collision maps need not be closed immersions. For the ordered fibres $(1,3)|(2)$, their image in the chart $1 < 2 < 3$ is $\Delta_{13} \setminus \Delta_{123}$, which is not closed in that chart.

Define $\mathcal{C}_X$ to be the category of coherent systems $F_I \in \mathcal{D}(\mathscr{R}_I)$ with $\delta_\alpha^! F_I \simeq F_J$, together with a separate empty coefficient. Differential modules on this possibly nonseparated scheme are defined by descent from its charts. For an ordered decomposition $I = I_1 \sqcup I_2$, let U_{I_1,I_2} be the locus of disjoint positions in different blocks. On that locus, orders between the blocks are identified by the gluing, so the atlas is the corresponding open part of $\mathscr{R}_{I_1} \times \mathscr{R}_{I_2}$. Define $F \star G$ by summing the localized external products over all such ordered decompositions, including empty blocks. The proof of the cut-product proposition applies: a decomposition splitting a collision fibre has empty pullback; every surviving decomposition descends to the quotient. All iterates localize on the same disjoint-block locus. This gives a symmetric monoidal product, whose symmetry exchanges the two blocks.

Restriction to the standard chart $1 < \cdots < n$ defines $\mathrm{res} : \mathcal{C}_X \to \mathcal{W}_X$.

PROPOSITION 2.7.2 *(Projection to consecutive cuts).* There are natural maps

$$\iota_{F,G} : \mathrm{res}\, F \star_{\mathrm{cut}} \mathrm{res}\, G \longrightarrow \mathrm{res}(F \star G),$$
$$\pi_{F,G} : \mathrm{res}(F \star G) \longrightarrow \mathrm{res}\, F \star_{\mathrm{cut}} \mathrm{res}\, G, \qquad \pi_{F,G}\iota_{F,G} = \mathrm{id}.$$

The maps ι make restriction lax monoidal, and the maps π make it colax monoidal. They transport algebra and coalgebra structures, respectively. Neither comparison is an equivalence in general.

Proof. On a standard chart the atlas product is the finite direct sum over all ordered decompositions of $[n]$. Include the summands whose first block is a prefix, or project onto those summands. Under a monotone collision, a surviving prefix is exactly the inverse image of a quotient prefix. The maps therefore respect the word coefficient equivalences.

Every iterated inclusion or projection selects the same final consecutive decomposition with the same localized coefficient. This proves their monoidal coherences, including those for empty blocks, and projection after inclusion is identity. For two positive systems equal to the dualizing system in positive arity, the separated two-point fibre of the atlas product is $J_U \oplus J_U$, indexed by $1|2$ and $2|1$. The cut product has only the $1|2$ summand. Thus π has a nonzero kernel there, and ι has a nonzero cokernel. □

With n positive inputs at n distinct positions, the same calculation gives $n!$ atlas summands and one cut summand. A bar–cobar theorem for the cut product therefore does not identify the corresponding construction on the full atlas. Any such comparison must retain its actual maps on the omitted orders and their collision coefficients.

2.8 Arithmetic places and position geometry

An arithmetic place is a label for a local coefficient object. It need not be a variable position on the curve carrying a field. This distinction already appears in the simplest functors of points. For every scheme S, there is exactly one map $S \to \operatorname{Spec} \mathbb{Z}$. Consequently the functor of nonempty finite subsets of $\operatorname{Spec} \mathbb{Z}(S)$ is terminal. The closed points $\operatorname{Spec} \mathbb{F}_p \to \operatorname{Spec} \mathbb{Z}$ use different test schemes; they are not several elements of this set for one fixed S.

Let $\mathbb{P}$ be the set of rational primes and $V = \mathbb{P} \sqcup \{\infty\}$ the abstract set of places. Its nonempty finite subsets and its nonempty finite multisets are the discrete sets

$$\operatorname{Fin}_+(V), \qquad \operatorname{Mult}_+(V) = \coprod_{n \geq 1} V^n/\mathfrak{S}_n.$$

The coproduct in the second formula records multiplicity; it does not require transition maps between different symmetric powers. For a commutative ring A, let $\mathcal{D}(A)$ here denote the derived category of A-modules. Given complexes $H_v \in \mathcal{D}(A)$, finite tensor products give

$$F(S) = \bigotimes_{v \in S, A}^{\mathbf{L}} H_v, \qquad F(S \sqcup T) \simeq F(S) \otimes_A^{\mathbf{L}} F(T) \quad (S \cap T = \varnothing). \tag{2.8}$$

We include the empty set by $F(\varnothing) = A$. The associators and symmetries of derived tensor give all coherences, with the usual Koszul signs on complexes. This supplies factorization for disjoint labels. Maps at coincident positions, normal derivatives and residue operations require a specified position geometry and further coefficient maps.

To assemble infinitely many places, units must also be specified. More generally, let $\mathcal{E}$ be a cocomplete symmetric monoidal ∞-category with unit $\mathbf{1}$, and let $H_v \in \mathcal{E}$. Choose a cofinite subset $V^{\mathrm{sph}} \subseteq V$ and maps $u_v : \mathbf{1} \to H_v$ for $v \in V^{\mathrm{sph}}$. Let $\operatorname{Fin}^{\mathrm{sph}}(V)$ be the poset of finite subsets containing $V \setminus V^{\mathrm{sph}}$, ordered by inclusion. For $S \subseteq T$, tensor with the maps u_v at the new places to obtain

$$\iota_{S,T} : \bigotimes_{v \in S} H_v \longrightarrow \bigotimes_{v \in T} H_v.$$

The colimit

$$\bigotimes_{v \in V}{}' (H_v, u_v) = \varinjlim_{S \in \operatorname{Fin}^{\mathrm{sph}}(V)} \bigotimes_{v \in S} H_v$$

is called the *Tate restricted tensor product* for these specified reference maps. It is a colimit of a covariant diagram.

Indeed, $\iota_{T,U}\iota_{S,T} = \iota_{S,U}$ coherently: both maps insert the same u_v's in the same labelled factors, and tensor coherence identifies their parenthesizations. The index poset is nonempty and filtered, since the exceptional set is finite and the union of two allowed finite sets is allowed. This constructs the diagram and its colimit. To obtain an algebra, coalgebra or monoidal category by this construction, its reference maps must preserve that structure and its colimit must be taken in a coefficient category that supports the required operations.

PROPOSITION 2.8.1 *(Three finite-place coefficient models).* Let p be a rational prime. Define the completed tensor below to mean the ordinary p-adic completion. Then

$$\varprojlim_r (\mathbb{Z}_p \otimes_{\mathbb{Z}} \mathbb{Z}_p)/p^r \simeq \mathbb{Z}_p, \tag{2.9}$$

$$\mathbb{F}_p \otimes^{\mathbf{L}}_{\mathbb{Z}} \mathbb{F}_p \simeq \mathbb{F}_p \oplus \mathbb{F}_p[1] \quad \text{as a complex,} \tag{2.10}$$

$$\mathbb{Z}_p[[t_1, t_2]]/(t_1 - t_2) \simeq \mathbb{Z}_p[[t]].$$

The kernel in the last line is the nonzero principal ideal $(t_1 - t_2)$.

Proof. Modulo p^r, the first tensor product is $(\mathbb{Z}/p^r) \otimes_{\mathbb{Z}} \mathbb{Z}_p = \mathbb{Z}/p^r$; multiplication induces this isomorphism compatibly for all r. Taking the inverse limit proves (2.9). The free resolution $[\, \mathbb{Z} \xrightarrow{p} \mathbb{Z} \,]$ of $\mathbb{F}_p$, in degrees -1, 0, becomes a complex with zero differential after tensoring with $\mathbb{F}_p$. This proves (2.10). Finally the formal change of variables $u = t_1 - t_2$, $t = t_2$ identifies the last ring before quotienting with $\mathbb{Z}_p[[u, t]]$. Evaluation at $u = 0$ has kernel (u), proving the last assertion. □

The completed base tensor, the derived closed-point intersection and the formal position disc thus retain different data. The first identity does not eliminate the normal class in the second or the position variable in the third. A finite-place field construction can use a chosen formal disc; crystalline or prismatic structures are further possible choices when their Frobenius data are required. None is forced solely by the discrete place index or by the first tensor identity. The arithmetic comparison must specify which position space and which coefficient operations its maps preserve.

Chapter 3

Bar–cobar and coefficient topology

A nonempty ordered configuration of n positions has $n-1$ gaps. A word of positive geometric factors therefore has length at most n. This bound makes the cut bar and cobar finite at each configuration. It does not bound the length of a resolution inside one coefficient module. Such a resolution can be infinite even at the empty configuration, where there are no geometric gaps.

We first prove the duality controlled by positive cuts. We then construct the coefficient bar with its signs and augmentation, and determine when it computes a derived tensor. The final sections compare three ways of allowing infinite words. A series may terminate at every finite precision while having unbounded length. An unrestricted product permits still more series but can destroy the continuity of an otherwise valid comparison.

3.1 Positive words and finite duality

Use the word category $\mathcal{W}_X$, cut product $\star_{\mathrm{cut}}$, and empty unit K of Chapter 2. Write $\star$ for this product throughout the present section. For $p \geq 0$, put

$$\mathcal{W}_{\geq p} = \{F \in \mathcal{W}_X : F_n = 0 \text{ for } n < p\}.$$

Thus $\mathcal{W}_{\geq 1}$ consists of the positive systems.

Lemma 3.1.1 *(Finite positive words).* The cut product sends $\mathcal{W}_{\geq p} \times \mathcal{W}_{\geq q}$ to $\mathcal{W}_{\geq p+q}$. In particular, $F_1 \star \cdots \star F_r \star M$ vanishes in arity $n < r$ when all F_i are positive, whether or not M is positive. If $V_r \in \mathcal{W}_{\geq r}$, then

$$\bigoplus_{r\geq 0} V_r \xrightarrow{\sim} \prod_{r\geq 0} V_r, \qquad \left(\bigoplus_{r\geq 0} V_r\right)_n = \bigoplus_{r=0}^{n} (V_r)_n.$$

Proof. A nonzero summand in a cut product assigns at least p positions to its first factor and q to its second. The mixed assertion uses one position for each positive factor and none necessarily for M.

The finite sums $V_n = \bigoplus_{r\leq n}(V_r)_n$ form a word system: for a monotone surjection $[n] \twoheadrightarrow [m]$, exact extraordinary pullback takes this sum to $\bigoplus_{r\leq n}(V_r)_m$, whose terms with $r > m$ vanish. Since these pullbacks preserve colimits, V is the coproduct. A family of maps $T \to V_r$ gives, in each arity, a map to the finite product defining V_n. These maps commute with collisions after every projection, and hence commute with them as maps to V. The same argument applies to coherent homotopies. It proves the product universal property. No assertion about pullback of an arbitrary infinite product is used. □

An augmented associative algebra in $\mathcal{W}_X$ is an associative algebra object A with an algebra map $A \to K$. It is *connected* if this map is an equivalence at the empty configuration. Its augmentation ideal $a = \mathrm{fib}(A \to K)$ is then positive, and the unit splits $A \simeq K \oplus a$. For a connected coaugmented coalgebra C, put $c = \mathrm{cofib}(K \to C)$. All algebra and coalgebra objects in this section retain their higher associativity or coassociativity homotopies.

The *cut bar* $B_{\mathrm{cut}}A$ is the geometric realization of the two-sided simplicial bar of K, A, K. Its faces multiply or augment, and its degeneracies insert the unit. The *cut cobar* $\Omega_{\mathrm{cut}}C$ is the totalization of the dual cosimplicial construction, whose cofaces comultiply or coaugment and whose codegeneracies apply the counit. For positive reduced parts their normalized terms are

$$\begin{aligned} B_{\mathrm{cut}}A &= K \oplus \bigoplus_{r\geq 1} (a[1])^{\star r}, \\ \Omega_{\mathrm{cut}}C &= K \oplus \bigoplus_{r\geq 1} (c[-1])^{\star r}. \end{aligned} \tag{3.1}$$

These expressions include the normalized differentials and higher attaching maps. They do not replace a homotopy-coherent algebra by its graded object with zero differential.

THEOREM 3.1.2 *(Finite cut duality).* Cut bar and cut cobar induce inverse equivalences between connected augmented associative algebras and connected coaugmented coassociative coalgebras in $(\mathcal{W}_X, \star, K)$. Each normalized construction in arity n has at most n positive factors. No global bound on word length or on coefficient cohomological degrees is imposed.

Proof. The differential-module categories are presentable, and the extraordinary pullbacks defining $\mathcal{W}_X$ are accessible and preserve colimits. Their limit is presentable. The associative bar–cobar adjunction therefore supplies coherent maps

$$u_A : A \longrightarrow \Omega_{\mathrm{cut}}B_{\mathrm{cut}}A, \qquad v_C : B_{\mathrm{cut}}\Omega_{\mathrm{cut}}C \longrightarrow C.$$

Here bar is left adjoint to totalized cobar. This adjunction uses the full mapping spaces of algebra and coalgebra objects.[1]

Splitting off the unit removes the degenerate simplicial terms; the normalized term in degree r is $a^{\star r}[r]$. The normalized cosimplicial term is $c^{\star r}[-r]$. By Lemma 3.1.1, the latter totalization tower stabilizes at step n in arity n. Its finite limits commute with collision pullback. The resulting compatible family is the totalization in $\mathcal{W}_X$: maps into a word system are the limit of its component mapping spaces, and that limit commutes with the cosimplicial limit. This proves (3.1) on the stated carrier.

Filter A increasingly by $F_0A = K$, $F_rA = A$ for $r \geq 1$. In its associated graded, a has weight one and zero multiplication. The induced filtration on $\Omega_{\mathrm{cut}}B_{\mathrm{cut}}A$ counts original a-factors. At two factors, the single gap is either inside a bar block or between two cobar factors. Splitting the block joins these two copies of the coefficient by an identity map, with its suspension sign. For r factors there are $r-1$ such gaps. The coefficient differential and block splitting preserve r; multiplication of original factors lowers it. The associated graded is thus the cube that changes an inside gap to an outside gap, with an identity map on the common coefficient at each edge. The suspension signs give opposite signs around each square. It is the tensor product of $r-1$ two-term identity complexes, tensored with the shifted coefficient $a^{\star r}$. For $r > 1$ it is contractible. The weights zero and one are K and a, and the associated graded map of u_A is the identity on these terms.

For C, use the decreasing filtration $F^0C = C$, $F^1C = c$, $F^2C = 0$, where the splitting by the counit regards c as a subobject. The associated graded reduced coalgebra is primitive. In $B_{\mathrm{cut}}\Omega_{\mathrm{cut}}C$, the corresponding filtration counts original c-factors. Cobar splitting increases this count, while bar multiplication preserves it. On the associated graded the same gap cube runs from outside bar cuts to inside product

[1] J. Lurie, *Higher Algebra*, Theorem 5.2.2.17 and Remark 5.2.2.19, pp. 827–828, author's text. Warning 5.2.2.16 explains why no preservation of both arbitrary realizations and totalizations by the tensor product is assumed.

gaps. Its weights greater than one are contractible; v_C is the identity on the surviving weights zero and one.

After evaluation in arity n, both filtrations are finite: terms with more than n original positive factors vanish. Their cofiber sequences prove that u_A and v_C are equivalences there. Component evaluation is jointly conservative, so they are equivalences of word systems. The construction in filtered objects retains coherent maps. Higher products lower the first filtration and higher coproducts raise the second; the same associated graded calculation applies. The adjunction gives the triangle identities and hence the asserted equivalence. □

Corollary 3.1.3. For the vacuum coalgebra J of Proposition 2.2.1, connected cut coalgebras equipped with a coalgebra map $J \to C$ correspond to connected augmented cut algebras equipped with an algebra map $\Omega_{\mathrm{cut}} J \to A$.

Proof. An equivalence of categories induces an equivalence on the categories of objects under any fixed object. Apply Theorem 3.1.2 to the object J. □

Thus the local vacuum marking survives as an algebra map with source $\Omega_{\mathrm{cut}} J$. It is different from the augmentation $A \to K$. The theorem concerns the cut tensor on words. A comparison with the full ordered atlas, or with prescribed field operations, must preserve the additional geometry and maps identified in Chapter 2.

3.2 The coefficient bar and its twisting maps

Let R be a commutative ring and A a unital differential graded R-algebra with a specified augmentation $\epsilon : A \to R$. Write $\bar{A} = \ker \epsilon$, so $A = R \oplus \bar{A}$ as a complex. All tensor products in this section are ordinary tensors over R. The cohomological differential has degree one. Put $sV = V[1]$ and $tV = V[-1]$; the maps s and t have degrees minus one and one.

The *coefficient bar* is

$$B_R A = T^c_R(s\bar{A}) = R \oplus \bigoplus_{r \geq 1} (s\bar{A})^{\otimes_R r}.$$

The superscript c denotes the tensor coalgebra: its coproduct deconcatenates each word at every position, including both ends. The empty word gives the coaugmentation and counit. Its reduced coproduct $\bar{\Delta}$ omits the end cuts. A coaugmented coalgebra is *conilpotent* if every element of its reduced part is killed by a sufficiently long iterated reduced coproduct. This property is called *conilpotence*. Finite words make $T^c_R(s\bar{A})$ conilpotent.

Define its differential as the coderivation whose components with one output factor are

$$b_1(sa) = -s(d_A a), \qquad b_2(sa, sb) = (-1)^{|a|} s(ab). \tag{3.2}$$

Inserting either degree-one component after $w_1, \dots, w_i$ has sign $(-1)^{|w_1|+\cdots+|w_i|}$. On degree-zero algebra inputs, the multiplication differential is therefore

$$b[a_1|\cdots|a_r] = \sum_{i=1}^{r-1} (-1)^{i-1} [a_1|\cdots|a_i a_{i+1}|\cdots|a_r].$$

The notation $[a_1|\cdots|a_r]$ abbreviates the tensor of the suspended entries; its degree is $\sum_i |a_i| - r$.

For a coaugmented counital differential graded coalgebra C, write $\bar{C} = \ker(C \to R)$. Its direct-sum coefficient cobar is the tensor algebra

$$\Omega_R C = T_R(t\bar{C}), \qquad d(tc) = -t(d_C c) + \sum_{\bar{\Delta} c = \sum c' \otimes c''} (-1)^{|c'|+1} (tc')(tc''). \tag{3.3}$$

The displayed map extends by the graded Leibniz rule. The coalgebra coproduct takes values in the ordinary algebraic tensor, so it gives a finite sum on each element.

PROPOSITION 3.2.1. The differentials in (3.2) and (3.3) square to zero. For conilpotent C, there are natural bijections

$$\mathrm{Hom}_{\mathrm{dgAlg}_R}(\Omega_R C, A) \cong \mathrm{Tw}_R(C, A) \cong \mathrm{Hom}_{\mathrm{dgCoalg}_R}(C, B_R A),$$

where algebra maps preserve augmentations, coalgebra maps preserve coaugmentations and counits, and $\mathrm{Tw}_R(C, A)$ consists of degree-one maps $\tau : \bar{C} \to \bar{A}$ satisfying

$$d_A \tau + \tau d_C + \mu_A(\tau \otimes \tau)\bar{\Delta} = 0. \tag{3.4}$$

The tensor of the two degree-one maps contributes $(-1)^{|c'|}$ on $c' \otimes c''$.

Proof. For the bar square, disjoint insertions cancel by their degree-one signs. The overlapping multiplication terms on three inputs give $(-1)^{|b|} s((ab)c - a(bc))$. Mixed terms vanish by the Leibniz identity for d_A, and the internal square is zero. These are all possibilities. The corresponding cobar calculation uses that $\bar{\Delta}$ is a chain map and is coassociative: the two orders of splitting one factor have opposite signs. Coderivation and derivation compatibility hold by construction.

A map from the tensor algebra $\Omega_R C$ is determined by $tc \mapsto \tau(c)$. Substitution in (3.3) shows that its chain-map condition is exactly (3.4). A coalgebra map to the tensor coalgebra is determined by its length-one component $s\tau$; its length-r component must be

$$(s\tau)^{\otimes r} \bar{\Delta}^{(r-1)}.$$

Conilpotence makes the sum of these components finite on each input. Coassociativity proves the coalgebra identity. The length-one part of its chain-map equation is (3.4), with (3.2); the coderivation identity then proves the equation in every length. These constructions are inverse and natural. □

This is a strict adjunction $\Omega_R \dashv B_R$ for algebraic tensor constructions and conilpotent coalgebras. It is distinct from the general enhanced adjunction between geometric bar and totalized cobar used in the finite cut theorem. On positive word systems the finiteness theorem makes both comparisons equivalences.

PROPOSITION 3.2.2 *(An algebra resolution).* For every augmented differential graded R-algebra A, the algebra map $\varepsilon_A : \Omega_R B_R A \to A$ that sends $t(sa)$ to a, and a cobar generator represented by a longer bar word to zero, is a quasi-isomorphism.

Proof. The desuspension $B_R A \to A$ is a twisting map, so the preceding proposition gives ε_A. Filter by the number r of original $\bar{A}$-entries. The target filtration is $F_0 A = R$, $F_r A = A$ for $r \geq 1$. The associated graded source is the gap cube of the finite cut proof, now with coefficient $\bar{A}^{\otimes_R r}$. Each gap contributes a two-term identity complex. Contracting the first gap contracts their tensor product for $r > 1$, over any ring R, without a flatness hypothesis. In weights zero and one, ε_A is the identity. Induction through the finite filtration stages proves a quasi-isomorphism at each stage. Every element belongs to some stage, and filtered unions of R-modules are exact. Passing to that union proves the result. No convergence of an infinite product is asserted. □

3.3 Which derived tensor the bar computes

A complex V of R-modules is *K-flat* if $N \otimes_R V$ is acyclic for every acyclic complex N. This condition concerns the whole complex; for an unbounded complex, degreewise flatness alone does not suffice.

Proposition 3.3.1. If $\bar{A}$ is K-flat over R, then

$$B_R A \simeq R \otimes^{\mathbf{L}}_A R.$$

The two modules R use the specified augmentation of A.

Proof. Let $\tau : B_R A \to A$ desuspend a word of length one and vanish elsewhere. On $L = A \otimes_R B_R A$, put

$$d_L(a \otimes c) = d_A a \otimes c + (-1)^{|a|} a \otimes bc - (-1)^{|a|} \sum a\tau(c_{(1)}) \otimes c_{(2)}.$$

The twisting identity proves $d_L^2 = 0$. Let $\epsilon_L : L \to R$ augment the length-zero term and vanish on positive lengths. With $\bar{a} = a - \epsilon(a)1$, define

$$h\big(a \otimes [a_1|\cdots|a_r]\big) = -1 \otimes [\bar{a}|a_1|\cdots|a_r].$$

The internal terms cancel in $d_L h + h d_L$, as do contractions away from the first slot. The first-slot term gives $\bar{a} \otimes c$; if $r > 0$, the terms that merge the inserted slot with the next one leave $\epsilon(a) \otimes c$. Thus $d_L h + h d_L = 1 - \iota\epsilon_L$, where ι includes the empty word. This proves $L \simeq R$.

The increasing length filtration has quotients $A \otimes_R (s\bar{A})^{\otimes_R r}$. Tensoring one with an acyclic right A-module N gives $N \otimes_R (s\bar{A})^{\otimes_R r}$, which is acyclic by K-flatness. The filtration is split on graded modules; induction and exact filtered unions show that L is a K-flat left A-resolution. Tensoring it with the right augmentation module kills the first-slot term and leaves $B_R A$. □

For a nonunital differential graded algebra P, the tensor bar on sP means the reduced bar of the unitization $R \oplus P$, augmented to R. It need not be the reduced bar of a unital algebra structure already present on P. Indeed, if P has a closed unit e, inserting se at the beginning of a nonempty word contracts this tensor bar onto R: $b(se \otimes c) + se \otimes bc = c$. A reduced bar of P itself instead requires a chosen augmentation and its kernel. This distinction determines the meaning of the endpoint bars in Chapter 11.

Example 3.3.2 *(An infinite bar at the empty configuration).* Take $A = k \oplus ka$, with $|a| = 1$, zero differential and $a^2 = 0$. Then $v = sa$ has degree zero and

$$B_k A = \bigoplus_{r \geq 0} k v^{\otimes r}, \qquad b = 0.$$

Put this algebra at the empty component of $\mathcal{W}_X$ and zero at every positive arity. Its cut bar is exactly this coefficient bar at the empty component. The augmentation is not an equivalence there, so the algebra is outside the connected class of Theorem 3.1.2. Arbitrarily long coefficient words survive in the same cohomological degree.

3.4 Length products and continuous Taylor maps

For R-modules V_n, the direct sum $\bigoplus_n V_n$ contains finite sums of words, whereas $\prod_n V_n$ contains an arbitrary word in every length. Give each V_n the discrete topology and the product its product topology. A linear map of direct sums has components $F_{mn} : V_n \to W_m$.

PROPOSITION 3.4.1 *(Continuity in length).* A linear map $F : \bigoplus_n V_n \to \bigoplus_m W_m$ extends to a continuous map of the products of discrete modules if and only if, for every m, only finitely many F_{mn} are nonzero. Such an extension is unique.

More generally, for a prime ℓ, let $R = \mathbb{Z}_\ell$, give each V_n its ℓ-adic topology, and assume every W_m is separated and complete for that topology. An R-linear F extends continuously to the products if and only if, for each m, j,

$$F_{mn}(V_n) \subseteq \ell^j W_m \quad \text{for all but finitely many } n.$$

Proof. Continuity of the m-th coordinate at zero implies that its kernel contains a basic product neighborhood. Outside finitely many input coordinates that neighborhood contains each whole module, so the corresponding F_{mn} vanish. Conversely, finite row sums define a continuous map coordinate by coordinate.

For the adic statement, apply the same argument to the m-th output modulo $\ell^j W_m$. The asserted condition makes $\sum_n F_{mn}(x_n)$ converge in W_m, uniformly modulo each ℓ^j; the finite remaining terms are continuous because they are R-linear. This constructs the extension. The direct sum is dense in the product, and the target is separated, proving uniqueness in both cases. □

A degree-zero coaugmentation-preserving map between tensor coalgebras is specified by its Taylor components $f_r : V^{\otimes r} \to W$. Its value on a word is the sum over consecutive subdivisions, applying one f_r to each block. Every finite word has finitely many subdivisions, but an output of length one can receive inputs of every length. Proposition 3.4.1 detects precisely this possible failure of continuity.

For example, let $V = \mathbb{Z}v$ in degree zero and set $f_r(v^{\otimes r}) = v$ for every $r \geq 1$. The resulting coalgebra map is defined on finite words. The sums $z_N = \sum_{r=1}^{N} v^{\otimes r}$ converge in the product of discrete length spaces, but the length-one output is Nv, which does not converge. In the relative identity example of Proposition 11.7.2, these are the Taylor components of the actual endpoint comparison.

A product also changes the recipient of deconcatenation. For $\widehat{T}(V) = \prod_{r\geq 0} V^{\otimes r}$, the natural recipient is

$$\prod_{p,q\geq 0} (V^{\otimes p} \otimes V^{\otimes q}),$$

with (p, q)-component given by cutting length $p + q$. It need not be $\widehat{T}(V) \otimes \widehat{T}(V)$. Over a characteristic-zero field, take $V = kv$ and the element $z = \sum_{r\geq 0} r!v^{\otimes r}$. Its coproduct coefficient matrix is $((p + q)!)_{p,q\geq 0}$. The leading d-square minor has determinant

$$\det\big((p + q)!\big)_{0\leq p,q<d} = \prod_{i=0}^{d-1} (i!)^2 \neq 0.$$

To see this, factor $p!$ from row p; the q-th column is then a monic polynomial of degree q in p, so its determinant is the Vandermonde determinant. Every element of an algebraic tensor is a finite sum of separated tensors and gives a finite-rank coefficient matrix. Thus Δz cannot belong to that algebraic tensor.

3.5 FINITE PRECISION AND DERIVED INVERSE LIMITS

Put $R_j = \mathbb{Z}/\ell^j$, and let A_j be a compatible tower of augmented differential graded R_j-algebras. Write $B_j = B_{R_j} A_j$. Define

$$\widehat{B} = \varprojlim_j B_j, \qquad \widehat{B} \mathbin{\widehat{\otimes}} \widehat{B} := \varprojlim_j (B_j \otimes_{R_j} B_j). \tag{3.5}$$

These are specified inverse limits, with discrete finite-precision terms. No identification with another completed tensor is implicit. The recipient of an iterated coproduct with r outputs is $\varprojlim_j B_j^{\otimes_{R_j} r}$. An element has only finitely many nonzero lengths at each precision, although that finite set can grow with j.

Proposition 3.5.1. A compatible family of differential graded coalgebra maps $F_j : B_j \to B'_j$ induces a continuous map $\widehat{F} : \widehat{B} \to \widehat{B}'$ preserving the coproduct with the recipients in (3.5). If every F_j has a compatible strict inverse, then $\widehat{F}$ is a continuous isomorphism.

Proof. Define the map by its projections. The chain and coproduct identities hold after every projection and therefore in the inverse limit. The output at precision j depends only on the input at that precision, proving continuity. The compatible inverses define its continuous inverse in the same way. □

For $A_j = R_j \oplus R_j a$ with the square-zero structure of Example 3.3.2, the element

$$z = \sum_{r \geq 1} \ell^r v^{\otimes r}$$

belongs to $\widehat{B}$. It is not elementwise conilpotent: for any number of cuts, a sufficiently long word has a nonzero coefficient in the corresponding tensor recipient. The Taylor map with $f_r(v^{\otimes r}) = v$ is nevertheless continuous on this restricted inverse limit. Its length-one value on z is $\ell(1-\ell)^{-1}v$. At precision j this is a finite sum, so no analytic summation is part of its definition.

The preceding proposition is about strict maps of complexes. A claim about their cohomology requires a different argument. For a countable tower of complexes M_j, with transition maps $q_j : M_{j+1} \to M_j$, define

$$R\varprojlim_j M_j = \operatorname{Cone}\left(\prod_j M_j \xrightarrow{1-T} \prod_j M_j\right)[-1], \qquad (Tx)_j = q_j x_{j+1}.$$

This is the derived inverse limit of the tower of module complexes.

Proposition 3.5.2. If every q_j is surjective in each cohomological degree, then the ordinary inverse limit represents this derived inverse limit. For each q there is an exact sequence

$$0 \longrightarrow \varprojlim{}^1{}_j H^{q-1}(M_j) \longrightarrow H^q(\varprojlim_j M_j) \longrightarrow \varprojlim_j H^q(M_j) \longrightarrow 0,$$

where $\varprojlim^1$ is the cokernel of $1-T$ on the product of the indicated cohomology groups.

Proof. Surjectivity permits the recursive solution of $x_j - q_j x_{j+1} = y_j$, starting with any x_1. Thus $1-T$ is degreewise surjective and its kernel is the ordinary inverse limit. The resulting short exact sequence of complexes identifies this kernel with the shifted cone. Products of modules are exact, so their cohomology is the product of the cohomologies. The long exact sequence of the cone gives the displayed sequence. □

In particular, commuting cohomology with the limit requires the stated $\varprojlim^1$ term to vanish. Scalar extension need not commute with the limit either:

$$\mathbb{Q}_\ell \otimes_{\mathbb{Z}_\ell} \varprojlim_j \mathbb{Z}_\ell/\ell^j = \mathbb{Q}_\ell, \qquad \varprojlim_j \left(\mathbb{Q}_\ell \otimes_{\mathbb{Z}_\ell} \mathbb{Z}_\ell/\ell^j\right) = 0.$$

The first identity uses ℓ-adic completeness; in the second, inverting ℓ kills each finite quotient.

3.6 Analytic bounds and the other bar constructions

There is a useful analytic counterpart to the continuity criterion. For real or complex Banach spaces V, W, use the completed projective tensor powers $V^{\widehat{\otimes}_\pi r}$. For $\rho > 0$, let

$$T^+_\rho(V) = \left\{ (x_r)_{r\geq 0} : \sum_{r\geq 0} \rho^r \|x_r\|_\pi < \infty \right\}.$$

The displayed weighted sum is its norm, and the length-zero summand is the scalar field. Suppose continuous Taylor maps $f_r : V^{\widehat{\otimes}_\pi r} \to W$ satisfy $\|f_r\| \leq M L^{r-1}$ for constants $M, L > 0$.

PROPOSITION 3.6.1. The subdivision map determined by these Taylor maps, acting as the identity in length zero, extends to a bounded linear map $T^+_\rho(V) \to T^+_\sigma(W)$ whenever $L + \sigma M \leq \rho$. Its norm is at most one, and on the positive-length part it is at most $\sigma M / \rho$.

Proof. There are $\binom{r-1}{m-1}$ consecutive subdivisions of a length-r word into m nonempty blocks. Each corresponding operator has norm at most $M^m L^{r-m}$. Hence its entire weighted output has norm at most

$$\sum_{m=1}^{r} \binom{r-1}{m-1} (\sigma M)^m L^{r-m} \|x_r\|_\pi = \sigma M (L + \sigma M)^{r-1} \|x_r\|_\pi \leq \frac{\sigma M}{\rho} \rho^r \|x_r\|_\pi.$$

Sum over r, retaining the scalar term separately. Finite words are dense, so the bounded extension is unique. □

This estimate concerns the Taylor map. Continuity of the differential and coproduct in the chosen recipients must also be checked. For example, give the completed two-index tensor the norm $\sum_{p,q\geq 0} \sigma^{p+q} \|z_{pq}\|_\pi$. Deconcatenation from radius ρ to this recipient, for $\sigma < \rho$, is bounded by $\sup_{r\geq 0} (r+1)(\sigma/\rho)^r$. At equal radii that bound need not be finite. Algebraic identities on finite words extend when all maps in those identities have continuous extensions to a common domain and a separated target.

A *transverse bar* uses another specified monoidal category $(\mathcal{E}, \otimes_{\mathrm{tr}}, \mathbf{1}_{\mathrm{tr}})$ and an augmented associative algebra T for that tensor. If geometric realizations exist and the tensor preserves them, its two-sided bar is

$$B_{\mathrm{tr}} T = \mathbf{1}_{\mathrm{tr}} \otimes^{\mathbf{L}}_{T} \mathbf{1}_{\mathrm{tr}}.$$

Its augmentation, coefficient category and convergence refer to this tensor. The positive-cut bound applies to it only if an additional compatible positive filtration is supplied.

Finally, for a covariant diagram F of complexes of k-vector spaces on a small category $\mathcal{I}$, its simplicial replacement has terms

$$B_n(\mathcal{I}, F) = \bigoplus_{i_0 \to \cdots \to i_n} F(i_0).$$

Its direct-sum total complex has $\mathrm{Tot}^q = \bigoplus_{n\geq 0} B_n^{q+n}$ and differential $(-1)^n d_{\mathrm{int}} + \sum_i (-1)^i d_i$, where the d_i are the simplicial faces. It computes the derived colimit. In Chapter 103, the ordered incidence construction is of this kind. It needs an actual coefficient diagram on its indexing category. Identifying that derived colimit with the homology of a geometric or physical field theory is a further comparison.

Chapter 4

Recognition and higher comparison

Two products can agree on cohomology while their primitives produce different triple operations. The cubic example in the prologue makes this distinction inside a strict differential graded algebra: $U^2 = DH$, but $UH + HU = -V$ represents a nonzero cohomology class. Strict associativity has encoded the higher operation; it has not removed it. A comparison must transport the primitive as well as the binary product.

Collision geometry imposes a further requirement. When the first and third positions meet, the second input remains between them. Moving an endpoint past that input uses an exchange map. Two binary products can agree while these exchanges permit different normal poles. We construct this example below, then give the complexes and equations that decide whether a specified partial comparison extends. The obstruction belongs to the operations allowed by that comparison, with its boundary values fixed.

4.1 Simultaneous operations and their recipients

Let k have characteristic zero and let X be the smooth curve of Chapter 2. For a finite nonempty set I, write $j_I : U_I \hookrightarrow X^I$ for the open immersion of the locus where every pair of positions is distinct, and $\Delta_I : X \hookrightarrow X^I$ for the small diagonal. For complexes of right differential modules M_i, N on X, define the complex of *simultaneous chiral operations* by

$$Q_X(M_i; i \in I; N) = \mathrm{RHom}_{\mathcal{D}(X^I)}\left(j_{I,*}j_I^! \boxtimes_{i\in I} M_i, \Delta_{I,*}N\right). \tag{4.1}$$

The external tensors and geometric functors are derived. The output retains the whole differential module on the diagonal, including its normal derivatives. Degree-zero cycles represent cochain operations in a chosen differential graded model; a degree-minus-one cochain is a possible homotopy between such operations. Passing to a scalar residue is a further map. For ordinary modules, the degree-zero construction is the chiral operation space of Beilinson and Drinfeld.[1]

To compose, let $\pi : I \twoheadrightarrow A$ have nonempty fibres I_a, so that $I = \coprod_{a\in A} I_a$, and let $d_\pi : X^A \to X^I$ identify positions in each block. Let $j_\pi : U_\pi \hookrightarrow X^I$ be the open immersion where positions in different blocks are distinct. Given operations

$$g_a \in Q_X(M_i; i \in I_a; L_a), \qquad f \in Q_X(L_a; a \in A; N),$$

[1] A. Beilinson and V. Drinfeld, *Chiral Algebras*, §§3.1.1–3.1.2, pp. 157–158. The composition below is the derived form of their displayed composition of chiral operations.

their composite is induced by

$$\begin{aligned} j_{I,*}j_I^!\boxtimes_I M_i &\simeq j_{\pi,*}j_\pi^!\boxtimes_A\left(j_{I_a,*}j_{I_a}^!\boxtimes_{I_a} M_i\right)\\ &\xrightarrow{\boxtimes g_a} j_{\pi,*}j_\pi^!\boxtimes_A \Delta_{I_a,*}L_a\\ &\simeq d_{\pi,*}j_{A,*}j_A^!\boxtimes_A L_a \xrightarrow{d_{\pi,*}f} \Delta_{I,*}N. \end{aligned}$$

The middle equivalence is open–closed base change. Every parenthesization of a nested partition uses the same disjoint open set and the same composite diagonal map. Coherent base change therefore makes these compositions associative, with all their homotopies. The unary identity is the identity of a differential module. Permuting labels transports the same diagram. Thus the operation complexes form a coherent coloured operad: the colours are the chosen differential modules, and an operation has its indicated list of input colours and output colour. Forgetting permutations leaves its nonsymmetric operad on ordered inputs. For equations between cochains, choose a differential graded operad model compatible with these geometric functors and their base-change maps.

The word carrier has a different endomorphism operad. For word systems $F_\lambda \in \mathcal{W}_X$, its complexes are

$$\mathcal{P}_F(\lambda_1,\dots,\lambda_r;\nu) = \mathrm{RHom}_{\mathcal{W}_X}(F_{\lambda_1}\star\cdots\star F_{\lambda_r}, F_\nu), \qquad r\geq 0, \tag{4.2}$$

where $\star = \star_{\mathrm{cut}}$ and the empty tensor is K. Substitution is $f\circ(g_1\star\cdots\star g_r)$, with the coherent cut associator. On homogeneous blocks x_i, the tensor of maps has sign $(-1)^{\sum_{i<j}|g_j||x_i|}$. The cut construction of Chapter 2 proves its operad coherences: both composites retain the same final consecutive decomposition and localized coefficient. Its arity-zero maps have source K, not the local vacuum J.

A field comparison has to relate independently specified operations to (4.2). For a chosen family whose operations are represented by a differential graded operad $\mathcal{Q}^{\mathrm{adm}}$, it includes maps

$$\rho_r : \mathcal{Q}^{\mathrm{adm}}(\lambda_1,\dots,\lambda_r;\nu) \longrightarrow \mathcal{P}_F(\lambda_1,\dots,\lambda_r;\nu) \tag{4.3}$$

compatible with differentials and the required substitutions. Here *admissible* means a specified complex of operations, with its coefficient domains, pole conditions and topology. In a meromorphic differential-module family it can be a subcomplex of (4.1); closure under the required substitutions must be proved. A fixed pole bound need not have this property, since compositions can increase pole order. Monodromic or analytic fields require their own coefficient recipient before such a map is defined.

Collision restrictions, exchanges, translation and local-vacuum insertion give additional diagrams for ρ. When their commutativity is only up to homotopy, the homotopies and their higher compatibilities are part of the comparison. The construction of either operad above does not produce (4.3). Nor does the singleton F_1 determine its target, which uses the whole word system.

Example 4.1.1 *(An undetected positive component).* For a differential module M, let $I(M)_n = \Delta_{n,*}M$ for $n>0$, with zero empty component. Closed base change gives its monotone collision equivalences. Put $I = I(J_X)$, where $J_X = p_X^!k$, and $H = I\star I$. Then $H_1 = 0$, while H_2 is nonzero on the separated two-point locus. The free augmented cut algebras

$$\mathbb{T}(I)\longrightarrow\mathbb{T}(I\oplus H), \qquad \mathbb{T}(E) = K\oplus\bigoplus_{r\geq 1}E^{\star r},$$

agree at the singleton and differ at two positions by the extra summand H_2. Each sum is finite in every geometric arity. Consequently singleton evaluation is not conservative even on connected augmented cut algebras.

4.2 The endpoint exchange at a ternary collision

Let $B = k[\epsilon]/(\epsilon^2)$, concentrated in cohomological degree zero. Give it an auxiliary parity by making 1 even and ϵ odd. For $\sigma = \pm 1$, define

$$R_\sigma(a \otimes b) = \sigma^{p(a)p(b)} b \otimes a$$

on the two homogeneous basis vectors, and extend linearly. The parity here specifies the exchange; it is not a cohomological Koszul sign. Both exchanges have the same unit crossings, are involutive, and satisfy the braid relation. For three basis vectors the two braid words have the same sign $\sigma^{p(a)p(b)+p(a)p(c)+p(b)p(c)}$. They also satisfy the two multiplication compatibility identities

$$R_\sigma(1 \otimes \mu) = (\mu \otimes 1)(1 \otimes R_\sigma)(R_\sigma \otimes 1),$$
$$R_\sigma(\mu \otimes 1) = (1 \otimes \mu)(R_\sigma \otimes 1)(1 \otimes R_\sigma).$$

When the multiplied entries are not both ϵ, their parities add; when both are ϵ, both sides vanish. This proves the identities on a basis. The binary multiplication μ is the same for both signs, and $\mu R_\sigma = \mu$.

To collide the first and third input while retaining the middle input, define

$$q_\sigma = (\mu \otimes 1)(1 \otimes R_\sigma) : B^{\otimes 3} \longrightarrow B \otimes B.$$

The first output is the product of the endpoints; the second is the unchanged middle state after exchange. For $\xi = \epsilon \otimes \epsilon \otimes 1 - 1 \otimes \epsilon \otimes \epsilon$, one obtains

$$q_+(\xi) = 0, \qquad q_-(\xi) = 2\epsilon \otimes \epsilon. \tag{4.4}$$

Thus an operation that vanishes for one exchange need not vanish for the other, although the binary products agree.

This discrepancy gives actual differential modules with different allowed poles. On the affine-line three-point chart put

$$Y = \operatorname{Spec} k[z_1, z_2, z_3, (z_1 - z_2)^{-1}, (z_2 - z_3)^{-1}], \qquad u = z_1 - z_3, \qquad T = B^{\otimes 3}.$$

Inside $T \otimes_k \omega_Y[u^{-1}]$, define right differential modules

$$\mathcal{M}_\sigma = T \otimes_k \omega_Y + (\ker q_\sigma) \otimes_k \omega_Y[u^{-1}]. \tag{4.5}$$

The kernels are constant coefficient spaces, so multiplication by regular functions and differentiation preserve these modules. In a coordinate density, the right derivative differentiates the coefficient with a minus sign. Every finite normal derivative of an allowed pole remains allowed.

Proposition 4.2.1 *(Binary agreement and a ternary failure).* Both modules in (4.5) restrict to the same meromorphic module off $u = 0$. The identity of that module extends to no map $\mathcal{M}_+ \to \mathcal{M}_-$, and to no map in the opposite direction. Their common binary coefficient extension, obtained from $\ker \mu$, does not decide this ternary extension problem.

Proof. Localizing at u makes the first summand in (4.5) the whole meromorphic module. The target is a submodule of that localization and has no u-torsion. A map restricting to the identity must therefore be the identity on every section: the difference vanishes after localization and hence vanishes already.

But $u^{-1}\xi\, dz_1 dz_2 dz_3$ belongs to $\mathcal{M}_+$ and not to $\mathcal{M}_-$, by (4.4). A nonzero constant coefficient of u^{-1} cannot become regular at $u = 0$. For the reverse direction, use $\eta = \epsilon \otimes \epsilon \otimes 1 + 1 \otimes \epsilon \otimes \epsilon$: $q_-(\eta) = 0$ and $q_+(\eta) = 2\epsilon \otimes \epsilon$. At two inputs the construction uses the common map $\mu : B^{\otimes 2} \to B$, so its kernel extension is identical. □

The proposition fixes the identity on the marked meromorphic coefficient space. It makes no assertion about isomorphisms that change those markings. It also constructs binary and ternary coefficient extensions, not a complete field system in every arity. An all-arity realization must additionally supply the collision maps and verify every substitution among them.

4.3 The complex controlling a higher comparison

Let R be a commutative ring. We use the suspended convention of Chapter 3. An augmented A_∞-algebra is specified here by a complex $V = s\bar{A}$ and a degree-one coderivation

$$b_A : T^c_R(V) \longrightarrow T^c_R(V), \qquad b_A^2 = 0, \qquad b_A(1) = 0.$$

Its Taylor components are maps $b_{A,r} : V^{\otimes r} \to V$ of degree one, with $b_{A,1}$ the differential on V. The augmented state algebra is the unitization $R \oplus V[-1]$: its new unit acts by the identity under binary multiplication, and every higher operation vanishes when one of its inputs is that unit. All displayed inputs belong to the augmentation ideal. For a differential graded algebra, only b_1, b_2 occur, with $b_1(sa) = -s(da)$ and $b_2(sa, sb) = (-1)^{|a|}s(ab)$.

For a second such algebra put $W = s\bar{B}$. A normalized A_∞-map is a coaugmentation-preserving degree-zero coalgebra map $F : T^c_R(V) \to T^c_R(W)$ satisfying $b_B F = F b_A$. Its components $f_r : V^{\otimes r} \to W$ determine it by consecutive subdivisions. Define the actual cochain complex

$$E_r = \mathrm{Hom}_R(V^{\otimes r}, W), \qquad \partial f = b_{B,1} f - (-1)^{|f|} f\, b^{(r)}_{A,1},$$

where $b^{(r)}_{A,1}$ is the tensor differential. For derived comparisons use specified cofibrant coefficient models, or replace this Hom by its derived model. The formulas below concern the chosen chain models, with no unmentioned resolution change.

Suppose $f_1, \dots, f_{n-1}$ already satisfy the comparison equations below length n. Define

$$\begin{aligned} O_n = &\sum_{\substack{q \geq 2,\ i_1+\cdots+i_q = n \\ i_j \geq 1}} b_{B,q}(f_{i_1} \otimes \cdots \otimes f_{i_q}) \\ &- \sum_{\substack{u+v+w=n \\ v \geq 2}} f_{u+1+w}(1^{\otimes u} \otimes b_{A,v} \otimes 1^{\otimes w}) \in E^1_n. \end{aligned} \tag{4.6}$$

All components on the right have index less than n, except the already specified algebra operations. The signs are tensor composition signs: insertion of $b_{A,v}$ after a homogeneous prefix has the sign given by its total degree. No division by two occurs.

THEOREM 4.3.1 *(One higher component).* The cochain O_n is closed. A component f_n extending the comparison through length n exists precisely when $[O_n] = 0$ in $H^1(E_n)$. It must satisfy

$$\partial f_n = -O_n.$$

When a solution exists, all solutions form a torsor for $Z^0(E_n)$. Modulo changes $f_n \mapsto f_n + \partial h$, with $h \in E_n^{-1}$ and all lower components fixed, they form a torsor for $H^0(E_n)$.

Proof. Extend the chosen components to a coalgebra map by setting the remaining Taylor components to zero. Put $D = b_B F - F b_A$. The square-zero equations imply

$$b_B D + D b_A = 0.$$

The map D is a coderivation over F. Since its length-one output vanishes on inputs shorter than n, the only part of this identity with n inputs and one output is $b_{B,1} O_n + O_n b_{A,1}^{(n)} = 0$. This is $\partial O_n = 0$. In the equation with one output and n inputs, the new f_n occurs only in the unary terms; all other terms are (4.6). This gives the displayed equation. Subtracting two solutions gives a degree-zero cocycle, and quotienting by degree-zero boundaries gives the final assertion. □

For strict differential graded inputs, the first equation is

$$\partial f_2 = f_1 b_{A,2} - b_{B,2}(f_1 \otimes f_1).$$

Thus f_2 is the multiplicativity homotopy in suspended coordinates. At length three, f_2 enters on both sides of the next equation. Choosing its cohomology class independently of that equation can obstruct the extension.

Example 4.3.2 *(A nonzero first ternary obstruction).* Let $R = k$, and take $V = kx \oplus ky$ with $|x| = -1$, $|y| = -2$. On $T^c(V)$, let the first coderivation be zero and let the second have the sole component

$$b_{B,3}(x, x, x) = y,$$

vanishing on inputs containing y. Its square is zero: nested insertions vanish, while disjoint degree-one insertions cancel. With $f_1 = 1_V$, both unary and binary comparison equations hold, for any f_2. But $O_3(x, x, x) = y$, and $\partial = 0$ on E_3. Hence no higher comparison with this linear term exists. The corresponding unsuspended states have degrees zero and minus one.

There is a version on the actual word carrier. Take the positive system $I = I(J_X)$ of Example 4.1.1, put $H = I^{\star 3}$, and use reduced states $G = I \oplus H[1]$. On the suspended states $G[1] = I[1] \oplus H[2]$, define b_3 to be the degree-one shifted identity

$$(I[1])^{\star 3} \simeq H[3] \longrightarrow H[2],$$

and zero if an input belongs to $H[2]$. Together with the internal differential it squares to zero by the same cancellation. Compare it to the structure with $b_3 = 0$ and the same unary differential and zero binary product. The first ternary defect projects to the identity of H. It is not a boundary, because H_3 is nonzero on the separated three-point locus. Thus the identity of the underlying word system and the agreement of binary operations do not extend to an A_∞-map. This example uses positive systems and lies within the geometric finiteness regime; coefficient completion is not its obstruction.

4.4 Fixed boundary values and allowed homotopies

Geometric conditions restrict the possible f_n. A restriction to an open set, a prescribed normal coefficient or a vacuum value can be represented, on fixed chain models, by a cochain map $r_n : E_n \to T_n$. Let $t_n \in T_n^0$ be the prescribed value of the new component. Compatibility with its chain equation requires

$$\partial t_n = -r_n O_n.$$

Several restrictions can be placed in the same target diagram; its maps and compatibility homotopies must be included when forming the derived restriction map.

First suppose r_n is degreewise surjective and require the strict boundary value $r_n f_n = t_n$. Put $K_n = \ker r_n$, and choose any degree-zero lift $\widetilde{f_n}$ of t_n.

THEOREM 4.4.1 *(The relative obstruction).* The cochain

$$o_n = O_n + \partial \widetilde{f_n}$$

is a degree-one cocycle in K_n. Its class in $H^1(K_n)$ is independent of the lift. The comparison extends with the prescribed boundary value if and only if this class vanishes. When it does, solutions modulo homotopies in K_n^{-1}, with all lower data fixed, form a torsor for $H^0(K_n)$.

Proof. The boundary equation gives $r_n o_n = 0$, and $\partial O_n = 0$ gives $\partial o_n = 0$. Changing the lift by $a \in K_n^0$ changes o_n by ∂a. A correction $a \in K_n^0$ makes $f_n = \widetilde{f_n} + a$ a solution precisely when $\partial a = -o_n$. Subtraction of two solutions and then quotienting by relative boundaries gives the asserted torsor. □

Without surjectivity, a strict lift of t_n is a separate first requirement. If the boundary is instead allowed to agree up to a specified homotopy, the correct complex is the *homotopy fibre*

$$\mathrm{Fib}(r_n)^q = E_n^q \oplus T_n^{q-1}, \qquad d(e,h) = (\partial e, r_n e - \partial h).$$

The pair $(O_n, -t_n)$ is closed. Its class vanishes precisely when there are $f_n \in E_n^0$, $h_n \in T_n^{-1}$ with

$$\partial f_n = -O_n, \qquad r_n f_n = t_n - \partial h_n.$$

Indeed, take the negative of the E_n-component of a primitive of $(O_n, -t_n)$, and retain its $T_n[-1]$ component. This proves the equivalence directly, including the sign of the boundary homotopy. Replacing a strict boundary condition by this homotopy condition changes the comparison problem unless that replacement was allowed.

Example 4.4.2 *(An inadmissible primitive).* Let E have basis h in degree zero and c in degree one, with $\partial h = c$. Let $T = kh$ in degree zero and let $r : E \to T$ be the quotient by kc. The obstruction $O = c$ is exact in E. With prescribed boundary $t = 0$, however, $K = kc$ has $H^1(K) = kc$, so no allowed primitive exists. The unique ambient solution $-h$ has the wrong boundary value. This is the distinction between finding a primitive and finding one in the permitted support or vacuum sector.

COROLLARY 4.4.3 *(Extension through all lengths).* Suppose the restriction complexes are specified at every length, each r_n is degreewise surjective, and $H^1(K_n) = 0$ for $n \geq 2$. An admissible unary comparison extends to a normalized A_∞-map if compatible boundary values can be supplied successively for its partial lifts. If contracting homotopies $h_n : K_n \to K_n[-1]$, satisfying $\partial h_n + h_n \partial = 1$, are supplied, one can take

$$f_n = \widetilde{f_n} - h_n o_n.$$

Over a field, a quasi-isomorphism f_1 gives a quasi-isomorphism of the resulting direct-sum bar complexes.

Proof. Apply Theorem 4.4.1 recursively. For the displayed choice, closedness of o_n gives $\partial h_n o_n = o_n$. At each finite word length the coalgebra formula uses only finitely many components, so the resulting map is defined on the direct-sum bars and satisfies the chain identity there.

Filter these bars by word length. On the associated graded, the comparison is $f_1^{\otimes r}$ in length r. Over a field tensor powers preserve quasi-isomorphisms. Finite-stage induction and exact filtered unions prove the final assertion. □

The hypotheses include compatibility of the prescribed boundary values with the partial solution chosen at the previous stage. Vanishing cohomology does not supply incompatible boundary data. Nor does it by itself imply uniqueness in a full mapping space: $H^0(K_n)$ describes this stage's choices, and negative-degree cohomology can describe homotopies between those choices. For completed coefficient bars, the same construction must also satisfy the continuity conditions of Chapter 3.

4.5 Operations, deformations, and a recognition problem

There is a parallel obstruction for constructing the operations themselves. Fix b_1 on a suspended coefficient complex V and choose $b_2, \dots, b_{n-1}$ satisfying $b^2 = 0$ below length n. Then

$$C_n = \sum_{\substack{i+j=n+1 \\ i,j\geq 2}} \sum_{u=0}^{i-1} b_i(1^{\otimes u} \otimes b_j \otimes 1^{\otimes(i-1-u)}) \in \operatorname{Hom}_R(V^{\otimes n}, V)^2.$$

Its differential is zero. To see this without dividing by any integer, use the identity $b\,b^2 = b^2 b$ for the partial coderivation. Its first nonzero component is $b_1 C_n - C_n b_1^{(n)} = 0$. A new operation b_n must satisfy $\partial b_n = -C_n$, so the obstruction is in degree two and the choices, modulo boundaries, are in degree one. This differs by one degree from the comparison problem, where f_n has degree zero.

In characteristic zero these equations also have a Lie-algebra form. Let

$$\mathfrak{g} = \prod_{r\geq 2} \operatorname{Hom}_k(V^{\otimes r}, V), \qquad d_{\mathfrak{g}} = [b_1, -].$$

Identify a collection with its coderivation of $T^c(V)$. The bracket is the graded commutator of coderivations, projected back to one output. Give arity r weight $r-1$, and let $F^p\mathfrak{g}$ consist of collections supported in weights at least p. Then $[F^p, F^q] \subset F^{p+q}$, and the product is complete and separated for this filtration. Each fixed-arity bracket coefficient is a finite sum.

A degree-one $\alpha \in \mathfrak{g}$ gives square-zero $b_1 + \alpha$ precisely when

$$d_{\mathfrak{g}}\alpha + \tfrac{1}{2}[\alpha, \alpha] = 0.$$

If α solves this equation modulo F^p, its curvature in F^p/F^{p+1} is a degree-two cocycle. The identity $d_{\mathfrak{g}}C + [\alpha, C] = 0$ follows by expanding the curvature, and its leading term proves closedness. A correction $\beta \in F^p\mathfrak{g}^1$ changes that class by $d_{\mathfrak{g}}\beta$. This gives the same extension criterion as the integral coderivation equation. For deformations around a complete nonzero solution, the controlling differential is instead $d_\alpha = d_{\mathfrak{g}} + [\alpha, -]$; retaining that twist is essential. These formulas apply to an admissible operation subcomplex only if it is closed under the differential and the required insertions.

To compare an entire coloured operation system, one can specify a differential graded operad resolution $\mathcal{R}$ with successive free generators e, each having differential in the previously constructed part. If a partial map $\rho : \mathcal{R} \to \mathcal{P}_F$ is fixed, extending it over a generator of degree d asks for

$$x \in \mathcal{P}_F^d, \qquad dx = \rho(de).$$

The right side is closed because $d^2 e = 0$. Its class in $H^{d+1}(\mathcal{P}_F)$, or in the relative complex with the prescribed boundary values, is exactly the obstruction. Freeness then extends the map to composites; the chain identity on generators implies it on every composite by the Leibniz rule. This is an explicit obstruction calculation once the generators, their differentials and their operation recipients are supplied. A name for an operad or a Hochschild group supplies none of those data.

Question 4.5.1 *(Recognition of an arithmetic family).* For an independently specified arithmetic coefficient family, construct its simultaneous operation complexes and their geometric recipients, then the maps (4.3) on their full coefficient domains. Compare every differential, supported restriction, normal derivative, endpoint exchange and local-vacuum insertion used by the family, with compatible nested substitutions. Retain arithmetic operators and a state or trace when these marks have been independently defined. Determine the image of the resulting comparison, or prove an equivalence on a stated class of objects and full mapping spaces.

The preceding constructions locate this question's successive equations and give an extension theorem when their relative cohomology vanishes. The ternary pole example shows why the binary field product cannot replace the simultaneous operation system. The cubic example shows why a strict presentation cannot replace the comparison of primitives. Both distinctions persist when a scalar character or trace already agrees.

Chapter 5

Regular coefficient models

An associative coefficient algebra already produces fields: translate the first input and multiply it by the second. Their products have no poles. Nevertheless, their realization on collision strata must retain the order of the inputs. For the matrix units

$$a = c = E_{12}, \qquad b = E_{21}, \qquad ac = 0, \qquad abc = E_{12},$$

combining the outer coefficients before allowing the middle one to act changes a nonzero operation into zero. The obstruction concerns a partial collision, where the first and third positions agree and the second remains separate.

We construct coefficients on every such stratum by retaining each consecutive run of a position in the original word. Their principal-parts maps form a complex, and their collision and cut maps are coherent. A specified presentation permits recovery of the original differential algebra. We then construct a different coefficient system using an explicit exchange. It compresses the runs while retaining their evaluated products. The compression has a computable kernel; it need not be an equivalence.

5.1 Regular fields and the information in a word

Fix a field k of characteristic zero and $X = \mathbb{A}^1_k$ with coordinate z. A *differential coefficient algebra* is a unital differential graded associative k-algebra $(B, d, \mu, 1)$, with $1 \neq 0$, together with a degree-zero derivation T commuting with d. No finite-dimensionality or boundedness condition is imposed on B. Tensor products in this chapter are algebraic over k, unless another coefficient category is specified.

Put

$$Y_B(a,u)b = (e^{uT}a)b = \sum_{r\geq 0} \frac{u^r}{r!}(T^r a)b \quad \text{in } B[[u]]. \tag{5.1}$$

This is a formal power series, even when T is not locally nilpotent. Its coefficient in every fixed degree is defined. Writing $Y_B(a,u)b = \sum_{n\in\mathbb{Z}} a_{(n)}b\, u^{-n-1}$, we obtain

$$a_{(-r-1)}b = \frac{(T^r a)b}{r!} \quad (r \geq 0), \qquad a_{(n)}b = 0 \quad (n \geq 0).$$

In particular, $a_{(-1)}b = ab$.

Proposition 5.1.1. The fields (5.1) preserve the differential and satisfy the vacuum and translation identities

$$Y_B(1,u)b = b, \qquad Y_B(a,u)1 = e^{uT}a, \qquad Y_B(Ta,u)b = \partial_u Y_B(a,u)b,$$

$$T(Y_B(a,u)b) = Y_B(Ta,u)b + Y_B(a,u)Tb.$$

Their simultaneous product, rooted at the last position, is

$$m_n(b_1, \dots, b_n; z) = \prod_{i=1}^{n} e^{(z_i - z_n)T} b_i \tag{5.2}$$

in the original order. Consecutive substitutions give this same power series.

Proof. The unit and derivation identities give the displayed formulas coefficient by coefficient. For example,

$$\begin{aligned} Y_B(Y_B(a,u)b,v)c &= e^{vT}\big((e^{uT}a)b\big)c \\ &= (e^{(u+v)T}a)(e^{vT}b)c = Y_B(a,u+v)Y_B(b,v)c. \end{aligned}$$

There are no negative powers to obstruct the substitution. At several consecutive blocks, the same derivation identity moves each block to the common root. Associativity removes the parentheses. The graded Leibniz rule and $dT = Td$ prove compatibility with the differential. □

The order in (5.2) remains part of the operation. For constant fields, changing it replaces ab by ba. A rule relating those expressions requires additional maps.

To measure the information between occurrences, leave r inputs open and define

$$\Gamma_{B,r} : B^{\otimes(r+1)} \longrightarrow \mathrm{Hom}_k(B^{\otimes r}, B), \qquad \Gamma_{B,r}(a_0, \dots, a_r)(x_1, \dots, x_r) = a_0 x_1 a_1 \cdots x_r a_r.$$

PROPOSITION 5.1.2 *(Matrix coefficients with open inputs).* For $B = \mathrm{Mat}_d(k)$, the map $\Gamma_{B,r}$ is an isomorphism. A linear encoding of its source that retains every evaluation therefore has dimension at least d^{2r+2}. For $r = 1$ and $d > 1$, one copy of B cannot supply that encoding.

Proof. On matrix units, the value is

$$\Gamma_{B,r}(E_{i_0 j_0}, \dots, E_{i_r j_r})(E_{p_1 q_1}, \dots, E_{p_r q_r}) = \left(\prod_{\ell=1}^{r} \delta_{j_{\ell-1}, p_\ell} \delta_{q_\ell, i_\ell} \right) E_{i_0 j_r}.$$

Every elementary linear map between the indicated tensor bases occurs exactly once. This proves the isomorphism. If $\Gamma_{B,r}$ factors as $B^{\otimes(r+1)} \to L \to \mathrm{Hom}_k(B^{\otimes r}, B)$, its first map is injective, which proves the dimension bound. □

There is a stronger constraint when the encoding is required to be natural in the coefficient algebra.

PROPOSITION 5.1.3 *(Naturality retains the open word).* Suppose a quotient

$$q_B : B^{\otimes(r+1)} \twoheadrightarrow Q_B$$

is given for every differential coefficient algebra, is natural under injective unital maps commuting with d, T, and permits $\Gamma_{B,r}$ to factor through it. Then every q_B is an isomorphism. For finite-dimensional ordinary algebras, it suffices to require naturality under injections into other finite-dimensional algebras.

Proof. Adjoin noncommuting symbols $X_1, \dots, X_r$ with $dX_i = TX_i = 0$. The free B-algebra on these symbols is the tensor algebra over B of $B \otimes_k k\{X_1, \dots, X_r\} \otimes_k B$. Its summand with symbol word $X_1 \cdots X_r$ is a copy of $B^{\otimes(r+1)}$. Thus

$$a_0 \otimes \cdots \otimes a_r \longmapsto a_0 X_1 a_1 \cdots X_r a_r$$

is injective. If $w \in \ker q_B$, naturality sends w into the kernel of the corresponding quotient for the free algebra. Evaluating its open inputs at $X_1, \dots, X_r$ therefore gives zero. Injectivity implies $w = 0$. For finite-dimensional B, quotient the free algebra by symbol words of length greater than r. This algebra is finite-dimensional and retains both the injection of B and the separating summand. □

At one fixed algebra the kernel can be nonzero. For $B = k[\epsilon]/(\epsilon^2)$, $\epsilon \otimes 1 - 1 \otimes \epsilon$ evaluates to zero on every element of B. Under $\epsilon \mapsto E_{12}$, its evaluation on E_{21} becomes $E_{11} - E_{22}$. Enlarging the allowed intermediate inputs reveals information that the original evaluations lost.

5.2 Run coefficients and their residue maps

Use the word category $\mathcal{W}_X$ and its cut product from Chapter 2. For a partition π of an ordered set I, read its equality blocks along the word and remove only adjacent repetitions. The resulting list is the list of *runs*. Write $\ell(\pi)$ for its length and $\beta_\pi(r)$ for the block occupied by run r. At three positions,

π	run list	coefficient
$12\|3$	$(12, 3)$	$B^{\otimes 2}$
$1\|23$	$(1, 23)$	$B^{\otimes 2}$
$13\|2$	$(13, 2, 13)$	$B^{\otimes 3}$.

The equality $z_1 = z_3$ does not make those two occurrences adjacent in the original word.

A coarsening $\pi \le \rho$ relabels every run by its ρ-block. Multiply the factors in each newly consecutive run, retaining their order. This defines

$$p_{\pi\rho} : B^{\otimes \ell(\pi)} \longrightarrow B^{\otimes \ell(\rho)}. \tag{5.3}$$

For example, $p_{1|2|3,13|2}$ is the identity and $p_{13|2,123}(a, b, c) = abc$.

Lemma 5.2.1. The maps (5.3) are chain maps and obey

$$p_{\rho\sigma}\, p_{\pi\rho} = p_{\pi\sigma}.$$

For each block C of π, put $T_C = \sum_{\beta_\pi(r)=C} T^{(r)}$. Along a merger, $p_{\pi\rho}$ intertwines the sum of the input block translations with the output block translation.

Proof. A final run is an interval of the original word. An intermediate coarsening merely parenthesizes the ordered product on that interval. Associativity gives the composition identity. The two derivation identities give the assertions for d and T. No coefficient factors are permuted in this argument. □

Let X^π have one coordinate per equality block, ordered by first occurrence. Let

$$i_\pi : X^\pi \hookrightarrow X^I, \qquad j_\pi : \mathrm{Conf}_\pi(X) \hookrightarrow X^\pi$$

be the diagonal embedding and the open subset where different blocks occupy distinct positions. On X^{π}, set

$$M_{\pi}(B) = \omega_{X^{\pi}} \otimes_{k} B^{\otimes \ell(\pi)}.$$

The right differential-module structure is

$$(f\,\omega_{\pi} \otimes \mathbf{b})\partial_{z_C} = -\partial_{z_C} f\,\omega_{\pi} \otimes \mathbf{b} - f\,\omega_{\pi} \otimes T_C \mathbf{b}, \qquad \omega_{\pi} = dz_{C_1} \wedge \cdots \wedge dz_{C_{|\pi|}}. \tag{5.4}$$

Define the graded object

$$C^{\mathrm{run}}_{I}(B) = \bigoplus_{\pi \in \Pi(I)} i_{\pi,*} j_{\pi,*} j_{\pi}^{*} M_{\pi}(B)[|\pi|], \qquad C^{\mathrm{run}}_{\varnothing}(B) = k. \tag{5.5}$$

The sum is finite for each I. A coefficient of internal degree q in its r-block term has total degree $q - r$.

We specify the boundary, including its normal module. For a normal coordinate u, let e_j, $j \geq 0$, denote the class of u^{-j-1} times its normal density. In right-module notation,

$$e_0 u = 0, \qquad e_j u = e_{j-1}\ (j > 0), \qquad e_j \partial_u = (j+1) e_{j+1}.$$

Writing $\delta = e_0$, equivalently $e_j = \delta\, \partial_u^{j} / j!$. The map pp_u takes the negative part of a Laurent expansion to this full normal module. It retains all negative powers.

For an elementary merger of blocks $i < j$, take $u = z_{C_i} - z_{C_j}$, retain z_{C_j} as the merged coordinate, and put the merged block in position i. The face on unshifted coefficients is

$$D_{\pi\rho}(f \otimes \mathbf{b}) = (-1)^{j-2}\, \mathrm{pp}_u\big(f\, p_{\pi\rho} e^{u T_{C_i}} \mathbf{b}\big). \tag{5.6}$$

All other differences are expanded normally before taking principal parts. The sign is fixed by $\omega_{\pi} = (-1)^{j-2} du \wedge \omega_{\rho}$. Normal transfer extends this formula to the indicated diagonal direct image. A fixed localized input has a finite pole order, so only finitely many terms of the exponential contribute to its principal part. The output therefore has algebraic coefficients even for unrestricted T.

On the r-block summand the internal differential is $(-1)^{r} d_{B^{\otimes \ell(\pi)}}$. The total differential is this map plus the sum of the elementary faces. It has degree one. To prove that it squares to zero, the normal contacts must first be compared in a common target.

The three normal channels

Put $s = z_1 - z_3$, $t = z_2 - z_3$ and $r = s - t$. For any vector space P, take

$$\mathcal{G}(P) = P[[s,t]][(st(s-t))^{-1}].$$

Power series are formed before localization, so an element has a finite pole bound but can have infinitely many independent state coefficients. The full contact module $E_{s,t}(P)$ consists of finite sums of $p\, s^{-a} t^{-b}$, $a, b \geq 1$, with their normal densities and right differential actions.

The change from contact coordinates (r,t) to (s,t) is

$$J(r^{-a} t^{-b}) = \sum_{j=0}^{b-1} \binom{a+j-1}{j} s^{-a-j} t^{-b+j}.$$

Indeed, J sends the simple contact to $s^{-1}t^{-1}$, the derivative in r to that in s, and the old derivative in t to $\partial_s + \partial_t$. Applying those derivatives gives the displayed formula. Define

$$\begin{aligned} L(F) &= J\,\mathrm{pp}_t\,\mathrm{pp}_r\,F(r+t,t) && (r \ll t),\\ R(F) &= \mathrm{pp}_s\,\mathrm{pp}_t\,F(s,t) && (t \ll s),\\ N(F) &= \mathrm{pp}_t\,\mathrm{pp}_s\,F(s,t) && (s \ll t). \end{aligned}$$

The first principal part in each expression is the rightmost one. These are the channels 12, 23 and 13, expressed in one contact module.

Lemma 5.2.2. For every $F \in \mathcal{G}(P)$,

$$L(F) - R(F) + N(F) = 0.$$

Proof. Write $F = G/(s^a t^b (s-t)^c)$. A monomial surviving two principal parts has total degree at most -2. Consequently numerator terms of degree greater than $a+b+c-2$ contribute to none of the three maps. Only a finite polynomial part of G matters.

Over $k[t,t^{-1}]$, the polynomials s and $s-t$ are coprime. Partial fractions reduce to polynomials in s, terms $a_j(t)s^{-j}$, and terms $b_j(t)(s-t)^{-j}$, with Laurent coefficients in t. A polynomial in s gives zero. For $a_j(t)s^{-j}$, the expansion at $r=0$ is regular, so $L=0$ and $R=N=s^{-j}\,\mathrm{pp}_t(a_j)$.

For $b_j(t)(s-t)^{-j}$, the expansion in $s \ll t$ is regular in s, so $N=0$. In the other chamber,

$$(s-t)^{-j} = \sum_{n\geq 0} \binom{j+n-1}{n} s^{-j-n}t^n.$$

A term $t^{-\beta}$ of b_j, with $\beta \geq 1$, therefore gives $\sum_{n<\beta}\binom{j+n-1}{n}s^{-j-n}t^{n-\beta}$ in R. This is exactly $J(r^{-j}t^{-\beta})$, its contribution to L. The identity follows. □

For $F = 1/(s(s-t))$, the three values are $s^{-1}t^{-1}$, 0, $-s^{-1}t^{-1}$. Deleting the outer channel leaves a nonzero defect. For $F = 1/((s-t)^2t^2)$, they are

$$L(F) = R(F) = s^{-2}t^{-2} + 2s^{-3}t^{-1}, \qquad N(F) = 0.$$

The second term comes from the normal-coordinate transfer; keeping only the scalar residue would lose it.

Theorem 5.2.3 *(The regular residue complex).* The total differential on (5.5) is differential-linear and squares to zero. Unital differential algebra maps commuting with T induce chain maps by their tensor powers on the runs.

Proof. The derivative of $e^{uT_{C_i}}$ is $T_{C_i}e^{uT_{C_i}}$. Together with (5.4) and Lemma 5.2.1, this identifies the input and output tangential connections in every face. In the normal direction, $\mathrm{pp}_u(-\partial_u f)$ is right multiplication by ∂_u; differentiation of the Taylor factor gives precisely the input translation term. Multiplication by u agrees with the lowering action on the e_j. Thus the face extends to a differential-module map.

The internal square is zero. Each unshifted face is a chain map, and the two adjacent block numbers have opposite internal signs. The mixed terms therefore cancel. Two successive mergers either join disjoint pairs or join three blocks. For a final partition σ, translate each original run from its original

block coordinate to the retained coordinate of its σ-block. Denote this formal Taylor operator by $E_{\pi/\sigma}$. The derivation identity gives, for every intermediate ρ,

$$p_{\rho\sigma}E_{\rho/\sigma}\; p_{\pi\rho}E_{\pi/\rho} = p_{\pi\sigma}E_{\pi/\sigma}.$$

Intermediate products only parenthesize the same factors, and their translation displacements add. On a fixed localized input, each compared contact uses finitely many Taylor coefficients, so this formal identity determines the actual normal distributions.

The common coefficient can now be taken through every route. For disjoint pairs the two normal orientations have opposite signs. For three blocks the oriented sum is the identity of Lemma 5.2.2, with any remaining coefficients as spectators. These two cases exhaust the square of the boundary. Maps of differential algebras preserve every product, Taylor coefficient and internal differential in these formulas, proving the final assertion. □

5.3 COLLISION COHERENCE AND FRAMED RECOGNITION

The complexes just constructed live on the actual position charts. To obtain an object of $\mathcal{W}_X$, their exceptional collision comparisons must also be supplied.

THEOREM 5.3.1. The complexes $C_I^{\mathrm{run}}(B)$ have canonical coherent equivalences

$$d_\alpha^! C_I^{\mathrm{run}}(B) \simeq C_J^{\mathrm{run}}(B)$$

for every monotone surjection $\alpha : I \twoheadrightarrow J$. They form a connected coaugmented cut coalgebra. The construction is functorial in differential coefficient algebras and preserves quasi-isomorphisms.

Proof. A partition term survives $d_\alpha^!$ only when each α-fibre lies in one equality block. Otherwise that collision lands in a diagonal removed by j_π, and the exceptional pullback vanishes by $i^! j_* = 0$. A surviving partition is uniquely $\pi = \alpha^{-1}(\bar\pi)$. Since the fibres of α are consecutive, deleting their repetitions identifies the run lists of π and $\bar\pi$. The closed diagonal i_π factors through d_α; the closed-embedding identity $d_\alpha^! d_{\alpha,*} \simeq \mathrm{id}$ and open base change identify the surviving coefficient with its $\bar\pi$-term. Its density and shift are still $\omega_{X^{\bar\pi}}$ and $[|\bar\pi|]$. Formula (5.6) identifies the surviving differentials.

Under two collisions, the same partitions survive as under their composite, and the same adjacent repetitions are deleted. The transitivity maps for closed direct image and open base change therefore give all collision coherences.

For a consecutive cut $I = A|D$, restrict to the open where every position in A differs from every position in D. A partition with a block crossing the cut has empty support there. Every surviving partition is $\pi_A \sqcup \pi_D$, and its runs are the concatenation of the two run lists. Thus there is an equivalence

$$C_I^{\mathrm{run}}(B)|_{U_{A,D}} \simeq \big(C_A^{\mathrm{run}}(B) \boxtimes C_D^{\mathrm{run}}(B)\big)|_{U_{A,D}}.$$

Use the canonical tensor-shift isomorphisms when identifying the differentials. Explicitly, the map from $M[a] \otimes N[b]$ to $(M \otimes N)[a+b]$ multiplies $x \otimes y$, with x of unshifted degree $|x|$, by $(-1)^{b|x|}$. The block densities occur in their concatenated order.

Localization followed by this equivalence, summed over cuts, defines the coproduct. For three or more output blocks every parenthesization restricts to the same disjoint-block open and concatenates the same run coefficients. This proves coassociativity and its compatibility with collisions. Empty cuts are identity maps on the nonempty coefficient and use $C_\varnothing = k$, giving the counit and coaugmentation. More than $|I|$ positive output blocks are impossible.

Finally filter by the number of equality blocks, using the terms with at most r blocks for the r-th stage. The differential preserves this finite filtration. On its associated graded, a quasi-isomorphism of B's acts by finite tensor powers over a field, followed by derived coefficient functors. It is a quasi-isomorphism on every term, and hence on the finite total object. □

The four-point partial strata display the coherence before the general proof is needed again:

π	run pattern	coarsening from $1\vert2\vert3\vert4$
$12\vert34$	$AABB$	$a\otimes b\otimes c\otimes d\mapsto ab\otimes cd$
$13\vert24$	$ABAB$	$a\otimes b\otimes c\otimes d\mapsto a\otimes b\otimes c\otimes d$
$14\vert23$	$ABBA$	$a\otimes b\otimes c\otimes d\mapsto a\otimes bc\otimes d.$

Merging either pair first gives the displayed map. The final collision gives $abcd$ in every case. The corresponding normal residue routes still carry their orientation signs.

The coefficient unit $k\to B$ supplies a coalgebra map $C^{\mathrm{run}}(k)\to C^{\mathrm{run}}(B)$. On each partition it inserts the coefficient unit in every run. This source retains nonempty coefficients: already its singleton is $\omega_X[1]$. It is distinct from the isolated empty unit K. The singleton unit and every tested regular mode are therefore retained without assigning the empty coefficient the value B.

Theorem 3.1.2 now gives an associative geometric algebra

$$A^{\mathrm{run}}(B)=\Omega_{\mathrm{cut}}C^{\mathrm{run}}(B),\qquad B_{\mathrm{cut}}A^{\mathrm{run}}(B)\simeq C^{\mathrm{run}}(B).$$

Its multiplication is cobar concatenation. The field multiplication of B is recovered instead from the framed two-point boundary

$$r_B(f;a,b)=\mathrm{pp}_u\big(f(e^{uT}a)b\big),\qquad a_{(n)}b=[e_0]\,r_B(u^n;a,b).$$

The test u^{-1} recovers ab; all negative-index modes are retained in the same way. This recovery uses the full normal module, not evaluation of a distribution at $u=0$.

Definition 5.3.2. A *split presentation with run coefficients* consists of the following data for a complex E with a commuting degree-zero operator T: the literal direct sums (5.5) with E in every run; the connections (5.4); a nonzero closed degree-zero singleton vector 1 with $T1=0$; the saturated-partition collision identifications of Theorem 5.3.1, including their transitivity; and the cut maps given by concatenation. It also has a differential extending the shifted internal differential and a binary contact r. The contact is *regular* when $[e_0]r(u^n;a,b)=0$ for every $n\geq 0$. A morphism is the literal tensor power, on each run coefficient, of one singleton chain map commuting with T and 1, compatible with all the displayed maps. Morphisms are not identified up to chain homotopy.

The definition supplies the carrier and its comparisons. It does not assume a multiplication on E. Recover the candidate product by $\mu(a,b)=[e_0]r(u^{-1};a,b)$.

Theorem 5.3.3 *(Recognition with a specified presentation).* A split presentation with regular binary contact is isomorphic to $C^{\mathrm{run}}(B)$ as a framed presentation exactly when the following equations hold: μ is associative with unit 1; d and T are derivations of μ; every elementary face is (5.6) for this product; and the total differential has no further components. The inverse construction is $B=(E,d,T,\mu,1)$. These constructions give an equivalence of the stated strict categories.

Proof. Every condition holds for the constructed realization. Conversely the first two conditions make E a differential coefficient algebra. Its fields are $(e^{uT}a)b$. The face equations identify every normal contact, and the condition on the remaining components identifies the full differential. The prescribed splitting identifies the coefficient modules, their shifts and connections. The prescribed saturation and cut maps identify the exceptional comparisons, their coherences and the coproduct. This gives an isomorphism of all the framed data.

A morphism of presentations recovers its singleton map. Compatibility with $r(u^{-1}; a, b)$ makes this map multiplicative, while the other singleton requirements preserve d, T, 1. Conversely such an algebra map preserves every construction. The two assignments are inverse on morphisms as well as objects. □

Prescribing the collision comparisons is necessary. In the scalar presentation, multiply the comparison for $\alpha : I \twoheadrightarrow J$ by $\lambda^{|I|-|J|}$, where $\lambda \in k^\times$. The exponents add under composition and under cut decomposition, so all their coherences remain valid. The coefficients and differentials are unchanged. For $\lambda \neq 1$, no unital singleton map $k \to k$ induces a framed isomorphism with the original presentation.

Even the unframed word carrier has coefficients invisible in arities one and two. Choose distinct $a, b \in k$. For a rational point $p \in X^n$, let δ_p be its differential-module direct image. The system

$$F_0 = 0, \qquad F_n = \bigoplus_{\substack{r_1,r_2,r_3 \geq 1 \\ r_1+r_2+r_3=n}} \delta_{a^{r_1}b^{r_2}a^{r_3}}$$

has canonical monotone-collision comparisons. Indeed, the exceptional pullback of a summand vanishes unless the point is constant on each collision fibre. Every surviving point is the unique expansion of a corresponding point of the shorter word, and closed direct image gives the transitive identifications. Thus $F_1 = F_2 = 0$ but $F_3 = \delta_{(a,b,a)} \neq 0$. There are $\binom{n-1}{2}$ summands for $n \geq 3$. Binary data alone are not conservative on this carrier.

Strict differentials retain higher products

The recognition theorem is a statement about literal presentations. For

$$B = k1 \oplus (ku \xrightarrow{d} kv), \qquad |u| = -1, \quad |v| = 0, \quad du = v, \quad dv = 0, \quad T = 0,$$

give the second summand square-zero multiplication. The unital maps that multiply u, v by a scalar λ are distinct strict algebra maps. The augmentation $B \to k$ is a quasi-isomorphism and has the same composite with every such map. Consequently these maps all become the identity after localization. Strict faithfulness does not imply faithfulness of strict maps into a derived category. This example does not decide the faithfulness of the functor from the already localized source.

The cubic algebra in the prologue supplies a different test. Its strict endomorphism algebra E, with $T = 0$, is an allowed coefficient algebra. Hence $C^{\mathrm{run}}(E)$ is defined with no finite state truncation. The two-point contact recovers composition in E, and its coefficient differential retains the identities

$$DU = DV = 0, \qquad U^2 = DH, \qquad UH + HU = -V.$$

In particular the single-valued product $\langle [U], [U], [U] \rangle = \{-[V]\}$ from (3) remains encoded by the product and its primitive. It is nonzero. Replacing E by its graded cohomology algebra with zero differential would replace that product by zero.

There is therefore no zigzag of framed quasi-isomorphisms between these two presentations: taking the singleton and its recovered product would give a zigzag of quasi-isomorphisms of differential graded

algebras, contradicting the computed Massey product. A higher presentation can express the same information in a ternary operation. A strict presentation expresses it in the differential and the chosen primitives. Neither description justifies discarding it.

5.4 An exchange that permits contextual compression

Retaining every run is one construction. A different one keeps one coefficient for each occupied position and allows the intervening coefficients to enter a merger. Its basic map is

$$c_B(a \otimes b) = ab \otimes 1 + 1 \otimes ab - a \otimes b.$$

This is the $R_{1,1,1}$ member of the Dăscălescu–Nichita operators.[1] We shall need its multiplication identities as well as its braid relation.

Lemma 5.4.1. For every unital differential graded algebra B, c_B is a degree-zero chain map, natural in unital algebra maps, and

$$c_B^2 = 1, \qquad \mu c_B = \mu, \qquad c_B(a \otimes 1) = 1 \otimes a, \qquad c_B(1 \otimes a) = a \otimes 1,$$
$$(c_B)_{12}(c_B)_{23}(c_B)_{12} = (c_B)_{23}(c_B)_{12}(c_B)_{23},$$
$$c_B(1 \otimes \mu) = (\mu \otimes 1)(1 \otimes c_B)(c_B \otimes 1),$$
$$c_B(\mu \otimes 1) = (1 \otimes \mu)(c_B \otimes 1)(1 \otimes c_B).$$

Proof. Multiplication and insertion of the closed unit are degree-zero chain maps. They give chain compatibility and naturality. The first line follows by substitution. Both braid words on $a \otimes b \otimes c$ reduce to

$$abc \otimes 1 \otimes 1 + 1 \otimes ab \otimes c + a \otimes bc \otimes 1 + 1 \otimes 1 \otimes abc$$
$$- ab \otimes c \otimes 1 - 1 \otimes a \otimes bc - a \otimes b \otimes c.$$

The last two identities reduce, respectively, to $abc \otimes 1 + 1 \otimes abc - a \otimes bc$ and $abc \otimes 1 + 1 \otimes abc - ab \otimes c$. Only associativity and the unit have been used. □

Adjacent c_B's therefore give an action of the symmetric group on each $B^{\otimes n}$. Multiplication is invariant under these specified crossings. This assertion does not replace c_B by the usual graded flip.

For a coarsening $\pi \leq \rho$, start with one B-factor per π-block. Stably group the blocks belonging to the same ρ-block by adjacent c_B's, then multiply each group in order. Denote the resulting map by

$$q_{\pi\rho} : B^{\otimes|\pi|} \longrightarrow B^{\otimes|\rho|}.$$

Sorting the runs of each π-block together and multiplying them similarly gives $\kappa_\pi : B^{\otimes \ell(\pi)} \to B^{\otimes|\pi|}$.

Proposition 5.4.2. These maps are independent of the adjacent-transposition expressions used for the prescribed grouping and obey

$$q_{\rho\sigma} q_{\pi\rho} = q_{\pi\sigma}, \qquad \kappa_\rho p_{\pi\rho} = q_{\pi\rho} \kappa_\pi.$$

They are compatible with reordering the blocks by the specified symmetric-group action.

[1] G. Massuyeau and F. F. Nichita, *Yang–Baxter operators arising from algebra structures and the Alexander polynomial of knots*, Theorem 2.3, p. 2; arXiv:math/0404010.

Proof. The braid, involution and distant-commutation relations identify all words for a fixed permutation. Crossings inside a group disappear after multiplication because $\mu c_B = \mu$. The two multiplication identities in Lemma 5.4.1 move a merger through a crossing.

Apply these identities to two successive grouping diagrams. Move crossings before the mergers and combine successive multiplications by associativity. The result groups the original inputs directly into their final blocks. This proves the first identity. Applying the same argument to the original run list proves the second. Starting with a reordered list instead gives the stated order compatibility. □

At the first nonconsecutive collision this gives

$$\kappa_{13|2}(a,b,c) = abc \otimes 1 + a \otimes bc - ab \otimes c, \qquad \mu\kappa_{13|2}(a,b,c) = abc. \tag{5.7}$$

For $a = c = E_{12}$, $b = E_{21}$, the result is

$$E_{12} \otimes 1 + E_{12} \otimes E_{22} - E_{11} \otimes E_{12}.$$

Its product is E_{12}. Each term has used the middle input, so this map does not factor through the blind outer multiplication $a \otimes c \mapsto ac$. The units in the formula are coefficient units at retained positions; they do not remove a position.

For two interlaced pairs,

$$q_{13|24}(a,b,c,d) = abc \otimes d + a \otimes bcd - ab \otimes cd.$$

Its product is $abcd$. Taking $a = c = E_{12}$ and $b = d = E_{21}$ gives

$$2E_{12} \otimes E_{21} - E_{11} \otimes E_{11}, \qquad \mu q_{13|24} = E_{11},$$

whereas $ac \otimes bd = 0$. For the nested pair pattern,

$$q_{14|23}(a,b,c,d) = abcd \otimes 1 + a \otimes bcd - abc \otimes d.$$

Both orders of the two mergers give these formulas, by the proved grouping identities.

The exchange contains more than its product

For $B = k[x]/(x^2)$, both c_B and the usual flip τ have the same composite with multiplication. In the basis $1 \otimes 1, 1 \otimes x, x \otimes 1, x \otimes x$, c_B fixes the first vector, exchanges the middle two and negates the last. Hence

$$\operatorname{Tr} c_B = 0, \qquad \operatorname{Tr} \tau = 2.$$

The two exchanges are not linearly conjugate.

One can measure the difference from the ordinary flip for every finite-dimensional ordinary algebra. Put $n = \dim B$, $a_n = n(n-1)/2$, $q = \dim[B,B]$, and

$$s(b) = b \otimes 1 + 1 \otimes b, \qquad R_B = \tau c_B = s\mu - \tau.$$

Here $[B,B]$ is the linear span of all commutators. Write $J_m(\lambda)$ for a Jordan block of size m with eigenvalue λ.

Proposition 5.4.3. The operator $R_B^2 - 1$ is square-zero and has rank q. The Jordan form of R_B is

$$qJ_2(1) \oplus (n + a_n - 2q)J_1(1) \oplus a_nJ_1(-1).$$

Consequently

$$\operatorname{rank}(R_B - 1) = a_n + q, \qquad \operatorname{Tr} R_B = n, \qquad R_B^2 = 1 \iff B \text{ is commutative.}$$

Proof. Since $\tau s = s$ and $\mu s = 2\,\mathrm{id}$,

$$R_B^2 - 1 = s(\mu - \mu\tau).$$

The map s is injective and $(\mu - \mu\tau)s = 0$. This proves the square-zero and rank assertions.

On $\operatorname{Sym}^2 B$, the map $s\mu/2$ is a projection onto sB. The operator R_B is 1 on this image and -1 on its kernel, which has dimension a_n. On $\bigwedge^2 B$, it is $1 + s\mu$, with $s\mu$ taking values in sB and having rank q. Thus R_B restricts to identity plus a square-zero operator of rank q on $sB \oplus \bigwedge^2 B$, a space of dimension $n + a_n$. This gives the displayed blocks and all their consequences. □

For $B = \operatorname{Mat}_d(k)$, commutators span the trace-zero matrices, so $q = d^2 - 1$. At $d = 2$, the multiplicities of $J_2(1), J_1(1), J_1(-1)$ are 3, 4, 6. These are invariants of the specified coefficient exchange. Equality after multiplication forgets them.

5.5 Descent and the kernel of compression

First take $T = 0$. On each word chart of the ordered atlas $\mathscr{R}_I$ of Section 2.7, replace the run coefficient in (5.5) by $B^{\otimes|\pi|}$. In its faces replace $p_{\pi\rho}$ by $q_{\pi\rho}$. Call the resulting chart complex $C_I^{\mathrm{ctx}}(B)$. The same three-channel identity proves that its differential squares to zero: every route to a final partition has the single coefficient map $q_{\pi\sigma}$.

On an overlap of two charts, a surviving equality block has the same internal order in both charts. Only its order relative to other, separated blocks can change. Use the action generated by c_B to change that block order, together with the corresponding density and tensor-shift identifications. These are specified transition maps.

Theorem 5.5.1. For $T = 0$, these transitions glue the chart complexes to a coherent exceptional collision system on $\mathscr{R}_I$. It is a connected coaugmented coalgebra for the atlas convolution $\star$. The maps κ_π define a natural map of cut coalgebras

$$C^{\mathrm{run}}(B) \longrightarrow \operatorname{res} C^{\mathrm{ctx}}(B), \tag{5.8}$$

where restriction uses the colax comparison of Proposition 2.7.2. The map is an isomorphism in arities one and two.

Proof. The symmetric-group relations prove the transition cocycle on every triple overlap. The grouping identities make transitions commute with all surviving faces. A target stratum absent from an overlap has zero restricted face. Hence these are chain isomorphisms on the full overlaps.

For an ordered-fibre collision, choose an expanded chart where its fibres are consecutive. The saturated partitions are precisely the pullbacks of partitions of the shorter word. Their densities, shifts and block coefficients agree. The argument in Theorem 5.3.1 therefore gives the exceptional comparison there. Compatibility with transitions makes it a comparison on the actual atlas collision map, and saturation under composite collisions proves transitivity.

On an arbitrary cross-disjoint decomposition $I = A \sqcup D$, the surviving partitions are $\pi_A \sqcup \pi_D$. Regroup their coefficient blocks using c_B. This is invertible, and localization into the resulting external product defines the coproduct. All iterates use the same final disjoint open and the same regrouping. The braid and multiplication identities give coassociativity, collision compatibility and the empty-unit identities.

The identity $\kappa_\rho p_{\pi\rho} = q_{\pi\rho}\kappa_\pi$ proves that (5.8) is a chain map and preserves collisions. On a consecutive cut, sorting the runs splits into the sorting on its two sides; this proves compatibility with the cut coproduct. At one or two positions every run list has one occurrence of each equality block, so each κ_π is the identity. □

This construction supplies a chosen exchange. It does not extend a different prescribed overlap map by leaving it unchanged.

PROPOSITION 5.5.2 *(A split compression kernel).* The coefficient map $\kappa = \kappa_{13|2}$ is a split surjection for every unital differential graded algebra. A section and the resulting projection onto its kernel are

$$s_0(x \otimes y) = x \otimes y \otimes 1, \qquad P = 1 - s_0\kappa.$$

Explicitly,

$$\begin{aligned} P(a,b,c) = a \otimes b \otimes c - abc \otimes 1 \otimes 1 - a \otimes bc \otimes 1 \\ + ab \otimes c \otimes 1. \end{aligned}$$

For an ordinary algebra of finite dimension d, $\dim \ker \kappa = d^3 - d^2$.

Proof. Substituting $c = 1$ in (5.7) gives $\kappa s_0 = \mathrm{id}$. Thus $P^2 = P$, $\kappa P = 0$, and P is identity on $\ker \kappa$. All maps commute with the differential. The dimension follows from the split surjection. □

On the open equality stratum $S = \{z_1 = z_3 \neq z_2\}$, all other partition terms vanish under exceptional restriction. Both remaining terms have shift $[2]$. Consequently

$$i_S^! \operatorname{Cone}\big(C_3^{\mathrm{run}}(B) \to (\operatorname{res} C^{\mathrm{ctx}}(B))_3\big) \simeq \omega_S \otimes \ker \kappa[3].$$

The extra shift is the shift of a kernel in the cone of a split surjection. For $d > 1$, this proves that compression is not an equivalence.

PROPOSITION 5.5.3 *(An obstruction to unchanged descent).* Let B be an ordinary finite-dimensional algebra with $T = 0$ and $\dim B = d > 1$. The run complexes on the separate word charts cannot descend to $\mathscr{R}_I$ with their chart objects unchanged.

Proof. The charts 123 and 132 overlap wherever $z_2 \neq z_3$, and both contain S. The run list of $13|2$ is ABA in the first chart and AB in the second. Their exceptional restrictions to S are

$$\omega_S[2] \otimes B^{\otimes 3}, \qquad \omega_S[2] \otimes B^{\otimes 2}.$$

They have ranks d^3 and d^2 in the same degree. An overlap equivalence would induce a quasi-isomorphism between them, which is impossible. □

For a differential graded algebra the comparison must use cohomology, not the dimensions of the underlying complexes. The same argument applies when $H^*(B)$ has finite total dimension greater than one. In contrast, the square-zero contractible extension of k considered above has run complexes quasi-isomorphic to the scalar ones. Its underlying state dimensions give no obstruction of this kind.

5.6 Translation frames and the algebraic boundary

The run construction allowed every derivation T. For contextual descent, translation also enters the overlap maps. Suppose first that T is locally nilpotent, meaning that for each $b \in B$ some power $T^N b$ is zero. Then

$$E_z = e^{zT} : O_X \otimes B \longrightarrow O_X \otimes B$$

is an algebraic change of frame, with inverse E_{-z}, and

$$\partial_z E_z = E_z(\partial_z + T).$$

This is an identity of operators on sections. It changes the translation connection to the constant connection.

Conversely, an algebraic horizontal frame $E(z)$ with $E(0) = 1$ is necessarily this one. Writing $E(z) = \sum_n z^n E_n$ on each input, horizontality gives $(n+1)E_{n+1} = E_n T$, hence $E_n = T^n/n!$. Polynomiality on every vector is exactly local nilpotence. Thus the hypothesis is precise for this method of constructing an algebraic frame.

On a partition put

$$E_{\pi,\mathrm{run}} = \bigotimes_{r=1}^{\ell(\pi)} e^{z_{\beta_\pi(r)} T}, \qquad E_{\pi,\mathrm{block}} = \bigotimes_{C \in \pi} e^{z_C T}.$$

Conjugate every contextual face and overlap map by its source and target frames, and set

$$\kappa_\pi^T = E_{\pi,\mathrm{block}}^{-1} \kappa_\pi E_{\pi,\mathrm{run}}. \tag{5.9}$$

Theorem 5.6.1. For locally nilpotent T, the contextual chart complexes with these conjugated maps descend to the ordered atlas and form a connected $\star$-coalgebra. Formula (5.9) gives a map of cut coalgebras from $C^{\mathrm{run}}(B)$ to its restriction. It retains every regular field coefficient.

Proof. All frames are algebraic and invertible on sections and commute with d. At a merged position,

$$e^{zT} \mu = \mu(e^{zT} \otimes e^{zT}).$$

Conjugating a face therefore gives exactly its normal Taylor transport. Intermediate frames cancel in every composition identity, including the transition cocycle, the grouping equations and the collision and coproduct comparisons. Thus Theorem 5.5.1 applies in the translation frames. At two positions the resulting contact is $\mathrm{pp}_u(f(e^{uT}a)b)$, so its Laurent tests recover all the original modes. □

For two positions t, 0, written in the exchanged order 0, t, the transition is

$$\begin{aligned} c_T(t)(a \otimes b) = {} & (e^{tT}a)b \otimes 1 + 1 \otimes a(e^{-tT}b) \\ & - (e^{tT}a) \otimes (e^{-tT}b). \end{aligned}$$

The reverse transition uses $-t$. Conjugating the constant relations proves

$$c_T(-t)c_T(t) = 1, \qquad c_{12}(v)c_{23}(u+v)c_{12}(u) = c_{23}(u)c_{12}(u+v)c_{23}(v).$$

These identities hold on all states; they are the cancellation of intermediate Taylor frames around the two placed diagrams.

At the partial collision with coordinates $(t, 0, t)$, formula (5.9) becomes

$$\begin{aligned}\kappa^{T}_{13|2}(a, b, c; t) = a(e^{-tT}b)c \otimes 1 + a \otimes b(e^{tT}c)\\ - a(e^{-tT}b) \otimes e^{tT}c.\end{aligned} \tag{5.10}$$

The binary evaluation $x \otimes y \mapsto (e^{tT}x)\,y$ gives $(e^{tT}a)b(e^{tT}c)$: the second and third terms cancel, and the first gives that ordered product. Local nilpotence makes the displayed coefficient algebraic.

Example 5.6.2 *(A nonconstant polynomial exchange).* Take $B = k\langle x, y\rangle$, $Tx = 0$, $Ty = x$. Translation lowers the number of y's in a word, so it is locally nilpotent. Here $Y_B(y, t)\,y = y^2 + txy$, and

$$\begin{aligned}c_T(t)(y \otimes y) = y^2 \otimes 1 + 1 \otimes y^2 - y \otimes y\\ + t(xy \otimes 1 - 1 \otimes yx - x \otimes y + y \otimes x) + t^2 x \otimes x.\end{aligned}$$

This is a polynomial transition on the original algebraic overlap, with the proved braid and reverse-transition identities. Its position dependence is given by the stated Taylor frames; no nontrivial full-turn monodromy follows from it.

For a derivation that is not locally nilpotent, the same formula can instead be only formal. For example, on $B = \mathrm{Mat}_2(k)$ take $T = \mathrm{ad}\,\mathrm{diag}(1, 0)$. Then

$$c_T(t)(E_{12} \otimes E_{21}) = e^{t}E_{11} \otimes 1 + e^{t}1 \otimes E_{11} - e^{2t}E_{12} \otimes E_{21}.$$

Its formal coefficients satisfy the same identities. They are not algebraic functions on $\mathbb{A}^2 \setminus \Delta$. The run construction still exists, because each of its normal faces uses only a finite Taylor jet.

A compression excluded by unrestricted translation

An *algebraic two-state expression* for an output at positions $t, 0$, rooted at zero, is a finite sum with coefficients in $k((t))$ of

$$E^{\mathrm{L}}_t(x, y) = (e^{tT}x)\,y, \qquad E^{\mathrm{R}}_t(x, y) = x(e^{tT}y),$$

where the pairs $x, y \in B$ are fixed states. A coefficientwise series in $(B \otimes B)[[t]]$ is a different permitted input.

THEOREM 5.6.3. Let

$$B = k\langle a_i, b_i, c_i \mid i \geq 0\rangle, \qquad Ta_i = a_{i+1}, \quad Tb_i = b_{i+1}, \quad Tc_i = c_{i+1}.$$

The ordered output

$$F(t) = (e^{tT}a_0)b_0(e^{tT}c_0)$$

has no algebraic two-state expression.

Proof. Project to the span of words $a_i b_j c_k$ and identify that span with $k[p, q, r]$ by $a_i b_j c_k \mapsto p^i q^j r^k$. The output becomes $e^{t(p+r)}$. In a binary expression, the translated state is a contiguous prefix or suffix of the output word. Its projection is therefore a finite sum of terms

$$f(t)P(p, q, r)e^{tL}, \qquad L \in \{0, p, p + q, p + q + r, r, q + r\},$$

with polynomial P and Laurent f. This includes empty factors and arbitrary descendants in the two fixed states. Other generator patterns contribute zero.

Set $D = \partial_p + 2\partial_q + 4\partial_r$. The six exponential eigenvalues are st, $s \in S = \{0, 1, 3, 4, 6, 7\}$. If all the finitely many polynomials P have degree at most d, the commuting operator

$$\prod_{s \in S} (D - st)^{d+1}$$

kills the proposed expression. Applied to $e^{t(p+r)}$, it instead gives

$$(80t^6)^{d+1} e^{t(p+r)} \neq 0,$$

since D has eigenvalue $5t$ there. These calculations hold in $k((t))[[p, q, r]]$. They contradict the proposed finite expression. □

The obstruction fixes the binary coefficient class in advance. It does not exclude every compression for a non-nilpotent translation. For a commutative coefficient algebra, multiplying the runs of each block already gives horizontal block coefficients, using the ordinary flip. The derivation and commutativity identities make these maps compatible with all coarsenings. For instance, $B = k[x]$, $Tx = x$, has no polynomial horizontal frame, yet

$$(e^{tT} a)b(e^{tT} c) = (e^{tT}(ac))b$$

is a two-state expression.

For general B, allowing the formal expression (5.10) changes the coefficient tensor and its completion. Descent then requires actual continuous collision functors and overlap maps on that coefficient category, together with a comparison preserving all the field modes, vacuum data and cut maps. The algebraic obstruction above leaves that completed comparison open. The regular run construction itself needs none of those additional choices.

The next construction introduces a specified singular local field factor. Its poles alter the normal principal parts. The ordered coefficient words, their run maps and the distinctions between the empty unit, the local vacuum and a prescribed state remain necessary.

Chapter 6

Singular backgrounds and vacuum data

The simplest singular current already separates a vacuum from a scalar augmentation. At nonzero level κ, its first product satisfies

$$J_{(1)}J = \kappa \mathbf{1}.$$

Every first product in the scalar vertex algebra is zero. A unital field map from this current algebra to the scalars is therefore impossible. Nevertheless, the current has a vacuum, a vacuum expectation and a geometric realization with scalar empty coefficient. These are different structures.

We first construct that realization from all collision strata. We then allow infinitely many current species. Completing each energy space retains the local field operations, including quadratic fields with Hilbert–Schmidt coefficients. A change of coordinate can require self-contractions that are discontinuous in this completion. This leads to two further coefficient domains, one controlling projective tensor norms and one retaining contraction values as independent central coordinates.

Gaussian preparations give actual normalized states in a specified Hilbert sector. Their existence and their transport require their own estimates. We also determine when a formal state parameter may be identified with an insertion coordinate. The resulting completed products retain convergent mode identities on lower-bounded modules.

6.1 A current with a vacuum and no scalar augmentation

Let k be a field of characteristic zero and fix $\kappa \in k^{\times}$. The state space of one current is

$$H_\kappa = k[x_1, x_2, \dots], \qquad \mathbf{1} = 1.$$

Every state is a polynomial in finitely many variables. Give x_m energy m. For $m > 0$, define operators

$$a_{-m} f = x_m f, \qquad a_m f = \kappa m \frac{\partial f}{\partial x_m}, \qquad a_0 = 0.$$

They obey

$$[a_m, a_n] = \kappa m \delta_{m+n,0}, \qquad a_m \mathbf{1} = 0 \quad (m \geq 0). \tag{6.1}$$

The translation operator is

$$T = \sum_{m \geq 1} m x_{m+1} \frac{\partial}{\partial x_m}.$$

This sum is finite on each state. It satisfies $T\mathbf{1} = 0$ and $[T, a_m] = -m a_{m-1}$.

Put

$$J(z) = \sum_{m \in \mathbb{Z}} a_m z^{-m-1}, \qquad J^{[m]}(z) = \frac{\partial_z^{m-1} J(z)}{(m-1)!} \quad (m \geq 1).$$

Normal ordering, denoted by colons, moves negative modes to the left of positive modes. Define the field of a monomial by

$$Y(x_{m_1}\cdots x_{m_r},z) =: J^{[m_1]}(z)\cdots J^{[m_r]}(z) :, \qquad Y(\mathbf{1},z)=\mathrm{id}.$$

Linearity defines Y on H_κ. In the notation $Y(a,z)b=\sum_n a_{(n)}b\,z^{-n-1}$, the current state is $J=x_1$.

PROPOSITION 6.1.1. These formulas make H_κ a local vertex algebra with vacuum $\mathbf{1}$ and translation T. For states of energies E, F, the locality exponent $E+F$ suffices. The elementary contraction is

$$J^{[m]}(z)J^{[n]}(w)\sim\frac{\kappa(-1)^{m-1}(m+n-1)!}{(m-1)!(n-1)!(z-w)^{m+n}}. \tag{6.2}$$

Here $\sim$ records only the negative powers of $z-w$.

Proof. Split J into its negative- and positive-mode parts. Equation (6.1) gives

$$[J_+(z),J_-(w)]=\kappa\sum_{m\ge1}mz^{-m-1}w^{m-1}=\iota_{z,w}\frac{\kappa}{(z-w)^2},$$

where $\iota_{z,w}$ means expansion in powers of w/z. Commuting the positive modes in one normally ordered monomial past the negative modes in another gives a sum over cross pairings. A pairing uses a factor at most once. The unpaired factors remain normally ordered. Differentiating the displayed contraction gives (6.2).

This expansion is the Wick formula. A pair of energies m, n contributes a pole of order $m+n$. Thus states of energies E, F have total pole order at most $E+F$. The two orders of the fields expand the same rational contractions in the opposite chambers. Multiplication by $(z-w)^{E+F}$ removes their difference.

On the vacuum, the negative part of J is $\sum_{r\ge0}x_{r+1}z^r=e^{zT}x_1$. Differentiation and the product rule give $Y(a,z)\mathbf{1}=e^{zT}a$ for every monomial. The commutator relation with T gives $[T,Y(a,z)]=\partial_zY(a,z)=Y(Ta,z)$.

For three monomials, every nested Wick expansion enumerates the same pairings, with the same uncontracted factors. After clearing the finite pairwise pole bound, their coefficient identities agree. The chamber expansions of this identity are the vertex Jacobi identity. All its coefficients on a fixed state use finitely many annihilators. Thus lower truncation, the vacuum, translation and locality identities hold on the stated polynomial space.

These are also the explicit formulas of the Heisenberg construction.[1] □

For example,

$$Y(J,u)J=\kappa u^{-2}\mathbf{1}+(e^{uT}J)J, \qquad J_{(1)}J=\kappa\mathbf{1}, \qquad J_{(0)}J=0.$$

The product on the right in the regular term is polynomial multiplication of creation states. It should not be substituted for every field product.

PROPOSITION 6.1.2. There is no unital vertex-algebra map $H_\kappa\to k$, where k has its constant fields and zero translation. The polynomial constant-term functional $\epsilon_0:H_\kappa\to k$ still defines a normalized vacuum expectation.

[1] E. Frenkel, *Vertex Algebras and Algebraic Curves*, §§2.1–2.4, arXiv:math/0007054.

Proof. A field map would preserve the first product and the vacuum. It would send $J_{(1)}J$ to κ, but the first product of any two scalar states is zero. This contradicts $\kappa \neq 0$. The functional ϵ_0 is defined on every polynomial and has $\epsilon_0(\mathbf{1}) = 1$. Applying it to products of fields gives the Wick vacuum coefficients. No preservation of every field product is asserted for this functional. □

The construction extends to a finite-dimensional space of species with a specified symmetric pairing. For orthogonal level-one currents, contractions of different species vanish. Their vacuum tensor product is the tensor product of their vertex algebras. The creation-state energy has Hilbert series

$$\prod_{m\geq 1}(1-q^m)^{-r}$$

for r species. The coefficient of each power of q is finite. An arithmetic energy weighting or a chosen charge is additional data on this space.

A finite-place coefficient field and its diagonal

The same construction over $\mathbb{Q}_p$ has the nonzero formal pole $\kappa(z-w)^{-2}$. Its insertion variable is a coordinate on an auxiliary curve over $\mathbb{Q}_p$. It is independent of the p-adic topology on its coefficient field. An analytic interpretation requires specified norms and convergence domains.

Two completions of a tensor product illustrate why this distinction matters. Set $R = \mathbb{Z}_p \otimes_{\mathbb{Z}} \mathbb{Z}_p$, with multiplication map $\mu : R \to \mathbb{Z}_p$. Define its p-adic completion by $\widehat{R}_p = \varprojlim_r R/p^r R$.

Proposition 6.1.3. Multiplication induces $\widehat{R}_p \simeq \mathbb{Z}_p$. The ordinary multiplication map $R \to \mathbb{Z}_p$ is not injective. After inverting p, its diagonal ideal has nonzero conormal module.

Proof. For every $r \geq 1$, tensoring with $\mathbb{Z}/p^r$ gives

$$R/p^r R \cong (\mathbb{Z}_p/p^r) \otimes_{\mathbb{Z}} (\mathbb{Z}_p/p^r) \cong \mathbb{Z}/p^r.$$

These multiplication isomorphisms commute with reduction, proving the completion formula. No interchange of an ordinary tensor with an inverse limit is used.

Choose $a \in \mathbb{Z}_p \setminus \mathbb{Q}$. In $\mathbb{Q}_p \otimes_{\mathbb{Q}} \mathbb{Q}_p$, the element $a \otimes 1 - 1 \otimes a$ is nonzero. Indeed a $\mathbb{Q}$-linear functional $\ell : \mathbb{Q}_p \to \mathbb{Q}$ with $\ell(1) = 0, \ell(a) = 1$ detects it. Its antecedent in R is therefore nonzero, while multiplication kills it. The reduction formula also shows that it vanishes in every $R/p^r R$.

For the conormal assertion, choose a transcendental over $\mathbb{Q}$. Such elements exist because $\mathbb{Z}_p$ is uncountable and algebraic numbers are countable. Include a in a transcendence basis. The derivation sending a to 1 and all other basis elements to zero extends across the separable algebraic extension to $\mathbb{Q}_p$. Hence $\Omega_{\mathbb{Q}_p/\mathbb{Q}} \neq 0$.

If I is the kernel of multiplication on $\mathbb{Q}_p \otimes_{\mathbb{Q}} \mathbb{Q}_p$, the defining universal derivation gives

$$I/I^2 \cong \Omega_{\mathbb{Q}_p/\mathbb{Q}}.$$

It sends the class of $1 \otimes a - a \otimes 1$ to da. This proves nontriviality of the first infinitesimal neighborhood of that diagonal. □

Thus completion in p and completion in the diagonal ideal concern different directions. On the auxiliary line $\mathbb{A}^1_{\mathbb{Q}_p}$, the diagonal instead has normal parameter $u = z - w$. Its formal neighborhood has coefficient ring $\mathbb{Q}_p[z][[u]]$, and its principal parts retain every $u^{-r-1}du$. The formal current pole uses this parameter. The p-adic completion formula alone cannot eliminate these operations.

PROPOSITION 6.1.4. Any family of characteristic-zero fields (k_v) has an abstract common field extension over $\mathbb{Q}$. The formal Heisenberg algebra over $\mathbb{Q}$ also base changes to each k_v.

Proof. Form the filtered union

$$R_\infty = \varinjlim_{S \text{ finite}} \bigotimes_{v \in S, \mathbb{Q}} k_v,$$

where the maps insert units. Each finite tensor is a nonzero $\mathbb{Q}$-vector space. The transition maps are injective: a linear functional on the new field taking 1 to 1 gives a retraction. Hence R_∞ is a nonzero commutative ring.

Choose a maximal ideal. The quotient field receives a unital map from every k_v. Each such map is injective, since its source is a field. The explicit mode formulas and their identities commute with scalar extension, proving the final assertion. □

This field construction makes no topological or canonical choice. For example, an abstract embedding $\mathbb{Q}_p \to \mathbb{C}$ cannot be continuous: $p^r \to 0$ in $\mathbb{Q}_p$, while its images are the unbounded real numbers p^r. Likewise the adelic projection $\mathbb{A}_\mathbb{Q} \to \mathbb{Q}_p$ has the opposite direction from scalar extension of a $\mathbb{Q}_p$-algebra to the adeles. A placewise module construction must specify its actual rings, maps and restricted topology. Hecke actions and automorphic comparison maps are further structures on those coefficients.

6.2 The residue coalgebra of the singular background

Let $X = \mathbb{A}^1_k$. We use the word carrier $\mathcal{W}_X$, its cut tensor, and the partition embeddings i_π, j_π of Chapter 5. Order the blocks of π by first occurrence.

For $r = |\pi|$, put

$$M_\pi(H_\kappa) = \omega_{X^\pi} \otimes_k H_\kappa^{\otimes r}.$$

Its right derivative in the coordinate of block C is minus the scalar derivative minus T on its H_κ-factor. All external coefficient tensors in this construction are algebraic over k.

Define

$$(C_\kappa)_I = \bigoplus_{\pi \in \Pi(I)} i_{\pi,*} j_{\pi,*} j_\pi^* M_\pi(H_\kappa)[|\pi|], \qquad (C_\kappa)_\varnothing = k. \tag{6.3}$$

The state complex has zero differential. Its r-block term lies in cohomological degree $-r$.

For a merger of blocks $i < j$, take $u = z_{C_i} - z_{C_j}$, retain z_{C_j}, and place the merged block in position i. Replace its two states by $Y(v_i, u)v_j$, leaving the other block states in their original relative order. The face is

$$D_{\pi\rho}(f \otimes \mathbf{v}) = (-1)^{j-2} \operatorname{pp}_u \big(f \otimes v_1 \otimes \cdots \otimes Y(v_i, u)v_j \otimes \cdots \widehat{v_j} \cdots \big). \tag{6.4}$$

The principal part uses the full right normal module $e_m = u^{-m-1}du = \delta \partial_u^m / m!$. Other coordinate differences are expanded normally before taking the principal part. Normal transfer extends the map to the diagonal direct image. For each input, lower truncation and the finite pole order of f make its output a finite normal sum.

THEOREM 6.2.1. The sum of the faces (6.4) is a differential. The objects (6.3) have coherent exceptional comparisons for monotone collisions and form a connected coaugmented cut coalgebra C_κ.

Proof. Translation covariance of the field identifies the input and output tangential connections. In the normal direction the identity $e_m \partial_u = (m+1)e_{m+1}$, together with $Y(Ta, u)b = \partial_u Y(a, u)b$, gives differential linearity of every face.

Two consecutive faces either merge disjoint pairs or merge three blocks. In the first case the coefficient operations commute, and the two normal orientations have opposite signs. In the second case expand all three inputs by the Wick formula before taking any principal parts. There is one finite collection of contraction patterns. Each pattern is a simultaneous coefficient with a finite product of pairwise denominators and a formal regular numerator.

Locality permits its expansion in each of the three collision orders. The oriented contacts therefore obey $L - R + N = 0$, by Lemma 5.2.2, with the uncontracted states as coefficients. The normal-coordinate transfer in that lemma is part of the comparison. These two cases exhaust the square of the differential.

Let $\alpha : I \twoheadrightarrow J$ be monotone. Exceptional pullback kills a partition term unless each α-fiber lies in one of its blocks. Every other term meets a diagonal removed by j_π. Every surviving partition is $\pi = \alpha^{-1}(\bar{\pi})$. Its block-state tensor, density, shift and residue faces agree with the $\bar{\pi}$-term. Closed direct image and open base change give the exceptional equivalence.

Saturation for two collisions is saturation for their composite, so the same identifications give all the required coherences.

On the cross-disjoint open of a consecutive cut $I = A|D$, a surviving partition is uniquely $\pi_A \sqcup \pi_D$. Its states and densities split into the two consecutive blocks. Localization and this equivalence define the cut coproduct.

For any further cuts all composites use the same disjoint open, partition decomposition and ordered tensor factors. Thus the coproduct is coassociative and commutes with collisions. Empty cuts use the specified coefficient k. There are at most $|I|$ positive output blocks, which proves conilpotence in each arity. □

At three positions put $H_X = \omega_X \otimes_k H_\kappa$, and let each L denote the localized two-block coefficient with two H_κ-factors. Writing j for the three-point configuration open, the terms are

$$\begin{aligned}(C_\kappa)^{-3} &= j_* j^*(H_X^{\boxtimes 3}),\\ (C_\kappa)^{-2} &= i_{12,*} L_{12|3} \oplus i_{23,*} L_{1|23} \oplus i_{13,*} L_{13|2},\\ (C_\kappa)^{-1} &= i_{123,*} H_X.\end{aligned}$$

The third summand is present even though the cut tensor uses consecutive cuts. For independent currents J, P, the outer contraction in $J(z_1)P(z_2)J(z_3)$ is

$$\frac{\kappa P(z_2)}{(z_1 - z_3)^2}.$$

It survives on 13|2. Both adjacent contractions vanish. The scalar vacuum expectation of this term is zero. Thus that expectation does not retain the supported operation.

Insert $\mathbf{1}$ in every block of the scalar residue coalgebra $C^{\mathrm{run}}(k)$ from the preceding chapter. Since $Y(\mathbf{1}, u)\mathbf{1} = \mathbf{1}$, these maps commute with every face, collision and cut. They give a coalgebra map

$$C^{\mathrm{run}}(k) \longrightarrow C_\kappa. \tag{6.5}$$

Its singleton is $\omega_X[1] \to \omega_X \otimes H_\kappa[1]$, induced by the local vacuum. The source is not the isolated empty unit K.

Definition 6.2.2. The *Heisenberg geometric background* on the word carrier is the augmented associative algebra

$$A_\kappa = \Omega_{\mathrm{cut}} C_\kappa.$$

The vacuum background is $A_{\mathrm{vac}} = \Omega_{\mathrm{cut}} C^{\mathrm{run}}(k)$.

COROLLARY 6.2.3. There is an associative map $A_{\mathrm{vac}} \to A_\kappa$, and

$$B_{\mathrm{cut}} A_\kappa \simeq C_\kappa, \qquad (A_\kappa)_\varnothing = k.$$

The framed two-point boundary of this bar recovers every mode of H_κ.

Proof. Apply cut cobar to (6.5). The connected coalgebra satisfies the positive-cut hypotheses of Theorem 3.1.2. That theorem gives the bar comparison. Every positive cobar word vanishes at the empty input, so only its unit remains there.

In the framed two-point boundary,

$$r(f; a, b) = \mathrm{pp}_u(fY(a, u)b), \qquad [e_0] r(u^n; a, b) = a_{(n)} b.$$

All integer Laurent tests are allowed. This proves the mode recovery, including the central first product. □

The augmentation $A_\kappa \to K$ is a geometric augmentation of a cut cobar. It is not a unital vertex-algebra map $H_\kappa \to k$, which Proposition 6.1.2 excludes. Likewise cobar multiplication is concatenation. The field products are recovered from the framed contacts. The three-channel boundary identity does not identify those contacts with strictly associative composition of two consecutive residues.

For a unital differential coefficient algebra B, one may instead retain both the local field factor and the runs of B. The partition coefficient is

$$\omega_{X^\pi} \otimes H_\kappa^{\otimes|\pi|} \otimes B^{\otimes \ell(\pi)}.$$

Its merger combines Y_{H_κ} with the ordered run map and Taylor factor of (5.6). The same three-channel proof applies: every route has the same ordered B-coefficient after its formal translations. This gives $C^{\mathrm{run}}(H_\kappa, B)$ and its cut cobar, with empty coefficient k.

The relative envelope of Chapter 8 is $A_\kappa \otimes_k B$, with empty coefficient B. These are distinct constructions. An equivalence between them would already imply $B \simeq k$ after evaluation at the empty word. For an ordinary algebra of dimension greater than one this is impossible. A proposed comparison must therefore specify its relative base and its effect on the field contacts. The notation of scalar extension alone supplies neither.

6.3 THE DERIVED COEFFICIENT OF THE LOCAL VACUUM

There is a second geometric vacuum construction. The dualizing coalgebra J of Proposition 2.2.1 has $J_n = \omega_{X^n}[n]$ in positive arity. Its cut coproducts are localization maps. Write

$$Q_n = (\Omega_{\mathrm{cut}} J)_n, \qquad n > 0.$$

This definition uses J itself. Identifying it with the scalar residue background would require a comparison with $C^{\mathrm{run}}(k)$ preserving the coalgebra and collision maps.

We compute Q_n, including its support extensions. Let X now be any smooth separated geometrically connected curve over k, and put $Y_n = X^n$. Use the closed support Z_n of (2.3). Let U_t be the open where every position to the left of cut t differs from every position to its right. For $S \subseteq \{1, \dots, n-1\}$, put $U_S = \bigcap_{t \in S} U_t$, with inclusion j_S, and $U_\varnothing = Y_n$.

Define the localization cube

$$\mathsf{C}_n^r = \bigoplus_{|S|=r} j_{S,*}\omega_{U_S}, \qquad d_{S,S\cup\{t\}} = (-1)^{|\{s\in S : s<t\}|}\mathrm{loc}.$$

All derivatives normal to a diagonal are retained. Each localization permits arbitrary finite pole order. No completion in arity or pole order is used.

Proposition 6.3.1. For $n \geq 2$, there are natural comparisons

$$\mathsf{C}_n \simeq R\Gamma_{Z_n}\omega_{Y_n}, \qquad Q_n \simeq \mathsf{C}_n[n-1].$$

They retain the cube and its augmentation. With ordered density wedges and cobar desuspensions, the second comparison is the vertexwise sign $(-1)^{n|S|}$.

Proof. The opens U_t cover $Y_n \setminus Z_n$. The cube including its empty vertex computes the fiber of restriction to this union. Every intersection is locally a principal divisor complement, so its localization is exact. This proves the first comparison.

A set S gives $|S|+1$ consecutive cobar blocks. Their density shifts sum to $[n]$, while desuspending every block contributes $[-|S|-1]$. Thus its coefficient lies in degree $|S|+1-n$, as in $\mathsf{C}_n[n-1]$. Fix the suspension identification

$$(tc_1)\otimes\cdots\otimes(tc_b) \longmapsto (-1)^{\sum_{a=1}^{b}(b-a)|c_a|}(c_1\otimes\cdots\otimes c_b)[-b], \qquad t=[-1].$$

Splitting a block at the new cut t has sign $(-1)^{1+a}$, where $a = |\{s \in S : s < t\}|$. The shifted cube has sign $(-1)^{n-1+a}$. The identity

$$(-1)^{n(|S|+1)}(-1)^{1+a} = (-1)^{n-1+a}(-1)^{n|S|}$$

proves the claimed chain isomorphism. Both maps use the same localization at every face, including the empty vertex. □

An order with divisor intersections

For partitions p, q of $[n]$, write $p \leq q$ when every p-block lies in a q-block. Their join is $p \vee q$, and $c(p) = n - |p|$. Then $\Delta_p \cap \Delta_q = \Delta_{p\vee q}$. Call a partition indecomposable when its blocks cross every consecutive cut.

By Theorem 2.3.1, the minimal indecomposable partitions are the crossing chains

$$1 = i_1 < i_2 < j_1 < i_3 < j_2 < \cdots < i_c < j_{c-1} < j_c = n,$$

whose nonsingleton blocks are (i_a, j_a). The one-pair chain is $(1, n)$. Let $\mathcal{A}_n$ be their set, ordered lexicographically by

$$(-j_1, i_1, -j_2, i_2, \dots, -j_c, i_c). \tag{6.6}$$

Write $N \prec M$ for this order. No such list properly extends another: the last right endpoint is already n.

For an indecomposable p, replace each nonsingleton block by its hull $(\min B, \max B)$. Start with the hull containing 1. At a current right endpoint $r < n$, choose the eligible hull with largest right endpoint, where eligibility means

$$\min B < r < \max B.$$

Continue to n, and leave unused positions singleton. Denote this refinement by $g(p)$.

LEMMA 6.3.2. The partition $g(p)$ is the least crossing chain refining p. For $N \prec M$, let e be the first pair of N that differs from M, and put $p = M \vee e$. Then

$$g(p) \prec M, \qquad M \vee g(p) = p \leq M \vee N, \qquad c(p) = c(M) + 1.$$

Proof. The cut at r is crossed by a block with $\min B \leq r < \max B$. Equality on the left is impossible: r already belongs to the previously chosen block, whose maximum is r. Thus an eligible hull exists. Distinct blocks have distinct maxima. The right endpoint strictly increases, so the process terminates at n.

Write its selected pairs as (i_a, j_a). For $a \geq 3$, one has $i_a > j_{a-2}$. Equality would share an endpoint. A smaller value would make this hull eligible one step earlier, with a larger right endpoint than the greedy choice. Together with $i_a < j_{a-1} < j_a$, these inequalities give the crossing-chain order.

Compare the output with any chain refining p. At the first differing pair, the greedy right endpoint is at least the competing one. For the first pair this follows from the hull of the block containing 1. For a later pair, the competing pair lies in an eligible hull. If the right endpoints agree, they belong to the same block, and the greedy left endpoint is its minimum. This proves lexicographic minimality.

Now let the first differing pair be $e = (i, j)$, and let the corresponding pair of M be (i_a, j_a). Since $N \prec M$, either $j > j_a$, or $j = j_a$ and $i < i_a$. Suppose $g(M \vee e) = M$. In the first position, the new block containing 1 has maximum larger than j_1, contradicting this supposition.

At a later position put $r = j_{a-1}$. The block containing e has $\min B \leq i < r < j \leq \max B$. It is eligible.

A larger right endpoint contradicts greedy maximality. If its maximum equals j_a, uniqueness of that maximum forces this block to be chosen, with left endpoint at most $i < i_a$. This is again a contradiction. Hence $g(p) \prec M$.

Two distinct minimal indecomposable partitions are incomparable. Therefore

$$M < M \vee g(p) \leq p.$$

Adding one pair raises partition rank by at most one. The strict inequality forces $M \vee g(p) = p$ and $c(p) = c(M) + 1$. Since e is a pair of N, one also has $p \leq M \vee N$. □

For $M \in \mathcal{A}_n$, define

$$\mathcal{D}_M = \{\sigma : \sigma \text{ covers } M \text{ and } g(\sigma) \prec M\}.$$

A cover merges exactly two M-blocks. The exchange lemma proves the attachment equation

$$D_M := \Delta_M \cap \bigcup_{N \prec M} \Delta_N = \bigcup_{\sigma \in \mathcal{D}_M} \Delta_\sigma. \tag{6.7}$$

Indeed every earlier intersection lies in a cover supplied by the lemma. Conversely Δ_σ lies in both Δ_M and the earlier $\Delta_{g(\sigma)}$.

Each equality of two distinct block coordinates is a Cartier divisor on the smooth product Δ_M. Consequently D_M is empty or is the support of an effective Cartier divisor. On the affine line its equation is

$$h_M = \prod_{\substack{B<B' \\ g(M/(B\sim B'))\prec M}} (y_B - y_{B'}), \qquad D_M = V(h_M).$$

Blocks are ordered by their least label. The empty product is 1.

The support maps and exact width

Suppose $i : M \hookrightarrow Y$ is a closed embedding of smooth varieties of codimension c, and $A \subset Y$ is closed with $M \not\subset A$. If $D = A \cap M$ is a divisor support or is empty, there is a natural triangle

$$R\Gamma_A \omega_Y \longrightarrow R\Gamma_{A\cup M} \omega_Y \longrightarrow i_+ \omega_M(*D)[-c] \longrightarrow R\Gamma_A \omega_Y[1]. \tag{6.8}$$

Here i_+ is closed direct image with all finite normal derivatives.

To construct it, use the support square

$$\begin{array}{ccc} R\Gamma_D \omega_Y & \longrightarrow & R\Gamma_M \omega_Y \\ \downarrow & & \downarrow \\ R\Gamma_A \omega_Y & \longrightarrow & R\Gamma_{A\cup M} \omega_Y. \end{array}$$

Mayer–Vietoris makes this a homotopy pushout. Smooth purity identifies the upper row with

$$i_+ R\Gamma_D^M \omega_M[-c] \longrightarrow i_+ \omega_M[-c].$$

Its cofiber is $i_+ \omega_M(*D)[-c]$. Equality of the horizontal cofibers gives (6.8), including its connecting map.

The normalization can be checked directly. For ordered normal parameters $u_1, \dots, u_c$, the two-term localization complexes have cohomology only in degree c, with

$$\left[\frac{du_1 \wedge \cdots \wedge du_c \wedge \omega_M}{u_1^{a_1+1} \cdots u_c^{a_c+1}}\right] \longmapsto \frac{\omega_M \otimes \partial_{u_1}^{a_1} \cdots \partial_{u_c}^{a_c}}{a_1! \cdots a_c!}.$$

Right differentiation of densities gives the positive factorials. Normal-coordinate changes transform the density and residue determinant together, so these formulas glue.

The width of a nonzero bounded complex is the difference between its extreme nonzero cohomological degrees.

Theorem 6.3.3. For every $n \geq 2$,

$$\begin{aligned} H^j(Q_n) &= 0 \quad \text{unless } 2 - n \leq j \leq \lfloor n/2 \rfloor + 1 - n, \\ H^{c+1-n}(Q_n) &\neq 0 \quad (1 \leq c \leq \lfloor n/2 \rfloor). \end{aligned}$$

Thus $\operatorname{width}(Q_n) = \lfloor n/2 \rfloor - 1$. The successive support maps in the order (6.6) have cofibers

$$i_{M,+} \omega_{\Delta_M}(*D_M)[-c(M)]$$

before the common shift $[n-1]$.

Proof. Attach the components in their specified order. Each has codimension at most $m = \lfloor n/2 \rfloor$. Equation (6.7) and triangle (6.8) construct the asserted tower. Its factors have cohomology only in degrees between 1 and m. The long exact sequences propagate this bound. Proposition 6.3.1 then gives the vanishing range after the shift.

For each $1 \le c \le m$, the component count in Theorem 2.3.1 supplies a chain M of length c. Choose a geometric point with equality partition exactly M. No other minimal indecomposable partition occurs there. Locally Z_n is therefore this smooth codimension-c diagonal. Its class

$$\left[\frac{\omega_{Y_n}}{u_1 \cdots u_c}\right]$$

is nonzero in the normal Čech quotient.

Faithful extension to a geometric field detects nonzero sheaves over k. Thus every asserted degree occurs. □

The upper sheaf bound also holds for any quasicoherent coefficient over any field. At a codimension-c component, its support has c local equations. Its intersection with the preceding union has those equations and one lifted divisor equation. Their Čech complexes vanish above c and $c + 1$, respectively. The support Mayer–Vietoris sequence therefore propagates vanishing above $\lfloor n/2 \rfloor$. This argument uses no characteristic-zero purity.

Shifts preserve width. Consequently no arity-dependent shifts can put all Q_n into a fixed finite range of cohomological degrees. For $n \ge 4$, even a shifted heart object cannot represent Q_n.

The four-position extension

Take $X = \mathbb{A}^1_k$ and coordinates

$$a = z_1 - z_4, \quad b = z_1 - z_3, \quad c = z_2 - z_4, \quad s = z_4.$$

Then $Z_4 = V(a) \cup V(b, c)$. The ordered attachments first add 14, then 13|24 along its divisor $a = 0$. Put $E_x = k[x, x^{-1}]/k[x]$.

Suppressing the common density and $k[s]$-factor, triangle (6.8) gives

$$H^1_{Z_4} = E_a \otimes k[b, c], \qquad H^2_{Z_4} = k[a, a^{-1}] \otimes E_b \otimes E_c.$$

All other local cohomology vanishes. In particular there is an exact sequence

$$0 \longrightarrow k[a] \otimes E_b \otimes E_c \longrightarrow H^2_{Z_4} \longrightarrow E_a \otimes E_b \otimes E_c \longrightarrow 0.$$

This sequence does not split even as a sequence of ordinary modules. The quotient has a nonzero element killed by a, whereas multiplication by a is invertible on the middle module. A module section cannot preserve that relation. After the shift $[3]$, the cohomology of Q_4 lies in degrees $-2, -1$.

The tower retains its support and connecting maps. Its ordered factors cannot replace the coefficient by a direct sum. The ordering of components is auxiliary. Comparisons of these particular towers under cuts and monotone collisions must additionally preserve their extension maps and recover the operations of the unfiltered coefficient.

6.4 Infinitely many species at fixed energy

For the analytic constructions set $k = \mathbb{C}$ and normalize the level to one. Let H be a real separable Hilbert space. Its complexification $H_{\mathbb{C}}$ has both the Hermitian norm and the complex bilinear extension $(\ ,\ )$ of the real inner product. The bilinear pairing supplies contractions. The Hermitian norm supplies estimates. For $m \geq 1$, let H_m be its copy of energy m, with squared norm $m\|v\|^2$.

Define the Hilbert energy sector and the algebraic energy sum by

$$\mathcal{V}_E = \bigoplus_{\sum m r_m = E} \widehat{\bigotimes}_{m\geq 1} \widehat{\mathrm{Sym}}^{r_m} H_m, \qquad \mathcal{V} = \bigoplus_{E\geq 0} \mathcal{V}_E. \tag{6.9}$$

The symmetric tensors have the Fock normalization: a product of r identical unit creators has squared norm $r!$. Each displayed sum at fixed E has finitely many occupancy patterns. Only the sum over all energies remains algebraic. Denote its Hilbert completion by $\widehat{\mathcal{V}}$.

The creation and annihilation modes satisfy

$$[a_m(v), a_n(w)] = m\delta_{m+n,0}(v,w), \qquad a_0(v) = 0, \qquad a_m(v)\mathbf{1} = 0 \quad (m > 0).$$

They are complex linear in the species vector. For real vectors the paired creation and annihilation operators are adjoint. On finite species tensors set

$$J_v(z) = \sum_m a_m(v) z^{-m-1}, \qquad Y\left(\prod_{j=1}^{p} a_{-m_j}(v_j)\mathbf{1}, z\right) =: \prod_{j=1}^{p} \frac{\partial_z^{m_j-1} J_{v_j}(z)}{(m_j-1)!} : .$$

We next extend each coefficient of this formula.

Lemma 6.4.1. Contract r specified legs of a Hilbert tensor $a \in H_{\mathbb{C}}^{\widehat{\otimes} p}$ against r specified legs of $b \in H_{\mathbb{C}}^{\widehat{\otimes} q}$. The resulting tensor has norm at most $\|a\|\|b\|$. Consequently each mode extends to a bounded bilinear map

$$\mathcal{V}_E \times \mathcal{V}_F \longrightarrow \mathcal{V}_{E+F-n-1}, \qquad (a,b) \longmapsto a_{(n)}b. \tag{6.10}$$

A negative-energy sector is understood to be zero.

Proof. In a real orthonormal basis group the contracted indices together. A coefficient of the contraction has the form $\sum_\gamma a_{\alpha\gamma} b_{\gamma\beta}$. Cauchy–Schwarz gives

$$\sum_{\alpha,\beta} \left| \sum_\gamma a_{\alpha\gamma} b_{\gamma\beta} \right|^2 \leq \left(\sum_{\alpha,\gamma} |a_{\alpha\gamma}|^2 \right) \left(\sum_{\gamma,\beta} |b_{\gamma\beta}|^2 \right).$$

The same inequality applies to the complex bilinear contraction. Symmetrization is an orthogonal projection.

At fixed E, F, n, the Wick formula has finitely many occupancy, pairing and Taylor patterns. Their output energy is $E + F - n - 1$, so no unbounded choice of remaining creation modes occurs. The mode weights and Fock factorials contribute only a finite constant for these fixed indices. Summing the bounds proves the stated extension. □

To linearize a bounded bilinear coefficient, we use the completed *projective* tensor product of its two input sectors. No bounded linear map on their Hilbert tensor product is inferred from bilinear boundedness.

THEOREM 6.4.2. The extended coefficient maps make $\mathcal{V}$ a local vertex algebra. Its vacuum is $\mathbf{1}$, and its translation satisfies

$$T\mathbf{1} = 0, \qquad [T, a_{-m}(v)] = m a_{-m-1}(v).$$

For energies E, F, the locality exponent $E + F$ is independent of a species cutoff.

Proof. Output energy proves lower truncation in (6.10). Translation changes only finitely many occupancy patterns on $\mathcal{V}_E$, and is bounded into $\mathcal{V}_{E+1}$. Its identities and the vacuum identities therefore extend from finite species.

In a Wick contraction the pole order of a pair of derivative currents is the sum of their energies. Thus $E + F$ bounds the total pole order before taking any species limit. Clear these poles and apply locality to a third fixed-energy state. Each coefficient is a finite sum of bounded compositions of mode maps. It vanishes on finite species and hence on their dense completion. The mode Jacobi identities extend in the same way: the energy bound makes each of their fixed-index sums finite, uniformly in the approximants. □

There is a precise restriction in this argument. Contraction between two tensors is bounded. Contraction of two legs of one arbitrary Hilbert tensor need not be. For an orthogonal projection P_N of rank N, its tensor norm is $\sqrt{N}$, while its trace is N. Vacuum normal ordering has removed such internal contractions from the fixed-coordinate definition. They will return under general coordinate changes.

Quadratic fields and all their poles

For a real symmetric Hilbert–Schmidt operator A on H, define

$$q_A = \sum_{i,j} (e_i, Ae_j)\, a_{-1}(e_i) a_{-1}(e_j)\mathbf{1}, \qquad W_A(z) = Y(q_A, z).$$

The Hilbert–Schmidt norm is $\|A\|_2^2 = \sum_{i,j} |(e_i, Ae_j)|^2$.

PROPOSITION 6.4.3. The state $q_A \in \mathcal{V}_2$ is independent of the real orthonormal basis and satisfies

$$\|q_A\|^2 = 2\|A\|_2^2.$$

Conversely, for bounded symmetric A, convergence of $q_{P_N A P_N}$ for finite-rank orthogonal $P_N \to 1$ strongly implies that A is Hilbert–Schmidt.

Proof. The two pairings of two creation factors give the norm formula in finite rank. The intrinsic identification of symmetric Hilbert–Schmidt operators with symmetric Hilbert tensors then extends it and proves basis independence. For the converse the norm formula makes the compressions Cauchy in Hilbert–Schmidt norm. Their limit agrees with A in every matrix element, by strong convergence of P_N. □

For symmetric A, B, set

$$S_{AB} = \tfrac{1}{2}(AB + BA), \qquad D_{AB}(w) = \sum_{i,j} (e_i, ABe_j) : \partial J_{e_i}(w) J_{e_j}(w) : .$$

The product AB is trace class, hence Hilbert–Schmidt, so the latter is the field of an energy-three state.

Theorem 6.4.4. The full singular quadratic product is

$$W_A(z)W_B(w) \sim \frac{2\operatorname{Tr}(AB)}{(z-w)^4} + \frac{4W_{S_{AB}}(w)}{(z-w)^2} + \frac{4D_{AB}(w)}{z-w}. \tag{6.11}$$

Its coefficients converge in their Hilbert energy sectors under Hilbert–Schmidt approximation.

Proof. The two double contractions give the fourth-order pole. The four single contractions give

$$\frac{4}{(z-w)^2}\sum_{i,j}(e_i, ABe_j) : J_{e_i}(z)J_{e_j}(w) : .$$

Its constant Taylor term is $4W_{S_{AB}}$, since the equal-position creation factors are symmetric. Its linear term is $4D_{AB}$. All remaining Taylor terms are regular. The inequality $\|AB\|_1 \le \|A\|_2\|B\|_2$ controls both the trace and the coefficient tensors, and passes the finite-species calculation to the limit. □

The simple pole retains the order of the two operators. Indeed

$$D_{AB} + D_{BA} = \partial W_{S_{AB}}, \qquad 4D_{AB} = 2\partial W_{S_{AB}} + 2(D_{AB} - D_{BA}).$$

For $A = \operatorname{diag}(1, 0)$ and $B = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, the last term is

$$2(: \partial J_1 J_2 : - : \partial J_2 J_1 :).$$

Its two state components have modes $(-2, -1)$, are orthogonal and each have squared norm two. The total squared norm is sixteen. The Jordan product alone would miss this nonzero field.

For orthogonal rank-one projections P_1, P_2, the outer contraction in $W_{P_1}(z_1)W_{P_2}(z_2)W_{P_1}(z_3)$ is

$$\frac{2W_{P_2}(z_2)}{(z_1 - z_3)^4}.$$

All contractions meeting the middle species vanish. The normal test $(z_1 - z_3)^3$ therefore gives the nonzero residue $2W_{P_2}$, with squared state norm eight. Its scalar vacuum expectation is zero. This is the quadratic version of the supported operation lost by scalar evaluation.

On the specified affine coordinate, the right module $\mathcal{M} = \omega_X \otimes \mathcal{V}$ has derivative $-\partial_z - T$. Its local chiral operation is

$$j_* j^*(\mathcal{M} \boxtimes \mathcal{M}) \longrightarrow \Delta_! \mathcal{M}, \qquad f(u, z)(a \boxtimes b) \longmapsto \operatorname{pp}_u(f(u, z)Y(a, u)b).$$

Here the external tensor is algebraic when $\mathcal{V}$ is regarded as a vector space. Fixed-energy continuous coefficients linearize on projective external tensors.

Lower truncation makes every displayed normal sum finite. Translation proves differential linearity. Skew symmetry and Jacobi prove the chiral identities in the full normal module. This construction uses its stated auxiliary curve. It does not identify that curve with the support of an arithmetic random field.

The center and the energy grading

The ordinary vertex center consists of states whose field has no singular product with any state. Skew symmetry gives the equivalent condition that every nonnegative mode of every state annihilates the central state.

PROPOSITION 6.4.5. The ordinary vertex center of $\mathcal{V}$ is $\mathbb{C}\mathbf{1}$.

Proof. A central state is killed by every positive current mode $a_m(h)$. At fixed occupancy, these modes contract each occupied leg against h. The nondegenerate Hilbert pairing makes a tensor with all such contractions zero equal to zero. Different occupancy patterns remain distinguishable after the contracted mode is fixed. All positive-energy components therefore vanish. The vacuum is central. □

PROPOSITION 6.4.6. For a finite-rank orthogonal projection P, $L_P = \frac{1}{2}W_P$ satisfies the Virasoro operator product with central charge rank P. If H is infinite dimensional, no state of $\mathcal{V}$ is a conformal vector implementing its energy grading.

Proof. Since $P^2 = P$, (6.11) becomes

$$L_P(z)L_P(w) \sim \frac{\operatorname{rank}(P)/2}{(z-w)^4} + \frac{2L_P(w)}{(z-w)^2} + \frac{\partial L_P(w)}{z-w}.$$

Its grading concerns the projected species. The state has squared norm $\operatorname{rank}(P)/2$.

A conformal vector ω implementing the given energy must have energy two, because $L_0\omega = 2\omega$. Every vector there is $q_A + a_{-2}(v)\mathbf{1}$, for a complex symmetric Hilbert–Schmidt tensor A. Its mode (1) acts on the energy-one species space by $2A$. The improvement field ∂J_v contributes $-a_0(v) = 0$ to that mode. The required identity action would force $2A = 1_H$, which is not Hilbert–Schmidt in infinite dimension. □

Thus vacuum and translation survive without an energy-grading conformal state. The scalar ordinary center just computed also leaves the derived center and its geometric actions as separate objects of comparison.

A prime-labeled current cover

For each prime p, take two orthogonal level-one currents $a^{(p)}, b^{(p)}$. Their rank-two vertex algebra $\mathcal{H}^{(p)}$ has conformal state

$$\omega_p = \frac{1}{2}\Big((a^{(p)}_{-1})^2 + (b^{(p)}_{-1})^2\Big)\mathbf{1}_p.$$

The preceding calculation gives central charge two and integer oscillator grading $L_0^{(p)}$. For finite sets of primes S, the maps

$$\bigotimes_{p\in S} \mathcal{H}^{(p)} \longrightarrow \bigotimes_{p\in S'} \mathcal{H}^{(p)}, \qquad S \subset S',$$

insert the vacuum in each new factor. They preserve all field products and translation. Their filtered union defines the algebraic vacuum-restricted product

$$\mathcal{H}_{\mathbb{P}} = \bigotimes_{p}{}' \mathcal{H}^{(p)}.$$

Every state uses finitely many primes. For a finite set S, its conformal state is $\sum_{p\in S}\omega_p$, of central charge $2|S|$. The infinite sum is not a state of $\mathcal{H}_{\mathbb{P}}$.

There is also the logarithmically weighted operator

$$H_{\mathrm{ar}} = \sum_{p} (\log p) L_{\mathrm{o}}^{(p)}$$

on this algebraic product. Each state makes this sum finite. It assigns energy $m \log p$ to a mode-m creator at p. Its weights differ from the oscillator grading. Rescaling ω_p does not preserve its Virasoro normalization.

With species space $H = \ell^2(\mathbb{P}; \mathbb{R}^2)$, the algebraic product is dense in each Hilbert energy sector constructed above. An extension of H_{ar} to a closed Hilbert operator requires its own domain. A supported map from this current cover to independently defined arithmetic coefficients is further data.

6.5 Coordinate changes and coefficient norms

A coordinate change replaces the kernel subtracted in a normally ordered field. For a quadratic field this replacement contracts its two coefficient indices. The resulting trace determines whether the change acts on the chosen completion. Assume throughout this and the following sections that H is infinite dimensional.

Let f be a locally invertible holomorphic germ. The difference of the two current kernels is

$$H_f(z,u) = \frac{f'(z)f'(u)}{(f(z)-f(u))^2} - \frac{1}{(z-u)^2}.$$

It is regular along the diagonal. The Taylor expansion of $f(u+s)$ through order three gives

$$H_f(z,z) = \tfrac{1}{6}\{f,z\}, \qquad \{f,z\} = \frac{f'''(z)}{f'(z)} - \frac{3}{2}\left(\frac{f''(z)}{f'(z)}\right)^2.$$

Inserting the intermediate kernel under a second coordinate change gives the exact cocycle

$$H_{f\circ g}(z,u) = H_g(z,u) + g'(z)g'(u)H_f(g(z),g(u)). \tag{6.12}$$

Consequently a finite-rank quadratic coefficient has the transformation law

$$W_A^{(z)}(z) = f'(z)^2 W_A^{(w)}(f(z)) + \tfrac{1}{6}\operatorname{Tr}(A)\{f,z\}\mathbf{1}, \qquad w = f(z). \tag{6.13}$$

The sign follows by subtracting the old vacuum kernel from the pullback of the new one.

For a germ fixing zero, put

$$B_f(m,n) = [z^{m-1}u^{n-1}]H_f(z,u), \qquad m,n \geq 1.$$

The coordinate map on a finite-species state sums over its internal pairings. A paired pair of legs in modes m,n contributes its species pairing times $B_f(m,n)$. The unpaired legs undergo the finite triangular mode substitution defined below.

Theorem 6.5.1. If some $B_f(m,n) \neq 0$, this coordinate map on finite species is not closable in the Hilbert energy spaces of (6.9). Precisely the fractional-linear germs fixing zero act continuously on every bounded-energy space with the specified current and vacuum.

Proof. For an orthonormal sequence (e_i), consider

$$u_N^{mn} = \frac{1}{N}\sum_{i=1}^{N} a_{-m}(e_i)a_{-n}(e_i)\mathbf{1}.$$

Its squared norm is $2m^2/N$ if $m = n$ and mn/N otherwise. Thus $u_N^{mn} \to 0$. Its uncontracted coordinate image also tends to zero, because only finitely many bounded mode substitutions occur. Its contracted image is the fixed scalar $B_f(m,n)\mathbf{1}$. The closure of the graph therefore contains a nonzero vector over zero.

All coefficients $B_f(m,n)$ vanish exactly when H_f vanishes as a germ. In that case $\{f,z\} = 0$. Put $v = f''/f'$. Its equation is $v' = v^2/2$. Integration gives a fractional-linear function, including the affine case.

Conversely direct substitution of $f(z) = (az+b)/(cz+d)$, $ad - bc \neq 0$, gives $H_f = 0$. Its coordinate map and inverse then consist only of bounded mode substitutions on every finite set of energy sectors. □

The germ $f(z) = z + z^4$ has $B_f(1,1) = 0$ but $B_f(1,2) = 2$. Testing only the Schwarzian at the marked point therefore misses an obstruction at higher energy. Restricting to traceless finite-rank quadratics also fails to give a field algebra: for $A = \operatorname{diag}(1,-1)$, the quadratic product contains A^2, whose trace is two.

Projective tensors and all coordinate jets

For a finite tensor define its projective norm by

$$\|u\|_\pi = \inf_{u=\sum_\alpha v_{\alpha,1}\otimes\cdots\otimes v_{\alpha,p}} \sum_\alpha \prod_j \|v_{\alpha,j}\|.$$

Write $\widehat{\otimes}_\pi$ for the completion and $\widehat{\operatorname{Sym}}_\pi^{r}$ for the image of its continuous symmetrizing projection. Use the same Fock factorial weights as before and set

$$\mathcal{V}_E^\pi = \bigoplus_{\sum m r_m = E} \widehat{\bigotimes}_{\pi,m\geq 1} \widehat{\operatorname{Sym}}_\pi^{r_m} H_m, \qquad \mathcal{V}^\pi = \bigoplus_E \mathcal{V}_E^\pi.$$

Use the sum norm at each energy and the locally convex direct-sum topology over energies.

PROPOSITION 6.5.2. Every internal and cross contraction is bounded on the corresponding projective tensor sectors. The canonical map $\mathcal{V}_E^\pi \to \mathcal{V}_E$ is injective with dense image. For real symmetric quadratic coefficients,

$$\|q_A\|_\pi = \sqrt{2}\|A\|_1,$$

so this sector consists of symmetric trace-class operators. The field operations, vacuum and translation make $\mathcal{V}^\pi$ a local vertex algebra, and its map to $\mathcal{V}$ is a vertex homomorphism.

Proof. On a simple tensor, contraction multiplies the remaining factors by a pairing bounded by the two removed norms. Taking the infimum over decompositions proves the bound. Iterate it for a matching.

Finite species projections converge to the identity in projective norm, first on simple tensors and then by density and their uniform bound. If a projective tensor maps to zero in the Hilbert tensor product, each finite species projection is zero. Its projective limit is therefore zero. Finite species tensors also prove density of the image.

A real symmetric spectral decomposition gives the upper trace-norm bound. Pairing with the bounded sign operator gives the reverse bound. The Fock factor is $\sqrt{2}$. Each field coefficient at fixed energies has finitely many bounded Wick patterns. The finite-species identities extend by density, with the uniform locality exponent already proved. The two completions agree on their common finite-species subspace, so their inclusion preserves the coefficients. □

The unpaired mode substitution for a germ $f(0) = 0, f'(0) \neq 0$, is

$$T_f(m, j) = [z^{m-1}]f'(z)f(z)^{j-1} = \frac{m}{j}[z^m]f(z)^j, \qquad 1 \le j \le m.$$

The pair coefficient also has the expression

$$B_f(m, n) = mn[z^m u^n] \log \frac{f(z) - f(u)}{z - u}.$$

Indeed two derivatives of the logarithm give H_f. Its constant is immaterial.

Write $x_m(v) = a_{-m}(v)\mathbf{1}$. Define $R_f\mathbf{1} = \mathbf{1}$.

For a creation monomial sum over all partial matchings of its legs. An unpaired $x_m(v)$ contributes $\sum_{j\le m} T_f(m, j)x_j(v)$. A pair $x_m(v), x_n(w)$ contributes $(v, w)B_f(m, n)$. Multiply within each matching and sum. Energy at most E uses only the $(E + 1)$-jet of f.

Theorem 6.5.3. These formulas define bounded maps on every bounded-energy part of $\mathcal{V}^\pi$, with

$$R_f R_g = R_{f\circ g}, \qquad R_f^{-1} = R_{f^{-1}}.$$

For the recentered germ $f_z(u) = f(z + u) - f(z)$, they obey

$$R_f Y(a, z) R_f^{-1} = Y(R_{f_z} a, f(z)), \tag{6.14}$$

$$\partial_z R_{f_z} + f'(z) T R_{f_z} = R_{f_z} T. \tag{6.15}$$

The identities are coefficientwise in the coordinate variable.

Proof. Every matching is bounded by Proposition 6.5.2. Unpaired jets compose by the chain rule. In an iterated matching a pair is either formed at the first change or formed after that change. The kernel cocycle (6.12) adds these two contributions to the one-step pair. Partitioning matchings in this way proves composition at every tensor degree. The identity and inverse germs give the remaining group identities.

In finite species, the current transforms as a one-form. Wick expansion of a composite field adds exactly the difference of its normal-ordering kernels. This is the same matching rule, so it proves (6.14). Continuity at fixed coefficients extends it to projective tensors.

Applying it to the vacuum gives $R_f e^{zT} = e^{f(z)T} R_{f_z}$. Differentiation proves (6.15). These formal identities require no analytic exponential on the algebraic energy sum. □

For $n \ge -1$, the infinitesimal operators on finite species are

$$L_n = \sum_{m>\max(n,0),i} m x_{m-n,i}\partial_{x_{m,i}} + \frac{1}{2}\sum_{\substack{r+s=n\\ r,s\ge 1},i} rs\,\partial_{x_{r,i}}\partial_{x_{s,i}}.$$

Here $x_{m,i} = x_m(e_i)$. The sums on each bounded-energy sector are continuous by the contraction bounds. Direct commutation gives $[L_m, L_n] = (m-n)L_{m+n}$, with zero bracket when $m = n = -1$.

The only possible central cases have $m + n = 0$ and $m \in \{-1, 0, 1\}$, whose central coefficient vanishes. Thus this is the indicated part of the Witt action.

In particular

$$L_{-1} = T, \qquad L_0|_{\mathcal{V}_E^\pi} = E, \qquad L_2 q_A = \operatorname{Tr}(A)\mathbf{1}.$$

The operators L_{-1}, L_0, L_1 have no internal contractions and also act on the Hilbert sectors. Their existence does not require a state whose field implements the full action.

Descent to a curve

On a smooth complex analytic curve, use holomorphic sections which locally take values in a finite sum of the Banach sectors $\mathcal{V}_E^\pi$. For $w = f(z)$, glue their components by

$$s_w(f(z)) = R_{f_z} s_z(z).$$

The finite jet matrices are holomorphic in the root and locally bounded at each energy. Their composition law proves the overlap cocycle. Equation (6.15) glues $\nabla = d + T\,dz$. This connection raises the local energy bound by one and is flat on the curve.

Use completed projective external tensors, finite pole orders and finite normal derivatives for the local chiral operation. Its chart formula is the principal part of $h(u,z)Y(a,u)b$. Tensoring the left module with ω_X gives the right differential module. A normal class is still $\partial\,\partial_u^r/r!$. Covariance transports the expansion, density and all normal jets together. Translation and Jacobi therefore glue the analytic topological chiral operation.

There is a separate algebraic version on a smooth algebraic curve over $\mathbb{C}$. Regard $\mathcal{V}^\pi$ as a vector space and use algebraic external tensors. On a state of energy at most E, every word in positive L_n's with total index greater than E vanishes. The finitely many remaining words and the energy projections span a finite-dimensional stable subspace. Its coordinate action is algebraic and factors through a finite jet group.

Associate these subspaces to the formal-coordinate torsor and take their filtered union. The same identities descend its connection and finite principal-parts operation. The two versions use different external tensors.

One may instead keep the Hilbert sectors and choose a projective atlas, whose transitions are fractional linear. Their internal pair coefficients vanish, so the same descent works with the bounded Hilbert coefficient maps and projective external tensors. The projective atlas is part of this choice. On $\mathbb{P}^1$, inversion has the recentered germ

$$\frac{1}{p+u} - \frac{1}{p} = -\frac{u}{p(p+u)}, \qquad p \neq 0,$$

which is fractional linear. An affine uniformizing atlas of an elliptic curve gives another example. On a fixed such atlas, $\mathcal{V}^\pi \to \mathcal{V}$ is dense, injective and compatible with the operations, but is not a topological equivalence in infinite species.

Finally let P be a projective connection, with components $P_z = f'(z)^2 P_w(f(z)) + \{f, z\}$. For symmetric trace-class A, (6.13) shows that

$$\left(W_A^{(z)}(z) - \frac{\operatorname{Tr}(A)}{6} P_z(z)\mathbf{1}\right)(dz)^2$$

is coordinate independent. Changing P changes this field by the corresponding scalar quadratic differential. For a positive non-trace-class A, this subtraction has no value in the stated coefficient domain. It requires a trace, an operation stronger than the cross contractions which defined W_A.

6.6 A completion retaining the contractions

The sequence $q_{P_N/N}$ had Hilbert limit zero and trace one. To retain both limits, complete the finite-species states in the norm of their state tensor together with all their internal contractions. The new limit will be a central state, distinct from zero and from the vacuum.

Introduce symmetric variables

$$c_{mn} = c_{nm}, \qquad \deg c_{mn} = m + n, \qquad \Gamma = \mathbb{C}[c_{mn} : 1 \le m \le n].$$

Each homogeneous part Γ_d is finite dimensional. Define

$$\mathcal{W}_E = \bigoplus_{d=0}^{E} \mathcal{V}_{E-d} \otimes \Gamma_d, \qquad \mathcal{W} = \bigoplus_{E \ge 0} \mathcal{W}_E.$$

Give central monomials an orthonormal basis and use the finite Hilbert sum at each energy. Any choice of norms on these finite-dimensional central factors gives the same topology.

On finite-species oscillator polynomials put

$$\Delta_c = \frac{1}{2} \sum_{m,n \ge 1} c_{mn} \sum_i \partial_{x_m(e_i)} \partial_{x_n(e_i)}, \qquad \sigma = e^{\Delta_c}, \qquad j(a) = \sigma a.$$

The exponential terminates on each polynomial. Every derivative pair contracts two species legs by their intrinsic pairing, so the definition is independent of the orthonormal basis. The norm $\|j(a)\|_{\mathcal{W}_E}$ is the norm of all its contraction coefficients. Its constant coefficient in c is a, so it is indeed a norm.

The completed field operations

Define the central translation by

$$D_\Gamma c_{mn} = m c_{m+1,n} + n c_{m,n+1}.$$

The translation of $\mathcal{W}$ is $\mathsf{T} = T_x + D_\Gamma$, where $T_x x_m(v) = m x_{m+1}(v)$. For two modes set

$$P_m(z; v) = \sum_{r \ge 0} \binom{m + r - 1}{r} x_{m+r}(v) z^r,$$

$$\kappa_{mn}(z) = \frac{(-1)^{m-1}(m + n - 1)!}{(m - 1)!(n - 1)!} z^{-m-n},$$

$$G_{mn}(z) = \sum_{r \ge 0} \binom{m + r - 1}{r} c_{m+r,n} z^r.$$

The scalar κ_{mn} is the level-one contraction already computed. The new term G_{mn} retains its regular contraction data.

Define $Y_{\mathcal{W}}(a, z)b$ by matchings between the oscillator legs of its two polynomial inputs. A pair of modes m, n and species v, w contributes

$$(v, w)\big(\kappa_{mn}(z) + G_{mn}(z)\big). \tag{6.16}$$

An unpaired left leg contributes $P_m(z;v)$. An unpaired right leg stays at the root.

Translate the left central coefficient by e^{zD_Γ} and multiply it by the right one. The product of these terms, summed over partial matchings, is the field. Only contractions between separate Hilbert tensors occur in this rule.

PROPOSITION 6.6.1. The coefficient maps make $\mathcal{W}$ a local vertex algebra with vacuum 1 and translation T. Its fixed-energy mode maps are bounded bilinear, with locality exponent $E+F$ on input energies E, F. Both the finite-species map j and the projection

$$\pi : \mathcal{W} \longrightarrow \mathcal{V}, \qquad c_{mn} \longmapsto 0,$$

are vertex homomorphisms on their stated domains.

Proof. On finite species start with the tensor product of the Heisenberg vertex algebra and the commutative differential algebra (Γ, D_Γ). Its field on central coefficients is $(e^{zD_\Gamma}\gamma)\gamma'$. Conjugate its field operation by σ, whose polynomial inverse is $e^{-\Delta_c}$. The commutator $[T_x, \partial_{x_m}] = -(m-1)\partial_{x_{m-1}}$ shows, after reindexing, that $[T_x, \Delta_c] = -[D_\Gamma, \Delta_c]$. Thus σ commutes with T.

In the conjugated product, the internal contractions of σ^{-1} on each input cancel those of σ on that same input inside the output. The remaining pairs connect the two inputs. A translated left leg gives the new term G_{mn}, and the old singular pair gives κ_{mn}. This proves precisely (6.16).

At fixed energies and output coefficient, there are finitely many pairings, Taylor terms and central monomials. The cross contraction bound proves their continuity. The singular order is at most $E+F$, independently of species rank. The finite-species identities therefore extend by density as in Theorem 6.4.2. Conjugation proves the assertion about j. Evaluation at $c=0$ proves the assertion about π. □

THEOREM 6.6.2. The energywise completion of the finite-species states in the norm $a \mapsto \|j(a)\|_{\mathcal{W}_E}$ is exactly $\mathcal{W}$. The projection π is surjective and has the bounded linear section $v \mapsto v \otimes 1$, which is not a vertex homomorphism. The map j extends to a continuous, dense, proper vertex embedding $\mathcal{V}^\pi \hookrightarrow \mathcal{W}$.

Proof. For the states u_N^{mn} used in the coordinate obstruction,

$$j(u_N^{mn}) = u_N^{mn} + c_{mn}, \qquad \|u_N^{mn}\|^2 = \begin{cases} 2m^2/N, & m = n, \\ mn/N, & m \neq n. \end{cases}$$

Their limits put every c_{mn} in the closure of the image of j. That closure is stable under the continuous field coefficients. On central states the (-1)-product is polynomial multiplication, so it contains all central monomials.

For an oscillator polynomial a, the difference $j(a) - a$ is a sum of central monomials times polynomials with fewer oscillator legs. Induction on the number of legs therefore puts a, and then every ac^ν, in the closure. Such polynomials are dense in every finite Hilbert sum $\mathcal{W}_E$. This proves the completion assertion.

The linear section is not a vertex map. For a unit species, the completed current (-1)-product is $x_1^2 + c_{11}$. The section sends its old product to x_1^2, omitting the regular contraction.

Every internal contraction is bounded on projective tensors, so j extends continuously to $\mathcal{V}^\pi$. Its composite with π is the injective projective-to-Hilbert map. It is therefore injective. It has dense image because it contains the finite-species image of j. Its composite with π is injective, so the image contains no nonzero c_{mn}. The image is therefore proper. □

In the quadratic mode-one sector, this embedding is the dense graph

$$\mathcal{S}_1^{\mathrm{sym}}(H) \longrightarrow \mathcal{S}_2^{\mathrm{sym}}(H) \oplus \mathbb{C}c_{11}, \qquad A \longmapsto (A, \operatorname{Tr} A).$$

Here $\mathcal{S}_p$ denotes the Schatten class with summable p-th powers of singular values. The completion has an independent second coordinate. It has not defined a trace on every old Hilbert–Schmidt operator.

The central algebra and ordinary actions

THEOREM 6.6.3. The ordinary vertex center of $\mathcal{W}$ is Γ. With its translation it is the free commutative differential algebra on one generator of each positive even energy:

$$\Gamma = \mathbb{C}[D_\Gamma^r \chi_k : k \geq 1,\ r \geq 0], \qquad \chi_k = c_{kk}, \qquad \deg \chi_k = 2k. \tag{6.17}$$

Here a differential algebra means an algebra with a derivation. D_Γ is not a square-zero differential.

Proof. The regular term G_{mn} does not change the positive current modes. They remain $a_n(v) = n\partial_{x_n(v)}$, $n > 0$. Their common kernel on Hilbert oscillator tensors is the vacuum. Since the central monomial basis at each energy is finite, the same argument coefficient by coefficient puts every central state in Γ. Conversely its elements are central in the transported finite-species algebra. Continuity extends centrality to all of $\mathcal{W}$.

Identify the linear span of the c_{mn} with $\mathbb{C}[u, v]^{\mathfrak{S}_2}$ by

$$c_{mn} \longmapsto \frac{u^{m-1}v^{n-1} + u^{n-1}v^{m-1}}{2(m-1)!(n-1)!}.$$

Under this map D_Γ is multiplication by $u + v$. The symmetric polynomial ring $\mathbb{C}[u + v, uv]$ is free over $\mathbb{C}[u + v]$ on the powers of uv. Up to nonzero factorials, these are the images of c_{kk}. Taking the symmetric algebra proves both generation and algebraic independence in (6.17). □

For instance,

$$c_{12} = \tfrac{1}{2} D_\Gamma c_{11}, \qquad c_{13} = \tfrac{1}{4}(D_\Gamma^2 c_{11} - 2c_{22}).$$

The additional even-energy generators are needed to recover all two-mode contractions.

Let $B = \bigoplus_{r \geq 0} B_r$ be a commutative energy-graded algebra with Banach sectors, bounded multiplication and a bounded degree-one derivation D_B. Give it the commutative vertex operation $Y_B(b, z)b' = (e^{zD_B} b)b'$. In $B \otimes \mathcal{W}$, complete each external sector projectively and retain the algebraic energy sum. An ordinary action is an energy-preserving unital vertex homomorphism $\rho : B \otimes \mathcal{W} \to \mathcal{W}$, bounded on each sector and satisfying $\rho(1 \otimes w) = w$.

PROPOSITION 6.6.4. These actions are naturally in bijection with bounded graded algebra maps $\phi : B \to \Gamma$ commuting with the two derivations. The corresponding action is

$$\rho(b \otimes w) = \phi(b)_{(-1)} w.$$

Proof. The two tensor factors have no singular cross products. Since ρ fixes $\mathcal{W}$, its value on $b \otimes 1$ is central and hence lies in Γ. Preservation of (-1)-products and translation gives the stated algebra map. Conversely central multiplication gives the displayed bounded vertex homomorphism. The identity $b \otimes w = (b \otimes 1)_{(-1)}(1 \otimes w)$ proves uniqueness. Both constructions commute with maps of B. □

This universal property fixes ordinary continuous vertex actions and their coefficient topology. A derived center also requires its action spaces and higher comparisons. A factorizing transverse actor additionally requires the specified coactions and collision maps. Neither object is defined by this ordinary-action property alone.

Coordinates on the completed space

Use the coordinate coefficients $T_f(m, j)$ and $B_f(m, n)$ already defined. On the polynomial coordinates of $\mathcal{W}$, set

$$R_f x_m(v) = \sum_{j \le m} T_f(m, j) x_j(v),$$
$$R_f c_{mn} = \sum_{j \le m,\, k \le n} T_f(m, j) T_f(n, k) c_{jk} + B_f(m, n). \tag{6.18}$$

Extend by ordinary polynomial substitution. At every energy bound, this uses only finite-dimensional central maps and finitely many bounded Hilbert mode maps.

THEOREM 6.6.5. These substitutions extend continuously to $\mathcal{W}$, preserve bounded energy, and satisfy

$$R_f j = j R_f^{\mathrm{fin}}, \qquad R_f R_g = R_{f \circ g}, \qquad R_f^{-1} = R_{f^{-1}}.$$

Here R_f^{fin} is the finite-species matching formula. They also satisfy

$$R_f Y_{\mathcal{W}}(a, z) R_f^{-1} = Y_{\mathcal{W}}(R_{f_z} a, f(z)),$$
$$\partial_z R_{f_z} + f'(z) \mathsf{T} R_{f_z} = R_{f_z} \mathsf{T}.$$

Thus locally bounded-energy holomorphic sections glue on a smooth complex curve, with connection $d + \mathsf{T}\, dz$ and their continuous field coefficients.

Proof. Expand $j(a)$ into its self-pair matchings. For each pair, (6.18) chooses either the transported central coefficient or the scalar change in the vacuum kernel. Summing these choices is exactly the finite-species coordinate matching followed by j. This proves the first identity. The kernel and unpaired-jet cocycles prove composition, and the inverse germ proves inversion.

The field identity holds on the dense finite-species image by its established covariance. All coefficients are bounded at fixed energies, so it holds on $\mathcal{W}$. Applying it to the vacuum and differentiating gives the connection identity. Holomorphic dependence of the finite jets, their composition law and that identity glue the claimed sections and flat connection. □

For the generating series $C(z, u) = \sum_{m,n \ge 1} c_{mn} z^{m-1} u^{n-1}$, the central law reads

$$R_f C(z, u) = f'(z) f'(u) C(f(z), f(u)) + H_f(z, u). \tag{6.19}$$

In particular

$$R_f c_{11} = f'(0)^2 c_{11} + \tfrac{1}{6}\{f, 0\}, \qquad L_2 c_{11} = 1.$$

The infinitesimal operators for $n \ge -1$ are derivations of these polynomial coordinates:

$$L_n x_m(v) = \mathbf{1}_{m>n}\, m x_{m-n}(v),$$
$$L_n c_{pq} = \mathbf{1}_{p>n}\, p c_{p-n,q} + \mathbf{1}_{q>n}\, q c_{p,q-n} + pq\, \mathbf{1}_{p+q=n}.$$

Excluded terms are omitted. For $n = -1$ this is T. Differentiating the coordinate law gives the same positive-half Witt brackets.

Proposition 6.6.6. The old Fock form has a unique continuous extension along j, namely

$$\langle a, b\rangle_{0} = \langle \pi a, \pi b\rangle_{\mathrm{Fock}}.$$

Its radical is $\ker \pi$, which is not preserved by all coordinate changes. No conformal vector in $\mathcal{W}$ implements the displayed operator L_{2}.

Proof. The form agrees with the old one on $j(\mathcal{V}_{\mathrm{fin}})$. Density proves uniqueness on bounded-energy sectors. Its radical is the vertex ideal generated by the positive-degree central variables. But $L_{2}c_{\mathrm{II}} = 1$ sends one such variable to the vacuum. Every singular mode of every field annihilates a central state. A conformal vector implementing L_{2} would therefore give $L_{2}c_{\mathrm{II}} = 0$, a contradiction. □

In particular no positive-definite Hilbert form on this completion extends that specified vacuum form. A separately chosen state with different values on Γ is a different question.

A chosen bidifferential and its quotients

Choose a symmetric local bidifferential

$$\mathcal{B}(s,t) = \big((s-t)^{-2} + b(s,t)\big)\,ds\,dt,$$

with b regular near the diagonal. Its divided jets at the moving root p are

$$b_{mn}(p) = \frac{\partial_{s}^{m-1}\partial_{t}^{n-1}b(s,t)}{(m-1)!(n-1)!}\bigg|_{s=t=p}.$$

Take formal sections $\mathcal{W}_{E}[[p]]$, or holomorphic sections locally in finitely many energy sectors. Scalar functions carry the commutative vertex operation with translation ∂_{p}.

Proposition 6.6.7. The relations $c_{mn} = b_{mn}(p)$ generate a vertex ideal stable under $\mathsf{T} + \partial_{p}$. The quotient has the coefficient space of locally bounded-energy $\mathcal{V}$-valued sections, with the regular contractions G_{mn} evaluated at these jets. The quotients glue wherever $\mathcal{B}$ glues.

Proof. Differentiating both variables at the root gives

$$\partial_{p} b_{mn} = m b_{m+1,n} + n b_{m,n+1}.$$

Translation therefore takes each relation to a sum of such relations. Their coefficients are central, so the ideal is a vertex ideal. Evaluation in the finite central polynomial at each energy gives the quotient. Its kernel is this ideal: subtract the evaluated value of a monomial one factor at a time. The transformation law of the regular part of $\mathcal{B}$ is (6.19), which proves compatibility on overlaps. □

On $\mathbb{P}^{1}$, the bidifferential $ds\,dt/(s-t)^{2}$ has $b = 0$ in projective coordinates and recovers the Hilbert construction with that atlas. A choice on another curve is additional geometric data.

Two choices b, b' need not have a continuous current-preserving comparison on the unchanged Hilbert sectors. Such a comparison must send a finite-rank quadratic state by

$$q_{A} \longmapsto q_{A} + \mathrm{Tr}(A)(b'_{\mathrm{II}} - b_{\mathrm{II}}),$$

as follows by comparing the current (-1)-products. At a root where the jet difference is nonzero, the sequence $q_{P_{N}/N}$ proves nonclosability. Higher mode pairs test the other jet differences.

Both quotient families exist. Their specified comparison requires a stronger tensor domain. On $\mathcal{V}^{\pi}$, all the needed contractions are bounded and the comparison does extend.

6.7 GAUSSIAN PREPARATIONS AND THEIR OBSERVABLES

A vacuum specifies the field algebra. A preparation instead specifies a normalized vector and the observables on which its expectations exist. We construct such vectors in the first oscillator of $\widehat{\mathcal{V}}$, and then compute their scalar field matrix elements.

The first oscillator and Gaussian multiplication

Choose independent standard real Gaussians (ξ_i) in a real orthonormal basis (e_i) of H. The L^2 sum $\xi(h) = \sum_i (h, e_i)\xi_i$ has covariance $\mathbb{E}[\xi(h)\xi(k)] = (h, k)$. Let $\mathcal{F}_\xi$ be the completed sigma field they generate. For a symmetric tensor a of order p, define its multiple Gaussian integral $I_p(a)$ by polarization and the generating identity

$$e^{t\xi(h) - t^2\|h\|^2/2} = \sum_{p \geq 0} \frac{t^p}{p!} I_p(h^{\otimes p}).$$

Multiplying two such exponentials and taking their expectation gives

$$\mathbb{E}[I_p(a) I_q(b)] = \delta_{pq}\, p! \langle a, b \rangle. \tag{6.20}$$

This identity extends I_p to the symmetric Hilbert tensor power. Complex linear extension gives the corresponding complex L^2 space.

Write $a \widetilde{\otimes}_r b$ for contraction of r legs followed by symmetrization. Comparing coefficients in the same exponential identity gives

$$I_p(a) I_q(b) = \sum_{r=0}^{\min(p,q)} r! \binom{p}{r} \binom{q}{r} I_{p+q-2r}(a \widetilde{\otimes}_r b). \tag{6.21}$$

The coefficient chooses r legs on each side and a bijection between them. For finite tensors this proves the formula directly.

Under Hilbert tensor approximation, its right side converges in L^2, by Lemma 6.4.1. Its left side converges in L^1, by Cauchy–Schwarz and (6.20). The limits agree. Iterating the formula shows that finite sums of these completed chaoses form an algebra and belong to every finite L^p space.

Let $\mathcal{V}^{(1)} \subset \mathcal{V}$ consist of states using only mode-one creators, and let Π_1 be the projection onto this subspace. The map

$$\Phi\big(a_{-1}(h_1) \cdots a_{-1}(h_p)\mathbf{1}\big) = I_p\big(\mathrm{Sym}(h_1 \otimes \cdots \otimes h_p)\big)$$

preserves its Fock norm. Its product comparison is

$$\Phi\big(\Pi_1 Y(a, z) b|_{z=1}\big) = \Phi(a)\Phi(b), \qquad a, b \in \mathcal{V}^{(1)}.$$

Indeed each cross contraction contributes z^{-2}. The projection keeps only the constant mode-one term of every uncontracted transported creator. The result is the finite Laurent polynomial whose coefficients occur in (6.21). Thus projection precedes evaluation at $z = 1$.

For a unit current state j, this reads

$$\Pi_1 Y(j, z) j = j^2 + z^{-2}\mathbf{1}, \qquad \Phi(j^2) = \xi^2 - 1.$$

The contracted term restores ordinary Gaussian multiplication. The resulting product on $\mathcal{V}^{(1)}$ is associative, since Φ transports it to that multiplication. It differs from the vertex (-1)-product. In particular, Π_1 is not a vertex homomorphism.

Proposition 6.7.1. The map Φ extends to a unitary

$$U : \mathcal{F}_1 \xrightarrow{\sim} L^2(\Omega, \mathcal{F}_\xi, \mu),$$

where $\mathcal{F}_1$ is the Hilbert completion of $\mathcal{V}^{(1)}$. On finite-particle sectors, $a_{-1}(h) + a_1(h)$ becomes multiplication by $\xi(h)$. For a real symmetric Hilbert–Schmidt operator A, define

$$\mathsf{Q}_A = U^{-1} M_{I_2(A)} U, \qquad \mathrm{Dom}(\mathsf{Q}_A) = \{\psi : I_2(A) U\psi \in L^2\}.$$

This is a closed self-adjoint operator. On each finite-particle sector it equals

$$\sum_{i,j} A_{ij}\big(a_{-1}(e_i)a_{-1}(e_j) + 2a_{-1}(e_i)a_1(e_j) + a_1(e_i)a_1(e_j)\big).$$

Proof. The chaos isometry proves isometry. Hermite polynomials are dense for finitely many Gaussian coordinates. Conditional expectations onto increasing finite coordinate sigma fields converge in $L^2(\mathcal{F}_\xi)$, proving surjectivity. The one- and two-tensor product formulas give the two operator identities in finite rank.

On the p-particle sector, pair creation and pair annihilation have norm bounds

$$\sqrt{(p+1)(p+2)}\|A\|_2, \qquad \sqrt{p(p-1)}\|A\|_2.$$

The middle term has norm at most $2p\|A\|$. Hence the finite-rank expressions converge on every such sector. Multiplication by the real measurable function $I_2(A)$, on its displayed maximal domain, is self-adjoint. This specifies the closed operator and its domain. □

The sigma field in this unitary is essential. An additional independent centered sign is orthogonal to every Gaussian polynomial. It does not belong to the range of U in an enlarged probability space.

Connected contractions of quadratic fields

Put $Q_A = I_2(A)$. For variables with all moments, their joint cumulant is

$$\mathrm{cum}(Z_1, \dots, Z_n) = \sum_{\pi} (-1)^{|\pi|-1}(|\pi|-1)! \prod_{B\in\pi} \mathbb{E} \prod_{i\in B} Z_i,$$

where π ranges over partitions of $\{1, \dots, n\}$. The same partition expression defines a connected vacuum coefficient of fields.

Proposition 6.7.2. For symmetric Hilbert–Schmidt $A_1, \dots, A_n$, $n \geq 2$, one has

$$\mathrm{cum}(Q_{A_1}, \dots, Q_{A_n}) = 2^{n-1} \sum_{\sigma \in S_{\{2,\dots,n\}}} \mathrm{Tr}(A_1 A_{\sigma(2)} \cdots A_{\sigma(n)}).$$

Introduce symmetric independent variables $k_{ij} = k_{ji}$. For $i_1 = 1$, $i_j = \sigma(j)$ and $i_{n+1} = i_1$, the polynomial

$$2^{n-1} \sum_{\sigma \in S_{\{2,\dots,n\}}} \mathrm{Tr}(A_{i_1} \cdots A_{i_n}) \prod_{j=1}^{n} k_{i_j i_{j+1}} \tag{6.22}$$

gives this cumulant at $k_{ij} = 1$. At $k_{ij} = (z_i - z_j)^{-2}$, it gives the connected vacuum coefficient of the quadratic fields $W_{A_i}(z_i)$.

Proof. The partition sum cancels disconnected Wick graphs. Each remaining vertex has degree two, so the connected graph is a cycle. For $n \geq 3$, an unoriented cyclic order has 2^n choices of labeled legs. Its two orientations give the coefficient 2^{n-1} in the permutation sum. Reversal preserves the trace because the matrices are symmetric. For $n = 2$, there are two pairings and a double edge.

The species sum around each cycle is the displayed trace. Two Hilbert–Schmidt factors have trace-class product. The other factors are bounded. Thus each trace is continuous under Hilbert–Schmidt approximation. The Gaussian moments and the field coefficients converge by their contraction bounds. The two choices of edge kernel give the two evaluations of the same polynomial. □

For three fields, the formula is

$$\langle W_A(z_1)W_B(z_2)W_C(z_3)\rangle_0 = \frac{8\,\mathrm{Tr}(ABC)}{z_{12}^2 z_{23}^2 z_{31}^2}, \qquad z_{ij} = z_i - z_j.$$

Higher arity retains the order of noncommuting coefficients inside each trace. The Gaussian specialization is an evaluation of independent edge variables. It does not require complex positions with every pairwise contraction equal to one.

Normalized squeezed vectors

Let K be a real symmetric Hilbert–Schmidt operator with $\|K\| < 1$. Define the creation series

$$S_K = \exp\left(\frac{1}{2}\sum_{i,j} K_{ij}\, a_{-1}(e_i)a_{-1}(e_j)\right)\mathbf{1}, \qquad \Omega_K = \det(1-K^2)^{1/4} S_K. \tag{6.23}$$

The determinant is the Fredholm determinant: K^2 is trace class and $1 - K^2$ is strictly positive. The exponential is first interpreted in finite rank.

For real self-adjoint Hilbert–Schmidt A with $1 + A \geq \epsilon 1 > 0$, put

$$D_A = \det{}_2(1+A)^{1/2} e^{-I_2(A)/2}, \qquad \det{}_2(1+A) = \prod_j (1+a_j)e^{-a_j}.$$

Here a_j are its real eigenvalues. The logarithms of the product factors have a quadratic zero at zero, so they are summable.

THEOREM 6.7.3. The vectors in (6.23) exist in $\mathcal{F}_1$, independently of the finite-rank approximations, and

$$\|S_K\|^2 = \det(1-K^2)^{-1/2}, \qquad \|\Omega_K\| = 1.$$

The function D_A is a positive density of integral one. With

$$K = -A(2+A)^{-1},$$

one has $U\Omega_K = \sqrt{D_A}$. For two such preparations, with kernels K, L,

$$\langle \Omega_K, \Omega_L\rangle = \frac{\det(1-K^2)^{1/4}\det(1-L^2)^{1/4}}{\det(1-KL)^{1/2}} = \mathbb{E}\sqrt{D_A D_B}.$$

The square root is positive and continued from $K = L = 0$. No commutativity assumption is imposed.

Proof. For one oscillator the squared norm is

$$\sum_{m\ge 0}\frac{(2m)!}{4^m(m!)^2}k^{2m}=(1-k^2)^{-1/2}.$$

Diagonalization proves the finite-rank norm formula. The Hermite generating identity also gives

$$US_K=\det(1+K)^{-1/2}\exp\Big(\frac{1}{2}\xi^tK(1+K)^{-1}\xi\Big).$$

For the overlap of two such functions, the Gaussian precision is

$$P=1-K(1+K)^{-1}-L(1+L)^{-1}.$$

Each of the two subtracted self-adjoint operators has upper bound strictly less than $1/2$. Thus $P>0$, and direct multiplication gives

$$(1+K)P(1+L)=1-KL.$$

Gaussian integration proves $\langle S_K,S_L\rangle=\det(1-KL)^{-1/2}$. This argument fixes both the order and the branch.

Finite-rank compressions converge in Hilbert–Schmidt norm. Their squares and products converge in trace norm, so the displayed determinants converge. The overlap of two approximations to the same kernel makes their squeezed vectors Cauchy. It also proves independence of the approximation. Their fixed-particle components are the continuous tensor polynomials in K from (6.23).

For finite-rank A_N, the density is

$$D_{A_N}=\det(1+A_N)^{1/2}e^{-\xi^tA_N\xi/2},\qquad \mathbb{E}D_{A_N}=1.$$

Choose $p>1$ sufficiently close to one that $1+pA$ remains uniformly positive. Compressions retain common spectral bounds, and

$$\mathbb{E}D_{A_N}^p=\det{}_2(1+A_N)^{p/2}\det{}_2(1+pA_N)^{-1/2}.$$

The logarithm is uniformly bounded by a constant times $\|A_N\|_2^2$. Indeed the scalar logarithmic ratio has a quadratic zero at zero on the common bounded spectral interval.

The chaos isometry gives $I_2(A_N)\to I_2(A)$ in L^2. Regularized determinant convergence follows from

$$\log(1+A)-A=-\int_0^1 tA^2(1+tA)^{-1}\,dt.$$

Squares converge in trace norm, and the resolvents are uniformly bounded.

The densities therefore converge in probability. The L^p bound makes them uniformly integrable, so they converge in L^1. Their limit is D_A and has integral one. Their positive square roots converge in L^2.

On the bounded spectrum of A, separated from -1, the function $-a/(2+a)$ has absolute value strictly below one. It defines a Hilbert–Schmidt strict contraction. For $k=-a/(2+a)$, the one-coordinate identity is

$$(1-k^2)^{1/4}(1+k)^{-1/2}e^{k\xi^2/(2(1+k))}=(1+a)^{1/4}e^{-a\xi^2/4}.$$

The map $A\mapsto -A(2+A)^{-1}$ is continuous in Hilbert–Schmidt norm on this positive domain, by the resolvent identity. Passing to the two limits proves the square-root formula. The overlap identity follows by unitarity. □

The prepared covariance of the quadratures is $(1 + A)^{-1}$. More generally, for a bounded positive operator C, put $X(f) = \xi(C^{1/2}f)$. Its covariance in this preparation is

$$C^{1/2}(1 + A)^{-1}C^{1/2}.$$

Finite Gaussian characteristic functions give this formula before taking limits. The L^1 density limit preserves those bounded characteristic functions. The L^p estimates and Hölder's inequality also preserve every fixed polynomial expectation.

PROPOSITION 6.7.4. Suppose $A \geq 0$ is compact but not Hilbert–Schmidt. For $K = -A(2 + A)^{-1}$, the unnormalized squeezed norm product diverges. The normalized finite spectral preparations converge weakly to zero and have no norm limit in $\mathcal{F}_1$.

Proof. The eigenvalues $a_j \to 0$ give $|k_j| = a_j/(2 + a_j)$, comparable to a_j. Thus $\sum_j k_j^2 = \infty$, and

$$-\frac{1}{2}\sum_j \log(1 - k_j^2) = \infty.$$

The normalized vacuum overlap of a tail, $\prod_j (1 - k_j^2)^{1/4}$, tends to zero.

The overlap with any vector on finitely many eigenmodes contains this tail factor. Such vectors are dense, and all preparations have norm one. Hence their weak limit is zero. A norm limit would have norm one and the same weak limit, a contradiction. □

Prepared field matrix elements

The vector Ω_K usually has infinitely many energies. We use it to define scalar matrix elements, without defining $Y(\Omega_K, z)$ on all of $\widehat{\mathcal{V}}$.

Let N count particles in the first oscillator. If $s > 0$ and $e^{2s}\|K\| < 1$, then

$$\|e^{s\mathsf{N}}\Omega_K\|^2 = \det(1 - K^2)^{1/2} \det(1 - e^{4s}K^2)^{-1/2} < \infty.$$

This follows from $e^{s\mathsf{N}}S_K = S_{e^{2s}K}$. The overlap proof also gives convergence of the finite-rank preparations in this weighted norm. It controls every particle moment.

Define

$$N_K = K^2(1 - K^2)^{-1}, \qquad M_K = K(1 - K^2)^{-1}.$$

The first operator is trace class. The second is Hilbert–Schmidt. Writing $\langle O\rangle_K = \langle \Omega_K, O\Omega_K\rangle$, the first-mode contractions are

$$\langle a_{-1}(v)a_1(u)\rangle_K = (v, N_K u), \qquad \langle a_1(v)a_1(u)\rangle_K = (v, M_K u).$$

To see the full Wick rule, put $R = (1 - K^2)^{-1/2}$ and

$$b(v) = a_1(Rv) - a_{-1}(KRv).$$

These operators satisfy the canonical commutation relations and annihilate Ω_K. The identity $a_1(v) = b(Rv) + b(KRv)^*$ reduces its finite-rank contractions to vacuum contractions. The weighted bound passes each fixed polynomial mode identity to the limit. Higher oscillator modes remain in their vacuum.

Theorem 6.7.5. For real species vectors v, u, the scalar current matrix element is

$$\begin{aligned}\langle J_v(z)J_u(w)\rangle_K = \frac{(v,u)}{(z-w)^2} + (v, N_K u)(z^{-2}+w^{-2}) \\ + (v, M_K u)(1 + z^{-2}w^{-2}).\end{aligned} \tag{6.24}$$

For finitely many finite-energy states, finite oscillator and species cutoffs of their scalar matrix elements converge uniformly on compact subsets of

$$|z_1| > \cdots > |z_n| > 0.$$

The limits continue meromorphically. Their possible poles lie on pairwise diagonals and at the prepared punctures $z_i = 0$.

Proof. The vacuum current contraction is the convergent series $\sum_{m>0} m z^{-m-1} w^{m-1} = (z-w)^{-2}$. The two creation–annihilation orderings in mode one add the two N_K terms. The two anomalous contractions add the two M_K terms. This proves (6.24). The geometric series and every fixed derivative converge uniformly on compact nested annuli.

Each finite-energy state has finitely many occupancy types. Wick expansion gives finitely many contraction patterns for those types. Within one insertion, vacuum normal ordering removes the identity self-contraction. The remaining self kernels are derivatives of the prepared-minus-vacuum kernel. They are Hilbert–Schmidt in species. Cross kernels are bounded species operators.

Absorb each bounded cross operator into one tensor leg. Regard every self kernel as a separate two-leg Hilbert tensor. The resulting contraction graph has no self edge. Merge its vertices successively, contracting all edges between the two groups at each step. Lemma 6.4.1 bounds the result by the tensor norms.

The bounds are uniform on compact nested annuli. This proves the cutoff convergence. The finitely many positional factors are derivatives of the displayed rational kernel, so they have precisely the stated possible poles. □

For a quadratic field, the self-contraction is

$$\langle W_A(z)\rangle_K = 2z^{-2}\operatorname{Tr}(AN_K) + (1+z^{-4})\operatorname{Tr}(AM_K).$$

Both products have traces. Let $G_K(z,w)$ be the species operator of the current kernel in (6.24). The connected quadratic n-point coefficient is

$$2^{n-1}\sum_{\sigma\in S_{\{2,\dots,n\}}} \operatorname{Tr}\left(\prod_{j=1}^{n} A_{i_j} G_K(z_{i_j}, z_{i_{j+1}})\right),$$

with the cyclic indices from (6.22). The product retains its indicated order. Every trace contains two Hilbert–Schmidt A_i factors, which justify the same cycle proof.

For quadratures, the covariance instead becomes

$$1 + 2N_K + 2M_K = (1+K)(1-K)^{-1} = (1+A)^{-1}.$$

Thus the Gaussian and field comparisons concern specified observables. The puncture terms also show that the prepared state need not be translation invariant.

6.8 TRANSPORT OF GAUSSIAN PREPARATIONS

Coordinate covariance on finite-energy states does not itself transport an infinite-energy preparation. The cubic coordinate flow isolates the additional convergence problem:

$$f_t(z) = \frac{z}{\sqrt{1 - 2tz^2}}.$$

On finite-energy states its coordinate action is e^{tL_2}. On mode-one polynomials,

$$L_2 = \frac{1}{2}\sum_i \partial_{x_i}^2.$$

The sum is finite on each polynomial.

For a symmetric strict contraction K, write

$$K_t = K(1 - tK)^{-1}.$$

Every transport formula below uses a common real interval about zero on which its resolvents exist and all displayed response kernels remain strict contractions. Scalar branches start at one when $t = 0$.

THEOREM 6.8.1. If K is real symmetric and trace class, finite-species cubic transport has the Fock limit

$$\lim_{N\to\infty} e^{tL_{2,N}} S_{P_N K P_N} = \det(1 - tK)^{-1/2} S_{K_t}. \tag{6.25}$$

Here $P_N \to 1$ strongly are finite-rank orthogonal projections, and $L_{2,N}$ contracts only species in $P_N H$. If $K \geq 0$ is Hilbert–Schmidt but not trace class, the vacuum coefficients of these outputs diverge for sufficiently small $t > 0$.

Proof. In finite rank, insert $F_t \exp(x^t K_t x/2)$ in the heat equation. Comparison of its quadratic and constant terms gives

$$\dot{K}_t = K_t^2, \qquad \frac{d}{dt}\log F_t = \frac{1}{2}\operatorname{Tr} K_t.$$

The initial conditions yield the displayed resolvent and ordinary determinant. Their Gaussian series converges in Fock norm on the stipulated interval.

Trace-class compressions converge in trace norm. The resolvent identity gives convergence of their responses in that norm. Determinant continuity and the squeezed overlap formula prove (6.25).

For positive K and small positive t,

$$\log\det(1 - tP_N K P_N)^{-1/2} \geq \frac{t}{2}\operatorname{Tr}(P_N K P_N).$$

The traces tend to infinity if K is not trace class. Indeed strong convergence first captures any fixed finite spectral subspace. Those subspaces have unbounded traces. The determinant is the vacuum coefficient, so the proposed Hilbert limit cannot exist. □

For negative kernels the same normalization can have a zero limit instead of diverging. If $K \leq 0$ is Hilbert–Schmidt but not trace class, then for small $t > 0$,

$$e^{tL_{2,N}} S_{P_N K P_N} \longrightarrow 0.$$

To prove this, put $K_N = P_N K P_N$ and $q = \|K\|$. The response kernels converge in Hilbert–Schmidt norm and have a common strict-contraction bound. Their squeezed norms are consequently bounded. Meanwhile

$$\log\det(1 - tK_N)^{-1/2} \le -\frac{t}{2(1+tq)}\operatorname{Tr}|K_N| \longrightarrow -\infty,$$

using $\log(1+x) \ge x/(1+x)$. For small $t < 0$, the reverse sign gives diverging vacuum coefficients.

Normalized inputs Ω_{K_N} have the same zero positive-time limit, since their normalizing constants have a positive limit. Normalizing each output separately instead gives $\Omega_{(K_N)_t} \to \Omega_{K_t}$. This last operation changes the scalar normalization. It does not make the zero limit invertible.

These limits concern the specified Gaussian families. They do not construct a closable generator on full Hilbert Fock space. The finite-energy sequence in Theorem 6.5.1 still obstructs that extension.

A regularized scalar and its composition defect

For Hilbert–Schmidt K, define

$$\widehat{F}_t(K) = \det{}_2(1 - tK)^{-1/2}, \qquad \log\widehat{F}_t(K) = \frac{1}{2}\sum_{r\ge 2}\frac{t^r}{r}\operatorname{Tr}(K^r).$$

The series converges when $\|tK\| < 1$. It omits the possibly undefined term $t\operatorname{Tr}(K)/2$. That omission changes composition.

Proposition 6.8.2. On the common domain for $s, t, s+t$,

$$\widehat{F}_t(K)\widehat{F}_s(K_t) = \widehat{F}_{t+s}(K)\exp\Big[-\frac{st}{2}\operatorname{Tr}\big(K^2(1-tK)^{-1}\big)\Big]. \tag{6.26}$$

The multiplier depends on K.

Proof. The resolvent identities give

$$(1 - sK_t)(1 - tK) = 1 - (s+t)K, \qquad K_t - K = tK^2(1-tK)^{-1}.$$

In finite rank, ordinary determinants multiply. Their regularizing exponentials leave $-s\operatorname{Tr}(K_t - K)/2$ in the logarithm. This is the displayed exponent.

Hilbert–Schmidt approximation gives trace-norm convergence of the squared kernels and uniformly bounded resolvents. The logarithmic series converge locally uniformly, so the same identity holds in the stated domain. At $K = 0$ the multiplier is one. For nonzero positive rank-one K and positive s, t, it is not one. □

Consequently this multiplier cannot be removed on every squeezed line by a normalization depending only on the coordinate parameters. A map assigned to each such line also does not define a linear map on Fock space.

A chosen reference preparation gives a coherent comparison of lines along its orbit. Fix K_0, put $K_t = K_0(1 - tK_0)^{-1}$, and set

$$g(t) = \widehat{F}_t(K_0), \qquad \mathcal{R}(s,t) = g(t)/g(s).$$

The difference $K_s - K_0$ is trace class, and (6.26) gives

$$\mathcal{R}(s,t) = \widehat{F}_{t-s}(K_s)\exp\Big[\frac{t-s}{2}\operatorname{Tr}(K_s - K_0)\Big].$$

By its ratio definition, $\mathcal{R}(t,u)\mathcal{R}(s,t) = \mathcal{R}(s,u)$. This construction retains the reference preparation and its trace correction.

For a general coordinate germ, only two coefficients act on mode-one polynomials:

$$\lambda = f'(0), \qquad b = B_f(1,1) = \{f,0\}/6.$$

Assume these numbers are real and $\lambda \neq 0$. Let D_λ multiply a creation monomial of length p by λ^p. Each paired leg contributes b, and each unpaired leg contributes λ. Thus $R_f = D_\lambda e^{bL_2}$ on those polynomials.

For trace-class K, the corresponding cutoff limit is

$$R_f S_K = \det(1-bK)^{-1/2} S_{\lambda^2 K(1-bK)^{-1}}.$$

It has the same common-domain qualifications as the cubic formula. When $b = 0$, the formula holds for Hilbert–Schmidt K, provided $\|\lambda^2 K\| < 1$.

Kernel composition gives

$$b_{f\circ g} = b_g + \lambda_g^2 b_f, \qquad \lambda_{f\circ g} = \lambda_f \lambda_g.$$

These data determine the first-oscillator transport. Higher oscillator modes still detect the other coefficients $B_f(m,n)$.

Retaining a trace with the preparation

The contraction completion permits a more general transport datum. Retain modes $1,\dots,d$, with $d < \infty$, and put

$$y_m(v) = x_m(v)/\sqrt{m}, \qquad \mathcal{H} = \mathbb{R}^d \otimes H, \qquad C_{mn} = c_{mn}/\sqrt{mn}.$$

The central matrix C acts identically on species. For trace-class block operators on $\mathcal{H}$, define the partial trace

$$\operatorname{tr}_H(A)_{mn} = \operatorname{Tr}_H(A_{mn}).$$

It is bounded from the trace class to the finite matrix space. No such trace is assigned to an arbitrary Hilbert–Schmidt block operator.

Fix a real symmetric Hilbert–Schmidt strict contraction K on $\mathcal{H}$. Choose independently a real symmetric matrix τ of size d. If K is trace class, its canonical choice is $\tau = \operatorname{tr}_H(K)$.

LEMMA 6.8.3. Every pair (K,τ) has finite-rank symmetric approximations K_N with

$$\|K_N - K\|_2 \longrightarrow 0, \qquad \operatorname{tr}_H(K_N) = \tau.$$

The approximations are uniformly strict contractions for sufficiently large N. If $K \geq 0$ is not trace class, approximations with bounded prescribed traces cannot all be positive.

Proof. Compress K to the first N species in each mode, obtaining K_N°. Put $\delta_N = \tau - \operatorname{tr}_H(K_N^\circ)$. Choose an orthogonal reservoir of M_N further species and set

$$K_N = K_N^\circ + \delta_N \otimes P_{\mathrm{res}}/M_N, \qquad M_N > N^2\|\delta_N\|_F^2 + N + 1.$$

The added term has partial trace δ_N and Hilbert–Schmidt norm $\|\delta_N\|_F/\sqrt{M_N} < 1/N$. Hence $K_N \to K$ in Hilbert–Schmidt norm, and therefore in operator norm. The strict-contraction bound follows.

For positive approximations and any fixed finite-rank projection Q,

$$\operatorname{Tr}(QKQ) = \lim_N \operatorname{Tr}(QK_NQ) \le \liminf_N \operatorname{Tr} K_N.$$

The supremum of the left side is infinite for a positive non-trace-class K. Thus bounded prescribed traces require signed reservoir corrections in that case. □

In the product of energy sectors define

$$\begin{aligned}\mathscr{S}_{K,\tau}(y,C) = \exp\left[\frac{1}{2}\operatorname{tr}_d(C\tau) + \frac{1}{2}\sum_{r\ge 2}\frac{\operatorname{Tr}((CK)^r)}{r}\right] \\ \cdot \exp\left[\frac{1}{2}y^tK(1-CK)^{-1}y\right].\end{aligned} \tag{6.27}$$

The inverse is expanded in the positive-energy central variables. The traces for $r \ge 2$ exist because each contains two Hilbert–Schmidt factors.

Proposition 6.8.4. The formula defines an element of $\prod_E \mathcal{W}_E$. For every sequence from Lemma 6.8.3, it is the coefficientwise limit of jS_{K_N}. Under the sectorwise extension of π, it gives the Hilbert squeezed vector S_K.

Proof. In finite rank the Gaussian heat equation gives

$$e^{\Delta_c}e^{y^tKy/2} = \det(1-CK)^{-1/2}e^{y^tK(1-CK)^{-1}y/2}.$$

Separating the determinant's linear term gives (6.27). Closed cycles of length at least two have trace-class products. Open paths give Hilbert–Schmidt kernels, whose products give the required Hilbert tensors.

At fixed energy only finitely many paths, cycles and oscillator degrees occur. Their coefficients converge in trace norm or Hilbert tensor norm. The one-edge cycles converge by the prescribed partial trace τ. This proves the limit and its independence of the approximating sequence. At $C = 0$ the formula is S_K. Theorem 6.7.3 applies to the one-particle space $\mathcal{H}$. □

Response, trace and scalar under composition

A finite-mode Gaussian transformation consists of $T \in \mathrm{GL}_d(\mathbb{R})$ and $B \in \mathrm{Sym}_d(\mathbb{R})$. On polynomials it substitutes $y \mapsto Ty$ after contracting pairs with B. On the completed polynomial coordinates this is

$$y \longmapsto Ty, \qquad C \longmapsto TCT^t + B.$$

A coordinate germ gives such a pair by

$$T_{ij} = \sqrt{j/i}\,T_f(i,j), \qquad B_{ij} = B_f(i,j)/\sqrt{ij}.$$

An arbitrary matrix pair need not arise from a curve coordinate.

Write $\widetilde{T} = T \otimes 1_H$ and $\widetilde{B} = B \otimes 1_H$. Define

$$K^B = K(1-\widetilde{B}K)^{-1},$$

$$K' = \widetilde{T}^tK^B\widetilde{T}, \tag{6.28}$$

$$\tau' = T^t\tau T + \operatorname{tr}_H\big(\widetilde{T}^t(K^B-K)\widetilde{T}\big), \tag{6.29}$$

$$F_{T,B}(K,\tau) = e^{\operatorname{tr}_d(B\tau)/2}\det{}_2(1-\widetilde{B}K)^{-1/2}. \tag{6.30}$$

The resolvent identity

$$K^B = (1 - K\widetilde{B})^{-1}K$$

shows that the response is symmetric. The partial trace in (6.29) is legitimate:

$$K^B - K = K(1 - \widetilde{B}K)^{-1}\widetilde{B}K \in \mathcal{S}_1(\mathcal{H}). \tag{6.31}$$

Its two outside kernels are Hilbert–Schmidt.

Use a common domain where $\|\widetilde{B}K\| < 1$ and every response kernel is a strict contraction. These conditions must hold for each intermediate and composite transformation. The logarithmic determinant series beginning at degree two fixes its branch at the identity.

THEOREM 6.8.5. On this domain, the finite-rank transformations have the Gaussian cutoff limit

$$\mathscr{S}_{K,\tau} \longmapsto F_{T,B}(K,\tau)\mathscr{S}_{K',\tau'}.$$

If (T_2, B_2) is applied first, followed by (T_1, B_1), their composite data are

$$T = T_2T_1, \qquad B = B_2 + T_2B_1T_2^t. \tag{6.32}$$

The one-step and two-step responses and trace matrices agree, and

$$F_{T_2,B_2}(K,\tau)F_{T_1,B_1}(K_2,\tau_2) = F_{T,B}(K,\tau). \tag{6.33}$$

These identities hold under every finite regrouping of admitted transformations. No commutativity assumption is needed.

Proof. Finite-dimensional Gaussian heat integration followed by linear substitution gives (6.28) and the scalar $\det(1 - \widetilde{B}K)^{-1/2}$. Separating its linear trace term gives (6.30) when $\tau = \operatorname{tr}_H K$. Taking the partial trace of the response gives (6.29).

Apply the approximations of Lemma 6.8.3. Resolvents converge in operator norm, responses in Hilbert–Schmidt norm, and (6.31) in trace norm. For $r \geq 2$, the logarithmic series obeys

$$|\operatorname{Tr}((\widetilde{B}K)^r)| \leq \|\widetilde{B}K\|_2^2\|\widetilde{B}K\|^{r-2}.$$

It converges locally uniformly. Hence the scalar and trace matrix converge.

The Gaussian lift proposition gives the sectorwise limit. The overlap formula gives its Hilbert limit after applying π.

The substitutions on y, C give (6.32). The resolvent identity gives the same composition for K'. For the trace update, subtract the purely linear transform of K from the final response. Insert the intermediate response between them and take the partial trace. The two trace-class differences telescope, and finite mode matrices pass outside the partial trace. This proves the trace law.

It remains to check the scalar, including the sign of its regularized determinant. Put

$$A = \widetilde{B}_2K, \qquad D = \widetilde{T}_2\widetilde{B}_1\widetilde{T}_2^t, \qquad Q = DK.$$

By similarity, the second determinant has argument $1 - Q(1 - A)^{-1}$. The exact factorization is

$$(1 - Q(1 - A)^{-1})(1 - A) = 1 - A - Q.$$

For Hilbert–Schmidt U, V, the regularized product identity is

$$\det{}_2((1-U)(1-V)) = \det{}_2(1-U)\det{}_2(1-V)e^{-\operatorname{Tr}(UV)}.$$

In finite rank this follows by separating the linear trace from each ordinary determinant. Approximation in Hilbert–Schmidt norm extends it, since UV converges in trace norm.

This is also the $p = 2$ product formula for regularized Fredholm determinants.[2]

The two inverse square roots therefore leave the multiplier

$$\exp\Big[-\frac{1}{2}\operatorname{Tr}\big(Q(1-A)^{-1}A\big)\Big].$$

The trace update contributes its inverse:

$$\begin{aligned}\frac{1}{2}\operatorname{tr}_d(B_1\tau_2) - \frac{1}{2}\operatorname{tr}_d(T_2B_1T_2^t\tau) &= \frac{1}{2}\operatorname{Tr}\big(D(K^{B_2}-K)\big)\\ &= \frac{1}{2}\operatorname{Tr}\big(Q(1-A)^{-1}A\big).\end{aligned}$$

All traced products are trace class. The exponents cancel, proving (6.33). Associativity of the matrix pair law then proves every finite regrouping on its common domain. □

For $d = 1$, $T = 1$ and $B = t$, the construction becomes

$$K_t = K(1-tK)^{-1}, \qquad \tau_t = \tau + \operatorname{Tr}(K_t - K), \qquad F_t = e^{t\tau/2}\det{}_2(1-tK)^{-1/2}.$$

Differentiating the convergent series gives

$$\dot K_t = K_t^2, \qquad \dot\tau_t = \operatorname{Tr}(K_t^2), \qquad \frac{d}{dt}\log F_t = \tau_t/2.$$

The trace-class difference replaces an undefined $\operatorname{Tr} K$. Forgetting τ recovers the defect in (6.26).

Two trace data $\tau, \widehat\tau$ for the same K project to the same Hilbert vector S_K. Their transformed Hilbert limits instead differ by

$$\exp\Big[\frac{1}{2}\operatorname{tr}_d(B(\tau-\widehat\tau))\Big].$$

If this scalar is not one, no continuous operator on the old Hilbert space can realize both cutoff limits. Signed reservoirs do not alter the divergence of the original positive-cutoff sequence for a positive non-trace-class kernel. They specify a different trace datum.

Even the response endpoints do not determine the scalar. On one occupied oscillator take $0 < \kappa < 1$, $K = \tau = \kappa$, $T = a > 0$ near one, and $B = (1-a^2)/\kappa$. Then

$$K' = \kappa, \qquad F = a^{-1}.$$

The coordinate germ $f(z) = az/\sqrt{1-2Bz^2}$ has these first-mode data. The coordinate arrow and its normalization must therefore be retained even when the response returns to its initial kernel.

These formulas define a Gaussian domain in $\prod_E \mathcal{W}_E$. They do not extend every coordinate change to that unrestricted product. Coordinate contractions can lower energy without bound. The Gaussian resolvent is what supplies convergence on this domain.

[2] T. Britz, A. Carey, F. Gesztesy, R. Nichols, F. Sukochev and D. Zanin. *The product formula for regularized Fredholm determinants*, equations (1.3)–(1.5), arXiv:2007.12834.

Unitary implementation is a separate condition

Let a bounded invertible real symplectic map act on a one-particle Hilbert space. Relative to its chosen complex structure, write α for its linear block and β for its antilinear block. Shale's criterion says that its action on the canonical commutation relations has a unitary Fock implementer exactly when β is Hilbert–Schmidt.[3] A formal coordinate germ need not define such a bounded symplectic Hilbert map.

If the mode action is identical in every species, then $\beta = \beta_{\mathrm{mode}} \otimes 1_H$. For a unit mode vector v with $\beta_{\mathrm{mode}} v \neq 0$,

$$\sum_i \|\beta(v \otimes e_i)\|^2 = \sum_i \|\beta_{\mathrm{mode}} v\|^2 = \infty.$$

Thus this action has no unitary implementer. When $\beta = 0$ and α is unitary, ordinary second quantization does provide one.

For the uniform one-mode squeeze $\alpha = 5\,1_H/4$, $\beta = 3\,1_H/4$, the finite-species kernel is $K_N = 3P_N/5$, and

$$\|\beta_N\|_2^2 = 9N/16, \qquad \langle \mathbf{1}, \Omega_{K_N} \rangle = (16/25)^{N/4} \longrightarrow 0.$$

This distinguishes unitary implementation from convergence of selected preparations and from covariance of finite-energy fields.

A continuous prepared functional on a bounded-energy projective sector can be transported by precomposition with R_f. Preservation of positivity additionally requires its adjoint and positive cone to be preserved. This covector construction alone supplies neither a global state nor a physical sewing map.

6.9 State families and completed field operations

The preceding completions control species tensors or specified Gaussian families. A formal parameter raises a different question. When may that parameter be identified with an insertion coordinate? An arbitrary formal series does not suffice.

Return to a characteristic-zero field k with discrete coefficients. For the current $J \in H_\kappa$, introduce a parameter ξ, independent of the insertion coordinate u. The state family

$$A(\xi) = \sum_{r \geq 0} \frac{(-1)^r \xi^r}{(r+1)!} T^r J$$

exists in $H_\kappa[[\xi]]$. Its coefficientwise field on J has vacuum polar part

$$\kappa \sum_{r \geq 0} \xi^r u^{-r-2} \mathbf{1}.$$

The partial state sums converge ξ-adically. After the substitution $\xi = u$, their $u^{-2}\mathbf{1}$ coefficient is $N\kappa$ for a sum of N terms. It does not stabilize. Thus this substitution is not continuous on all formal state families with discrete scalars.

The exact domain for diagonal evaluation

Let V be a vertex algebra over k. The same discussion permits a differential graded vertex algebra, with all series taken in each cohomological degree. Give $V((u))$ the topology with neighborhoods $u^q V[[u]]$, $q \in \mathbb{Z}$. For $a, b \in V$, put

$$v_b(a) = \mathrm{ord}_u\, Y(a,u)b, \qquad \mathrm{ord}_u\, 0 = +\infty.$$

[3] L. Bruneau and J. Dereziński, *Bogoliubov Hamiltonians and one-parameter groups of Bogoliubov transformations*. Definition 3.1, Assumption 3.A and Theorem 3.2, arXiv:math-ph/0511069.

Define

$$\mathscr{A}_Y = \left\{ \sum_{r\ge 0} \xi^r a_r : r + \nu_b(a_r) \longrightarrow +\infty \text{ for every } b \in V \right\}. \tag{6.34}$$

The parameter ξ has cohomological degree zero. For a finite set $B \subset V$ and $q \in \mathbb{Z}$, let $U_{B,q}$ require

$$r + \nu_b(a_r) \ge q \quad \text{for every } r \ge 0,\ b \in B.$$

These subspaces define a linear topology on $\mathscr{A}_Y$. Equip $\mathrm{Hom}_k(V, V((u)))$ with pointwise Laurent convergence.

Proposition 6.9.1. Polynomial families are dense in $\mathscr{A}_Y$. Their diagonal evaluation extends uniquely to a continuous map

$$\mathrm{ev}_Y : \mathscr{A}_Y \longrightarrow \mathrm{Hom}_k(V, V((u))), \qquad \mathrm{ev}_Y(A)(u)b = \sum_{r\ge 0} u^r Y(a_r, u)b.$$

The limit condition in (6.34) is necessary and sufficient for convergence on every input. The domain is preserved by coefficient translation T, by ∂_ξ, and by the differential in the graded case. Evaluation commutes with that differential and satisfies

$$\mathrm{ev}_Y((T + \partial_\xi)A) = \partial_u \,\mathrm{ev}_Y(A), \qquad [T, \mathrm{ev}_Y(A)] = \mathrm{ev}_Y(TA).$$

Proof. The limit condition makes the series converge in the complete Laurent space on each fixed input. Conversely, successive differences of convergent partial sums must tend to zero, giving the same condition. The image of $U_{B,q}$ sends every $b \in B$ into $u^q V[[u]]$. This proves continuity.

Truncation tails tend to zero in every $U_{B,q}$, so polynomials are dense. The target is Hausdorff, proving uniqueness. The source is Hausdorff as well: the vacuum identity gives $\nu_{\mathbf{1}}(a) = 0$ for every nonzero a.

Translation covariance gives $\nu_b(Ta) \ge \nu_b(a) - 1$. Reindexing gives the same loss of at most one for ∂_ξ. For homogeneous a, the differential identity gives

$$\nu_b(da) \ge \min\{\nu_b(a), \nu_{db}(a)\}.$$

These estimates preserve the domain and justify termwise differentiation.

The product rule on $u^r Y(a_r, u)$ gives the first translation identity. Summing $[T, Y(a_r, u)] = Y(Ta_r, u)$ gives the second. The graded Hom differential gives the differential assertion. □

There are admissible infinite families with unbounded derivative order. For example,

$$\widetilde{A}(\xi) = (1 + \xi) \sum_{r\ge 0} \frac{(-1)^r \xi^{2r}}{(r+1)!} T^r J$$

belongs to $\mathscr{A}_Y$, since $\nu_b(T^r J) \ge \nu_b(J) - r$. Its vacuum coefficient on J after evaluation is

$$\kappa u^{-2}(1 + u) \sum_{r\ge 0} u^r = \kappa u^{-2} \frac{1 + u}{1 - u}.$$

This is expanded at $u = 0$. The parameter degree now outruns the derivative pole order.

A weight completion closed under every mode

Suppose V also has a nonnegative integer weight grading with

$$V=\bigoplus_{h\ge 0}V_h,\quad \mathbf{1}\in V_0,\quad T(V_h)\subset V_{h+1},\quad d(V_h)\subset V_h,\quad (V_h)_{(n)}V_{h'}\subset V_{h+h'-n-1}.$$

Negative weight spaces are zero. Weight is independent of cohomological degree, and its spaces need not be finite dimensional. Let $w(a)$ be the largest weight of a nonzero component of a, with $w(0)=-\infty$.

Put

$$\mathscr{A}_{\mathrm{wt}}(V)=\left\{\sum_{r\ge 0}\xi^r a_r : r-w(a_r)\longrightarrow+\infty\right\}. \tag{6.35}$$

Define

$$\gamma(A)=\inf_{r\ge 0}\{r-w(a_r)\},\qquad \mathcal{F}^q=\{A:\gamma(A)\ge q\},\qquad \gamma(0)=+\infty.$$

The $\mathcal{F}^q$ are the neighborhoods of zero. Each sum is still taken in a fixed cohomological degree.

On polynomials $W=V\otimes k[\xi]$, use the tensor-product fields

$$Y_W(\xi^r a,z)(\xi^s b)=(\xi+z)^r\xi^s Y_V(a,z)b. \tag{6.36}$$

The second factor has its commutative differential-algebra vertex structure. Translation on W is $D=T+\partial_\xi$. In an iterated field, the shifted parameter becomes $\xi+z_2+z_0$. This equals $\xi+z_1$ under $z_1=z_2+z_0$. Thus the tensor product retains the vertex identities.

THEOREM 6.9.2. The space $\mathscr{A}_{\mathrm{wt}}(V)$ is the Hausdorff completion of W for the degree $\deg(\xi^r a)=r-h$, $a\in V_h$. Every mode extends to the continuous bilinear product

$$A_{[n]}B=\sum_{r,s\ge 0}\sum_{j=0}^{r}\binom{r}{j}\xi^{r+s-j}(a_r)_{(n+j)}b_s. \tag{6.37}$$

Each parameter coefficient is a finite sum, and

$$\gamma(A_{[n]}B)\ge\gamma(A)+\gamma(B)+n+1,\qquad \gamma(A_{[n]}B)-n\longrightarrow+\infty\quad(n\to+\infty). \tag{6.38}$$

The vacuum, differential and translation extend with their usual identities. For homogeneous A,B,C and integers p,q,n, the three series in the identity

$$\begin{aligned}\sum_{j\ge 0}\binom{p}{j}(A_{[n+j]}B)_{[p+q-j]}C=&\sum_{j\ge 0}(-1)^j\binom{n}{j}A_{[p+n-j]}(B_{[q+j]}C)\\&-(-1)^{n+|A||B|}\sum_{j\ge 0}(-1)^j\binom{n}{j}B_{[q+n-j]}(A_{[p+j]}C)\end{aligned} \tag{6.39}$$

converge and satisfy the displayed equality. Every fixed coefficient of ξ receives only finitely many summands from each series.

Proof. Decompose the polynomial space as

$$W=\bigoplus_{\delta\in\mathbb{Z}}W_\delta,\qquad W_\delta=\bigoplus_{\substack{r,h\ge 0\\ r-h=\delta}}\xi^r V_h.$$

Its completion consists of sums bounded below in δ, with finitely many pairs (r, h) below every degree cutoff. This is equivalent to the limit condition in (6.35). For fixed r, every weight satisfies $r - h \le r$, so its coefficient remains a finite sum in V. This proves completeness, Hausdorffness and density of the polynomial subspace.

Expanding (6.36) gives the mode formula on polynomials. A nonzero summand at parameter exponent $\ell = r + s - j$ has weight at most $w(a_r) + w(b_s) - n - j - 1$. Hence

$$\ell - w((a_r)_{(n+j)}b_s) \ge (r - w(a_r)) + (s - w(b_s)) + n + 1.$$

Nonnegative output weight also gives

$$(r - w(a_r)) + (s - w(b_s)) \le \ell - n - 1.$$

The two sequences on the left tend to infinity and are bounded below. Only finitely many pairs (r, s) can contribute to a fixed ℓ. Then j is determined.

As $\ell \to \infty$, any contributing pair satisfies $r + s \ge \ell$. Its sum of surpluses therefore tends to infinity. This proves that the product belongs to the completion, with the first bound in (6.38). The bound also proves continuity.

Approximate A, B by polynomials A_0, B_0 with errors of arbitrarily large γ. For all sufficiently large n, $(A_0)_{[n]}B_0 = 0$. Apply the first bound to

$$(A - A_0)_{[n]}B + (A_0)_{[n]}(B - B_0).$$

After subtracting n, its lower bound can be made arbitrarily large, uniformly in n. This proves the second limit.

The differential preserves the filtration. D lowers it by at most one. Thus their polynomial identities extend continuously.

Each summand in the three iterated products of (6.39) has filtration lower bound

$$\gamma(A) + \gamma(B) + \gamma(C) + p + q + n + 2.$$

This bound is independent of j. Replacing any input by a high-filtration error raises it uniformly. Approximate all three inputs by polynomials with bounded-below filtrations. Their three series are finite, by ordinary mode truncation. Beyond the last polynomial term, every completed summand therefore lies in any prescribed $\mathcal{F}^N$, once the approximations are sufficiently close.

The series converge and inherit the polynomial Borcherds identity.

Finally, an element of $\mathcal{F}^{L+1}$ has zero ξ^L coefficient, since that coefficient would have negative weight. The preceding convergence proof places all sufficiently late summands there. This proves the asserted finiteness of each parameter coefficient. □

Modules and the lower weight bound

Let $M = \bigoplus_{\ell \ge b_0} M_\ell$ be a weight-graded V-module, where $b_0 \in \mathbb{Z}$, the differential preserves weight, and

$$(V_h)_{(m)}M_\ell \subset M_{h+\ell-m-1}.$$

Equip $\mathrm{Hom}_k(M, M((u)))$ with pointwise Laurent convergence.

PROPOSITION 6.9.3. Polynomial evaluation extends continuously to

$$\widehat{Y}_M : \mathscr{A}_{\mathrm{wt}}(V) \longrightarrow \mathrm{Hom}_k(M, M((u))), \qquad \widehat{Y}_M(A,u)b = \sum_{r\geq 0} u^r Y_M(a_r,u)b.$$

Its mode on $b \in M_\ell$ is the finite sum

$$A^M_{[m]}b = \sum_{r\geq 0}(a_r)_{(m+r)}b, \tag{6.40}$$

and

$$\mathrm{ord}_u\, \widehat{Y}_M(A,u)b \geq \gamma(A) + b_0 - \ell.$$

The module identities hold with the completed products (6.37). Their sums are locally finite on each fixed module vector. The action is natural in strict weight-preserving module maps, commutes with the differential, and intertwines D with ∂_u.

Proof. The r-th summand of (6.40) has weight at most

$$\ell - m - 1 - (r - w(a_r)).$$

It vanishes when this is less than b_0. The surplus limit proves finiteness and the common Laurent lower bound. That same bound proves continuity. On polynomials this is the tensor-product module where $f(\xi)$ acts by $f(u)$.

In a module Borcherds identity, each composite summand sends a weight-ℓ input to weights at most

$$\ell - p - q - n - 2 - \gamma(A) - \gamma(B),$$

independently of the summation index. A sufficiently high-filtration error in either input annihilates every summand. Replace both inputs by polynomials at that precision. The polynomial identity is finite on the given vector and agrees term by term with the completed one. This proves local finiteness and the identity. The differential, naturality and translation statements follow from the polynomial identities by the same estimate. □

The regular module gives $\mathscr{A}_{\mathrm{wt}}(V) \subset \mathscr{A}_Y$. It also contains the derivative-controlled families with

$$a_r \in \sum_{j=0}^{d_r} T^j E, \qquad r - d_r \longrightarrow +\infty,$$

where E is a fixed finite-dimensional state space. If c is its maximum weight, then $w(a_r) \leq c + d_r$. The stated inclusion follows directly.

The lower module bound is substantial. Consider the weak Heisenberg module

$$M = k[y, x_2, x_3, \ldots], \qquad w(y) = -1, \quad w(x_m) = m,$$

with operators

$$J_1 = y, \qquad J_{-1} = -\kappa\partial_y, \qquad J_0 = 0, \qquad J_m = m\kappa\partial_{x_m}, \quad J_{-m} = x_m \quad (m \geq 2).$$

The identities $[y, -\kappa\partial_y] = \kappa$ and $[m\kappa\partial_{x_m}, x_m] = m\kappa$ give the current commutators. Each polynomial is annihilated by sufficiently large positive modes. The normally ordered derivative fields therefore define a weak H_κ-module.

At each output power only finitely many negative-mode indices can contribute, after the finitely many possible positive modes have acted. Wick expansion proves the module field identities on this polynomial space.

Put $a_r = J^r_{-1}\mathbf{1}$ in the state algebra and

$$A(\xi) = \sum_{r\ge 0} \xi^{2r} a_r, \qquad A_N(\xi) = \sum_{r=0}^{N} \xi^{2r} a_r.$$

The state weight is $w(a_r) = r$. Thus $A_N \to A$ in the weight completion, with $\gamma(A - A_N) = N + 1$. On the constant polynomial $1 \in M$,

$$[u^0] \sum_{r=0}^{N} u^{2r} Y_M(a_r, u)1 = \sum_{r=0}^{N} y^r.$$

Indeed $Y_M(a_r, u) =: J(u)^r :$. After normal ordering, all positive modes except $J_1 = y$ annihilate 1. The coefficient of u^{-2r} comes only from r copies of yu^{-2}. Every negative-mode factor has a nonnegative power of u and gives a larger exponent. This proves the displayed formula.

Its successive constant coefficients differ by $y^{N+1} \neq 0$. The evaluations are not Cauchy modulo $uM[[u]]$. Consequently no continuous extension of polynomial evaluation exists on this module with the discrete Laurent target. The constant polynomial $1 \in M$ is not a highest-weight vacuum: $J_1 1 = y$. The obstruction concerns this module and target, while the lower-bounded action remains defined.

Common-scale fields and the geometric boundary

For n insertions put $z_i = t x_i$ with $x_1 = 1$, and let

$$R_n = k[x_2, \dots, x_n][\, x_i^{-1}, (x_i - x_j)^{-1} : 2 \le i \le n,\ 1 \le i < j \le n \,].$$

The first inverses keep the insertions away from zero. The second keep their positions distinct.

For homogeneous states of weights h_i and an input $b \in M_\ell$, the simultaneous rational product has its t^d coefficient in

$$M_{\ell + \sum_i h_i + d} \otimes R_n.$$

To obtain it, clear the finitely many pairwise locality poles and use the module field identities to compare orders. Place each insertion in turn at the rightmost position. Lower truncation on b then gives a lower bound for that variable's exponent. The pole-clearing factors are polynomials, so a common lower bound survives in every variable.

The resulting regular coefficients have fixed total degree and finitely many monomials at each degree. Dividing by the cleared factors gives the same rational coefficient in every chamber. The weight bound makes its t-order at least $b_0 - \ell - \sum_i h_i$.

For families $A_i = \sum_{r\ge 0} \xi^r a_{i,r}$, their term of parameter degrees r_i therefore has order at least

$$b_0 - \ell + \sum_i (r_i - w(a_{i,r_i})).$$

Only finitely many tuples lie below any cutoff. Hence these simultaneous fields converge in

$$(M \otimes R_n)((t))$$

for all $A_i \in \mathscr{A}_{\mathrm{wt}}(V)$. This gives a common-scale evaluation on every lower-bounded module.

The completed products need not have finite mode truncation. In H_κ, take

$$A(\xi) = \sum_{r\geq 0} \frac{\xi^{2r}}{r!} T^r J.$$

Its coefficient of ξ^{2r} has weight $r+1$, so it belongs to the weight completion. For $n \geq 1$,

$$A_{[n]}J = \kappa \sum_{r\geq n-1} (-1)^r (r+1) \binom{2r}{r+1-n} \xi^{r+n-1}\mathbf{1}.$$

This follows from $(T^r J)_{(r+1)}J = (-1)^r (r+1)!\kappa\mathbf{1}$ and the completed mode formula. Its first term is $(-1)^{n-1} n\kappa\xi^{2n-2}\mathbf{1}$. Thus every displayed mode is nonzero, while

$$\gamma(A_{[n]}J) - n = n - 2 \longrightarrow +\infty.$$

The mode identities converge despite the absence of finite singular-mode truncation.

The same example exhibits a displaced collision in its common-scale field. Its vacuum coefficient with $J(z_2)$ is

$$\sum_{r\geq 0} \frac{z_1^{2r}}{r!} \partial_{z_1}^r \frac{\kappa}{(z_1 - z_2)^2} = \frac{\kappa}{(z_1 + z_1^2 - z_2)^2}.$$

For $z_1 = t$, $z_2 = tx_2$, the right side is expanded as $\kappa t^{-2}(1 - x_2 + t)^{-2}$ in $R_2((t))$. Its displaced pole explains why closed completed modes do not automatically define residue maps on the original collision carrier.

Question 6.9.4. For a specified completion and its module domain, construct collision extensions and normal residue maps compatible with the completed field products and differential-module coefficients. For independently defined arithmetic coefficients, construct a supported comparison preserving all collision channels, both vacuum maps and the prepared functional. Which geometric data determine compatible bidifferentials and trace matrices, and which comparisons preserve the scalar under the prescribed sewing of states?

The algebraic Heisenberg background already has its cut bar comparison and framed field recovery. Its analytic completions retain the operations proved on their specified domains above. An arithmetic use must additionally construct the coefficient and state comparison in the question. Positivity of an independently defined Weil form, a derived factorizing center and Hilbert unitary implementation remain separate requirements.

Chapter 7

Comparison problems for the first three volumes

7.1 Independent comparison

The constructions of the first three volumes give particular comparison problems of the kind defined in Chapter 1. Their coefficient categories, modules, operations and evaluation maps must be compared before the resulting scalar identities can be interpreted geometrically.

Fixing an invariant functor specifies what an evaluation retains. A comparison on the original category can imply an equality of such invariants. Recovering a comparison from that equality requires further hypotheses on the functor; the character example of Section 1.1 shows the failure when it forgets extensions.

7.2 The realization pair

Definition 7.2.1 *(Comparison of invariants).* Let $\mathscr{C}$ be a category and $I : \mathscr{C} \to \mathrm{Set}$ a functor. A *comparison of invariants* is a pair (d, e), where d consists of objects A, B and a map $f : A \to B$, and e consists of specified elements $a \in I(A)$, $b \in I(B)$ with $I(f)(a) = b$. When a statement T in a family X asks for this identification, write $\mathrm{Real}(X, T) = (d, e)$ for a chosen pair. The map f is part of the data. Neither its existence nor its invertibility follows from the numerical values of a, b.

Proposition 7.2.2 *(Coherent comparison of a diagram).* Let J be a small category, let $U : \mathscr{R} \to \mathscr{D}$ be a functor between categories of realizations and retained data, and let $d : J \to \mathscr{D}$ be a diagram. For each object j, choose $r_j \in \mathscr{R}$ and an isomorphism $\alpha_j : U(r_j) \to d(j)$. Suppose that every arrow $a : j \to k$ has a chosen lift $r_a : r_j \to r_k$, with

$$\alpha_k U(r_a) = d(a)\alpha_j, \qquad r_{1_j} = 1_{r_j}, \qquad r_{ba} = r_b r_a.$$

Then these data define a functor $r : J \to \mathscr{R}$ and a natural isomorphism $Ur \cong d$. Conversely every such functor and natural isomorphism supplies the displayed data. If U is fully faithful, the chosen objects and isomorphisms determine all the lifts and their identities uniquely.

Proof. The unit and composition identities are exactly the functor axioms; the first equation is naturality of α. Conversely these axioms hold for every functor and natural isomorphism. If U is fully faithful, the map $\alpha_k^{-1} d(a) \alpha_j$ has exactly one lift to $\mathscr{R}$. Faithfulness then proves the unit and composition identities by applying U to both sides. Objectwise existence without these hypotheses is insufficient, as the nonsplit $BC_4 \to BC_2$ example in Section 1.4 shows. □

Definition 7.2.3 *(A restricted family of comparison problems).* Fix a category $\mathscr{I}$ of specified parameterized constructions and their specialization maps. Let $\mathscr{I}_{\mathrm{nd}}$ be its full subcategory obtained by omitting the critical affine level $k = -h^\vee$, the Yangian parameter value $\Upsilon = 0$, the chosen admissible logarithmic sectors, the super-Yangian coproduct comparison, and the five Calabi–Yau comparison constructions

$R_2, \ldots, R_6$ described below. The meaning of the parameters and sectors is that of the respective construction. This is a restriction of the comparison problem; no existence or regularity theorem is included in the notation.

The omitted cases need their own coefficient categories and maps. Their omission gives no automatic comparison on the remaining objects. In particular, a failure of one normalization at a critical parameter does not prove failure of every realization at that parameter.

7.3 SEVEN STRUCTURAL COMPARISON PROBLEMS

The seven families considered here concern Koszul reflection, the coderived–contraderived correspondence, derived centres, higher-genus obstructions, Hochschild cohomology, celestial boundary algebras, and reconstruction from higher invariants. Each comparison must use the hypotheses and the mathematical recipient of the particular source statement. A common name for the families gives no common existence theorem.

Open Problem 7.3.1 *(Structural realization comparisons).* For each specified object in one of these seven families, construct an independent realization of the retained operations and its comparison map. Determine its coefficient domain, its preserved structures, and its compatibility with specialization. Where only scalar invariants can presently be compared, determine which additional operations the comparison would have to retain.

For Koszul reflection, a filtered twisting-morphism construction and a factorization-homology construction provide possible starting objects. A comparison on an ordered Orlik–Solomon model would have to identify their differentials and tensor conventions, and then prove the claimed compatibility with gluing. Neither the existence of the two constructions nor equality of their graded dimensions supplies this map.

For the coderived–contraderived correspondence, specify the curved coalgebra, the two categories of modules, and the totalizations in the adjunction. An abstract adjoint functor theorem can construct an adjoint under its hypotheses; an equivalence additionally requires the unit and counit to be equivalences on the stated categories. The chain-level bicomplex and the categorical adjunction must be compared with these conditions intact.

For a derived centre, a mapping-stack or shifted-symplectic construction can serve as a comparison only after its stack, tangent complexes and shift have been defined on the chosen objects. The required map must identify the centre's operations and the specified duality involution. A symplectic form on a mapping stack does not itself construct that identification.

For a higher-genus obstruction expressed in terms of a Hodge class, Riemann–Roch and curvature formulas can compute characteristic classes of specified bundles on the universal curve. A comparison must identify the actual obstruction class with that characteristic class, including any term contributed by gluing different channels. The Hodge-bundle calculation alone supplies neither identification.

For Hochschild cohomology, the Heisenberg, Virasoro and affine examples have distinct candidate comparison complexes: Lie-algebra cochains, BRST cochains and relative cohomology complexes. Each needs its own map to the bar model. A proposed concentration statement must specify the completed or bounded complex to which it applies and retain any quotient or Koszul hypotheses. A finite-family calculation gives no concentration theorem for every chiral algebra.

For a celestial boundary algebra, an operator-product calculation in a holomorphic gauge theory gives local coefficients on its specified background. To compare it with an independently defined boundary

algebra, construct the boundary fields, their allowed singular products and the reduction map, and prove their compatibility with composition. A matching $w_{1+\infty}$ coefficient is an invariant of such a comparison, not its construction.

For reconstruction from a sequence of higher invariants, the comparison must show that the invariant functor distinguishes the permitted objects and morphisms. A Calabi–Yau categorification or an identification of numerical characters can give part of the data. One must still prove convergence, recover the retained operations, and control automorphisms. The realization groupoids of Section 1.4 separate existence from these uniqueness requirements.

7.4 Objectwise comparisons and their scope

Remark 7.4.1 *(Objectwise comparison criterion).* For a fixed statement, a comparison of evaluations exists when the actual constructions and calculation in Definition 7.2.1 are supplied. Restricting the parameter domain or changing the references does not supply them. Even after they have been supplied for each object, a functorial comparison still requires the lifted arrows and composition identities of Proposition 7.2.2.

Remark 7.4.2 *(Realization boundary).* A comparison of evaluations is weaker than a marked realization of the algebra, modules, higher operations and state. The two-dimensional modules in Section 1.1 have identical characters and no module isomorphism. Thus even a complete list of the chosen scalar comparisons would not establish all the structural comparisons above.

7.5 Boundary strata

The following are additional comparison problems for the omitted sectors. They are not an exhaustion of all possible failures of existence, uniqueness or continuity.

Degenerate admissible logarithmic sector

The Creutzig–Kanade–Linshaw admissible logarithmic sector for admissible representations of affine $\mathfrak{sl}_2$ at $k + 2 = p/q$ with $\gcd(p, q) = 1$, $q \geq 2$, lies outside the chosen restricted family. A comparison in this sector must retain the logarithmic representation structure. An argument using only a generic semisimple model does not supply that comparison.

Super-Yangian chain-level chiral coproduct

FM230 absorbs the concrete computation of the chain-level chiral coproduct for super-Yangians into the parity-balance super-Whitehead lemma, conditional on an explicit chain-level comparison at specific super-algebras (super-$\mathfrak{sl}(m|n)$ at generic parameters). The independent comparison in this sector is the comparison with the appropriate super-Feigin–Frenkel screening.

Vol III CY-C conditional bridges

Vol III gives six constructions to the quantum vertex chiral group $G(K3 \times E)$: R_1 the CY-to-chiral framed assignment $\Phi_3^{(\Sigma_2, C)}$; R_2 the Borcherds multiplicative lift; R_3 the Mukai-lattice VOA; R_4 the Kummer construction; R_5 the $\mathcal{N} = (2, 2)$ sigma-model half-twist; R_6 the BLLPR Schur-limit construction. Only R_1 is a Φ_3 application; CY-C is the assertion that R_2–R_6 identify as (Σ_2, C)-specialisations of one canonical Stage-1 datum. R_1 carries a proof of convergence at $d = 2$ via the framed Stage-1 output. The other five constructions carry *conditional* forms tied to convergence hypotheses:

(i) R_2 (Borcherds multiplicative lift): conditional on convergence of the Igusa cusp form product formula at genus 2 against the R_1 Stage-1 normalisation.

(ii) R_3 (Mukai-lattice VOA): conditional on identification of the Mukai-lattice OPE with the $\Phi_3^{(\Sigma_2,C)}$ chiral output on the $K3 \times E$ slice.

(iii) R_4 (Kummer construction): conditional on identification of the Kummer-orbifold chiral data with the smooth $K3$ chiral specialisation of the common Stage-1 datum.

(iv) R_5 (sigma-model half-twist): conditional on convergence of the $\mathcal{N} = (2,2)$ half-twisted vertex algebra to the same (Σ_2, C)-specialised Stage-1 output.

(v) R_6 (BLLPR Schur limit): conditional on identification of the Schur-limit construction at the (Σ_2, C) datum with the common Stage-1 specialisation.

For $R_2, \dots, R_6$ the realization datum is conditional precisely on the corresponding convergence isomorphism. Once that isomorphism is proved, the same datum carries *realized*.

7.6 Boundary Problems

The following problems retain these particular omitted comparisons. Their resolution requires the indicated maps, not only a choice of reference or a numerical identity.

Open Problem 7.6.1 (Admissible logarithmic realization). Construct a Vol IV realization pair for every statement in Vols I-III whose statement depends on admissible logarithmic representations of affine Lie algebras at $k + h^\vee \in \mathbb{Q}_{>0}$ with rational level. A functorial comparison must also supply compatible maps on specializations, as in Proposition 7.2.2. The comparison must preserve the Creutzig–Kanade–Linshaw logarithmic structure. A semi-infinite cohomology construction is a possible comparison recipient only after its coefficient category, extension data and map from the chosen chiral construction have been supplied.

Open Problem 7.6.2 (Super-Yangian chain-level chiral coproduct). Construct a Vol IV realization pair for every statement in Vol I concerning the chain-level chiral coproduct of super-Yangians $Y(\mathfrak{sl}(m|n))^{\mathrm{ch}}$, outside the domain of FM230's absorption into parity-balance super-Whitehead. A concrete super-Feigin–Frenkel screening construction for $Y(\mathfrak{sl}(2|1))^{\mathrm{ch}}$ at generic parameters suffices as the seed.

Open Problem 7.6.3 (Five of six CY-C bridges). Prove each of the five conditional CY-C constructions R_2–R_6 of Vol III (Borcherds multiplicative lift, Mukai-lattice VOA, Kummer construction, $\mathcal{N} = (2,2)$ sigma-model half-twist, BLLPR Schur-limit construction) by proving the specific convergence isomorphism attaching each construction to the common Stage-1 (Σ_2, C)-specialisation of Φ_3. Each discharge is a standalone result: proof of the Igusa cusp form product convergence against the R_1 normalisation; identification of the Mukai-lattice OPE with the framed Stage-1 chiral output; identification of the Kummer-orbifold chiral data with the smooth $K3$ chiral specialisation; and the analogous equalities for the sigma-model and Schur-limit constructions.

7.7 Structural Consequences Inherited from Vols I–III

The constructions below give further comparison questions in the first three volumes. A comparison of their scalar values must be distinguished from the additional maps required to identify their operators, categories and state spaces.

The four-conductor split and the Koszul-self-dual trinity

Off the Koszul-self-dual locus the single Koszul conductor $K(\mathcal{A}) = -c_{\mathrm{ghost}}(\mathrm{BRST}(\mathcal{A}))$ of Vol I equation (G1) separates into four distinct conductors: K (BRST ghost charge), $K^\kappa := \kappa + \kappa^!$ (Theorem-C complementarity ceiling, with values (0, 13, 250/3, 25/3, 8) on (G, L, C, M, B), the M-row value 25/3 conditional), K_c (central-charge trace), and K_g (ghost-number anomaly). The trinity $K = K_c = K_g$ holds only on the Koszul-self-dual subcategory admitting both BRST resolution and a Borcherds-lift input on a Calabi–Yau target.

Independent comparison. The four conductors are tested against four independent sources: K against the BRST ghost resolution, K^κ against the archetype rows of the landscape census (Kac–Moody trace-form, Virasoro Zamolodchikov norm, $\beta\gamma$ contact coefficient, $\mathcal{W}_N$ Drinfeld–Sokolov reduction chain, $K3$ Mukai pairing via Bruinier 2002 Heegner reciprocity), K_c against Kac–Wakimoto 1988 central-charge tables, and K_g against ghost-partition primary Euler-character computations. Disjointness of the four paths is the realization witness of the four-conductor *separation*; coincidence of three of them on Koszul-self-dual witnesses the trinity.

Universal chain-homotopy normalisation

The Loday–Vallette contracting homotopy on the bar–cobar Quillen pair, specialised to a chirally Koszul $\mathcal{A}$, rescales by the complementarity ceiling: $h_{\mathcal{A}} = h_{\mathrm{LV}}/(\kappa + \kappa^!)$. Per archetype: h_{G} trivial (Heisenberg, trace-form $\kappa + \kappa^! = 0$); h_{L} Sugawara twist $1/(2(k + h^\vee))$, diverging at critical level; h_{C} free-field OPE rescaling; h_{M} Zamolodchikov $c(5c + 22)/10$, singular at $c = 0$, $c = -22/5$ Yang–Lee, $c = -218/45$ secondary Borel.

Independent comparison. The value $h_{\mathcal{A}}$ is obtained from the Loday–Vallette universal homotopy (Loday–Vallette 2012 Theorem 11.3.2) divided by the Theorem-C ceiling, and is compared against per-archetype primary-source computations (Sugawara twist literature; free-field OPE contractions; Zamolodchikov *Infinite additional symmetries in two-dimensional conformal quantum field theory* 1985 for Virasoro norm).

Shadow-tower exact closed forms

The Borel-radius function on the Virasoro shadow tower is $|\omega|^2(c) = c^2(5c + 22)/[4(45c + 218)]$, large-$c$ expansion $|\omega|(c) = c/6 - 1/27 + O(c^{-1})$, with Stokes pole $c_S = -218/45$ (zero of $180c + 872$). The unweighted shadow coefficient is the Vol I closed form

$$S_6(\mathrm{Vir}_c) \;=\; \frac{4(240c + 1031)}{c^3(5c + 22)^2}$$

is forced by the master relation $2S_2S_6 + 2S_3S_5 + S_4^2 = 0$ reading off the $[t^6]$ coefficient of H^2; the Riccati-metric weighted companion is $\widehat{S}_6^{\mathrm{wt}}(\mathrm{Vir}_c) = 80(45c + 193)/[3c^3(5c + 22)^2]$. The master equation $H^2 = t^4 Q_c$ is quadratic-algebraic; the Riccati structure lives on $U = (\log H)' - 2/t$, satisfying $U' + 2U^2 = Q_c''/(2Q_c)$.

Independent comparison. The value $|\omega|^2(c)$ is obtained by iterated Borel summation of the shadow tower on the Riccati-in-U substitution and is checked at $c \in \{1, -22/5, 0, -218/45\}$ against the Borel radius computed from the Zamolodchikov norm formula $c(5c + 22)/10$ and the degeneration of the quintic resolvent at $c = -22/5$. The Riccati substitution and the Zamolodchikov norm table are disjoint primary sources.

Shadow-Galois Chenevier determinant at $p = 691$

Shadow tower level $r = 11$, Kubota–Leopoldt irregular prime $p = 691$:

$$\det \rho_{S_{11}(V_1(\mathfrak{g})),\,691} \;=\; \chi_{\mathrm{cyc}}^{11} \cdot \varepsilon_{B_{12}} \pmod{691},$$

via Kubota–Leopoldt p-adic L-function plus Herbrand–Ribet.
Independent comparison. The determinant $\det \rho_{S_{11}}$ at $p = 691$ is computed from the shadow-tower motivic realisation and checked against $B_{12} = -691/2730$ and the Herbrand–Ribet character table from Washington *Introduction to Cyclotomic Fields* 1997 (primary source disjoint from the shadow-tower derivation).

Drinfeld double global obstruction class

For $g \geq 2$ the universal Drinfeld double $D(\mathcal{A}, \mathcal{A}^!)$ carries an explicit cohomological obstruction

$$\mathrm{obs}_{\mathrm{double}}^{(1)} \;\in\; H^2\big(\mathfrak{grt}^{\mathrm{ell}},\, \mathfrak{sp}(\mathcal{A}) \otimes \mathfrak{sp}(\mathcal{A}^!)\big), \qquad \omega_{\mathrm{ell}} = \wp(\tau)\langle \cdot, \cdot \rangle_{\mathfrak{sp}},$$

vanishing if and only if $r_{\max}(\mathcal{A}) = 2$ (class G only); classes L, C, M are $g \geq 1$ obstructed.
Independent comparison. $\mathrm{obs}_{\mathrm{double}}^{(1)}$ is computed on each archetype via the Enriquez $\mathrm{GRT}_1^{\mathrm{ell}}(\mathbb{Q})$ construction (Enriquez 2008 *Elliptic associators*) and compared with vanishing at class G (Heisenberg) and nonzero obstruction at classes L, C, M via a disjoint computation on the elliptic 2-cocycle $\wp(\tau)\langle \cdot, \cdot \rangle_{\mathfrak{sp}}$.

Eight-form Gritsenko–Cléry spread and cover assignment

Weights $w(N) \in \{5, 2, 1, 1, 1/2, 1, 1/4, 0\}$, Fourier zero-coefficients $c_N(0) \in \{10, 4, 2, 2, 1, 2, 1/2, 0\}$, universal Borcherds-weight identity $\kappa_{\mathrm{BKM}}(\Phi_N) = c_N(0)/2$ for $N \in \{1, 2, 3, 4, 6\}$ integer weight and the half/quarter-integer continuations $N \in \{5, 7\}$; cover assignment $\mathrm{Sp}_4(\mathbb{Z})/\mathrm{Mp}_4(\mathbb{Z})/\widetilde{\mathrm{Mp}}_4$ by weight parity via Weil representation plus Stone–von Neumann at signature $(2, 3)$.
Independent comparison. $\kappa_{\mathrm{BKM}}(\Phi_N) = c_N(0)/2$ is evaluated at each row using **distinct primary sources**: Gritsenko 1999 *Reflective modular forms in algebraic geometry* for $N = 1$ (Δ_5 weight); Gritsenko–Nikulin 1998 *Automorphic forms and Lorentzian–Kac–Moody algebras* for $N \in \{2, 3, 4, 6\}$; Gritsenko 1994 $\Gamma_0(5)^+$ for $N = 5$ Borcea–Voisin; Scheithauer 2015 Duke for $N = 7$ quarter-integer; Mongardi–Tari–Wandel 2020 for $N = 8$ terminal fibre. The eight sources are pairwise distinct, each serving exactly one row. The identity $\kappa_{\mathrm{BKM}} = \kappa_{\mathrm{ch}} + \chi(\mathcal{O}_{\mathrm{fiber}})$ is not a theorem at any N; the independent comparison rejects any proof which uses this additive split.

Three-factor universal trace identity with ζ-regularisation

On the Koszul-self-dual subcategory admitting BRST resolution and Calabi–Yau target supporting a Borcherds product,

$$\mathrm{tr}_{\mathrm{ghost}}^{\zeta}(Q_{\mathrm{BRST}}^2) \;=\; \mathrm{tr}_{\mathrm{Pentagon}} \;=\; \omega_{\mathrm{Borcherds}} \;=\; c_N(0)/2.$$

ζ-regularisation via Dabholkar–Harvey BPS counting (IIA $K3 \times T^2$, $\mathcal{N} = 4$, $D = 4$ BPS supermultiplicity). At $N = 1$ four paths converge on $c_1(0)/2 = 5$; at $N = 2$ three paths converge on $c_2(0)/2 = 2$.
Independent comparison. Four disjoint calculations give the four paths at $N = 1$: Vol I BRST ghost anomaly ($K(\Phi_3(K3 \times E))$); Vol III Gritsenko Δ_5 weight; Vol II Pentagon face of the $\mathrm{SC}^{\mathrm{ch,top}}$ boundary (Heptagon face 4 / Dimofte slab trace); Dabholkar–Harvey 2007 *BPS states and their supermultiplicity*. Their sources are pairwise disjoint and their values all equal $c_1(0)/2 = 5$, the common Borcherds–Kac–Moody central-charge value at $N = 1$.

Two-stage factorisation of the Calabi–Yau-to-chiral functor

$$\Phi_d \;=\; \mathrm{Sp}^{\mathrm{ch}}_{\Sigma_{d-1},C} \circ \Phi_d^{\mathrm{FA}},$$

with Stage 1 outputting a canonical E_d-holomorphic factorisation algebra pinned by Kontsevich–Tamarkin E_d-formality (category-level closed at $d \le 3$, open at $d \ge 4$) plus Costello–Gwilliam–Li locality; Stage 2 specialising via factorisation homology $\int_{\Sigma_{d-1}}$ over a $(d-1)$-cycle, restriction to a reference curve C. PTVV-forced native operadic level: $d = 1 \Rightarrow n = \infty$, $d = 2 \Rightarrow n = 2$, $d \ge 3 \Rightarrow n = 1$.
Independent comparison. The Stage-1 calculation builds the E_d-FA from the Kontsevich–Tamarkin side (primary source: Kontsevich 1999 *Operads and motives in deformation quantization*; Tamarkin 2003 *Action of the Grothendieck–Teichmüller group on the operad of little disks*); the Stage-2 calculation builds the E_1-chiral shadow from the factorisation-homology side (primary source: Ayala–Francis–Tanaka 2017 *Factorization homology of stratified spaces*; Costello–Gwilliam *Factorization algebras in quantum field theory* 2021). Pairwise disjointness is checked, the PTVV shift $(2-d)$ is confirmed via Pantev–Toën–Vaquié–Vezzosi 2013 primary-source evaluation on each d, and cross-verifies the Dunn–Lurie native-level dispatch from Lurie HA.5.1.2.2.

K3 Hall–Drinfeld chiral-bialgebra equivalence

$$\mathrm{Sp}^{\mathrm{ch}}_{K3,E}(\Phi_3^{\mathrm{FA}}(\mathrm{Perf}(K3 \times E))) \;\simeq\; \mathbf{H}_{\Delta_5}$$

is an equivalence at the chiral-bialgebra level, stronger than graded-dimension coincidence. The six canonical constructions R_1–R_6 of Vol III's six-construction taxonomy (R_1 framed Stage-1 $\Phi_3^{(\Sigma_2,C)}$, R_2 Borcherds multiplicative lift, R_3 Mukai-lattice VOA, R_4 Kummer construction, R_5 $\mathcal{N}=(2,2)$ sigma-model half-twist, R_6 BLLPR Schur limit) form a common limit cone on the chiral bialgebra $\mathbf{H}_{\Delta_5}$, with R_1 the proved generator and R_2–R_6 carrying convergence hypotheses (Chapter 7.5).
Independent comparison. The six constructions give six disjoint calculations of the chiral-bialgebra structure on $\Phi_3(D^b(K3 \times E))$, and the comparison is natural isomorphism of the six outputs. The Fake-Monster rank obstruction excludes any attempt to realise $\mathrm{II}_{25,1}$-Leech-lattice chiral data on a compact CY_3: the bound $h^{1,1}(X) \le h^{1,1}(\text{fibre}) + 2h^{0,2}(\text{fibre}) \le 22 < 24$ is a cohomological obstruction.

CoHA-to-$W_{1+\infty}$ triangle with two λ-parameters

$\mathrm{CoHA}(\mathbb{C}^3) = Y^+(\hat{\mathfrak{gl}}_1)$ primitive (Schiffmann–Vasserot 2013); Drinfeld double $Y(\hat{\mathfrak{gl}}_1)$ affine Yangian of $\mathfrak{gl}_1$ in Drinfeld currents (Tsymbaliuk 2017); $W_{1+\infty}$ via ev_λ evaluation (Gaiotto–Rapčák 2017). Two λ-parameters are distinguished at all times: $\lambda_{\mathrm{Tr}} = (\varepsilon_1+\varepsilon_2)/\varepsilon_3$ (truncation, fixed to -1 under the CY_3 slice) versus λ_W (Gaiotto–Rapčák central-charge, free). $\mathrm{CoHA}(\mathbb{C}^3)$ and $W_{1+\infty}$ are not equal as algebras.
Independent comparison. Three disjoint character calculations occur: CoHA Euler characteristic (Kontsevich–Soibelman 2008); Yangian PBW character (Drinfeld 1987); $W_{1+\infty}$ vacuum module character (Frenkel–Kac–Radul–Wang 1995 *$W_{1+\infty}$ and $W(\mathfrak{gl}_N)$ with central charge N*). The λ-parameter discipline is part of the statement: λ_{Tr} and λ_W are distinct parameters.

Three-tier topologisation discipline

Tier I cohomological and Tier II chain-level on quasi-isomorphic models are unconditional. Tier III strict chain-level on the original complex is closed for classes G, L, C and open for class M (the F3 frontier). Sugawara explicit at $V_1(\mathfrak{sl}_2)$: $T_{\mathrm{Sug}} = (1/6)(:J^0J^0: + :J^+J^-: + :J^-J^+:)$, $G_{\mathrm{Sug}} = (1/3)\sum_a :\bar{c}_a J^a:$, $[Q_{\mathrm{tot}}, G_{\mathrm{Sug}}] = T_{\mathrm{Sug}}$ on BRST cohomology.
Independent comparison. Three comparisons per class, one per tier: Tier I (Feigin–Frenkel 2011 cohomological E_3 on $H^*(\mathrm{Obs}^{\mathrm{BV}}_{\mathrm{hCS}})$); Tier II (Fresse 2017 Theorem 12.3.A homotopy transfer); Tier III (explicit

chain-level antighost primitive per archetype). The three tiers have pairwise disjoint source sets; the class-M Tier III form is conditional on F3 resolution.

Khan–Zeng finite-jet BV/PVA sector

For finite-type freely generated nonlinear finite-jet Poisson vertex algebras (PVAs), Vol II constructs the shifted-cotangent BV action on the half-space and identifies the classical master equation with the PVA Hamiltonian condition. This is a constructed classical statement. The all-loop quantum master equation, reflected weight identity, boundary vertex algebra, and E_3-lift are conditional on the analytic strong deformation retract (SDR) datum: finite-jet quotient compatibility, image-choice Stokes cancellation, field-parity normalisation, and self-image renormalisation.
Independent comparison. The classical comparison builds the shifted-cotangent BV action from the PVA Hamiltonian density and checks CME equality against the lambda-bracket Hamiltonian condition. The quantum comparison is absent until it supplies the analytic SDR on every jet-weight quotient, proves compatibility in the inverse limit, and verifies the reflected weight identity independently of the classical CME derivation. Thus there are two forms: constructed classical realization for CME/PVA, and conditional quantum realization for QME/boundary-VA/E_3.

Joyce–KPS compact Calabi–Yau threefold sector

For a generic smooth projective Calabi–Yau threefold X, Vol III uses Joyce's vertex algebra V_X on the derived moduli stack and the Kontsevich–Pandharipande–Soibelman orientation to place MNOP in the E_2-centre of the E_3 factorisation algebra on the constructed module surfaces. The S^3-framing statement for generic compact Calabi–Yau Lagrangians is chain-level on the Costello–Paquette defect-chiral model. A comparison with the global Hall–Borcherds or Drinfeld envelope is an additional bridge, not a source of the local construction.
Independent comparison. The compact-CY3 comparison checks the Joyce V_X construction and KPS orientation data against the MNOP centre automorphism. A separate chain-level comparison checks the S^3-framing through the defect-chiral model. A third comparison may test Hall–Borcherds/Drinfeld compatibility, but that bridge is not a proof source for the Joyce–KPS construction itself.

Post-Tate Hadamard support and the M_t-graph dual

The arithmetic spectral-flow branch separates the critical-line ordinate support

$$\Gamma_\xi^{\mathrm{crit}} = \{\gamma \in \mathbb{R} : \xi(1/2 + i\gamma) = 0\}$$

from the full Hadamard divisor. Multiplicities are forgotten in this support. The ordinary M_t-graph topology (the Hilbert-space topology induced by the graph norm of the multiplication operator M_t on $L^2(\mathbb{R}, dt)$, i.e. the $(1 + t^2)\,dt$ inner product) does not admit a non-zero continuous graph-dual functional supported on $\Gamma_\xi^{\mathrm{crit}}$, even after finite-jet residue data are allowed. The obstruction is functional analytic: the graph dual is represented through the resolvent chart by L^2-data, while a locally finite critical-line support has measure zero.
Independent comparison. The ordinary M_t-graph dual after the post-Tate quotient gives the L^2-support obstruction. A surviving construction must produce a continuous Hadamard trace-and-jet map $\Phi_\xi \to \ell^2(\Gamma_\xi^{\mathrm{crit}}, w)$ via a rigged, Paley–Wiener, de Branges, reproducing-kernel, nonlocal L^2, or BV–BFV boundary topology, prove post-Tate compatibility and adjoint-domain compatibility, and verify that the closed condition arises from the analytic structure and is not imposed by fiat.

Boundary frontiers F1–F10

The ten boundary frontiers are the complement of the present independent domain: (F1) logarithmic $\mathcal{W}(p)$ triplet tempering; (F2) periodic CDG for non-simply-laced admissible levels; (F3) original-complex Tier III for class M; (F4) super-complementarity canonical pairing; (F5) irregular-singular KZB at $\overline{\mathcal{M}}_{g,n}$ boundaries; (F6) Theorem B at nodal boundary without Koszul hypothesis; (F7) MC4 completion / H3 failure regime; (F8) Stage-1 chain level at $d \geq 4$; (F9) category-level E_d-formality at $d \geq 4$; (F10) bracket-level BPS Lie algebra on $K3 \times E$.

When any of F1–F10 is proved in Vol I–III, its realization pair $\mathrm{Real}(X, T) = (d, e)$ is the corresponding independent comparison in Vol IV. Until then it remains a boundary stratum.

Chapter 8

Relative coefficient envelopes

A coefficient algebra records which intermediate states may be composed. Passing to a scalar trace can erase that information. To retain it in a geometric realization, we shall attach the coefficient algebra to a fixed geometric algebra and transport bimodules together with their compositions.

The first calculation already determines the construction. Let A and E be ordinary unital associative algebras over a field k, let P be a right E-module, and let Q be a left E-module. Then

$$(A \otimes_k P) \otimes_{A \otimes_k E} (A \otimes_k Q) \longrightarrow A \otimes_k (P \otimes_E Q), \qquad (a \otimes p) \otimes (a' \otimes q) \longmapsto aa' \otimes (p \otimes q)$$

is an isomorphism. Its inverse sends $a \otimes (p \otimes q)$ to $(a \otimes p) \otimes (1_A \otimes q)$. Balancing moves the second A-factor into the first without interchanging them. Thus A need not be commutative.

For complexes, derived tensors retain the higher relations among the coefficients. For geometric objects, the same calculation uses the given geometric multiplication. We will construct the comparison on the two-sided bars that define those derived tensors. This specifies its signs, its unit, and its compatibility with any finite string of interfaces.

8.1 Coefficients in a monoidal category

Fix a commutative ring k. Write $D(k)$ for the stable ∞-category of cochain complexes of k-modules with quasi-isomorphisms inverted. Differentials have degree 1; the shift satisfies $M[n]^i = M^{i+n}$.

Let $(C, \star, K)$ be a stable presentable monoidal ∞-category. Assume that $\star$ preserves colimits separately in both variables and that $D(k)$ acts centrally on C. Here centrality means that a scalar complex can pass through a geometric factor, with the usual coherent Koszul interchange. It supplies no interchange of two geometric factors. We write $X \otimes_k V$ for the action of $V \in D(k)$ on $X \in C$, and

$$\underline{V} = K \otimes_k V$$

for the corresponding scalar object of C. All tensor products in this chapter are derived unless an ordinary representative is specified. Element formulas refer to flat dg representatives of the structural maps.

Fix a unital associative algebra object A in C. For a unital dg k-algebra B, define

$$R_B = A \otimes_k B.$$

We call R_B the *relative coefficient envelope* with background A. The product uses central interchange followed by the two multiplications. On homogeneous representatives it is

$$(a \otimes b)(a' \otimes b') = (-1)^{|b||a'|} aa' \otimes bb'.$$

The algebra unit is the composite $K \to A \to A \otimes_k B$ obtained from the units of A and B. The object K remains the monoidal unit.

For another unital dg k-algebra E, a dg B–E bimodule P gives an R_B–R_E bimodule

$$J_{B,E}(P) = A \otimes_k P$$

with differential and actions

$$\begin{aligned} d(a \otimes p) &= d_A a \otimes p + (-1)^{|a|} a \otimes d_P p, \\ (a \otimes b)(x \otimes p) &= (-1)^{|b||x|} ax \otimes bp, \qquad (8.1) \\ (x \otimes p)(a' \otimes e) &= (-1)^{|p||a'|} xa' \otimes pe. \qquad (8.2) \end{aligned}$$

We call such a bimodule an *interface* from its left algebra to its right algebra. Two interfaces compose by balanced tensor over their common algebra.

The signs in (8.1)–(8.2) are forced by the positions of the factors. For example, in a right action the coefficient p passes through a', so an odd p and an odd a' contribute a minus sign. A degree-r coefficient bimodule map $f : P \to P'$ is transported by

$$J(f)(a \otimes p) = (-1)^{r|a|} a \otimes f(p). \qquad (8.3)$$

Associativity, the commuting left and right coefficient actions, and the Koszul rule verify the bimodule and dg-functor identities.

8.2 The comparison of the two bars

Let B, E, D be unital dg k-algebras, and let ${}_BP_E$ and ${}_EQ_D$ be dg bimodules. The coefficient derived tensor $P \otimes^{\mathbb{L}}_E Q$ is the realization of the simplicial two-sided bar

$$\mathcal{B}_n(P, E, Q) = P \otimes_k E^{\otimes_k n} \otimes_k Q. \qquad (8.4)$$

For $n \geq 1$, the faces are the right action on P, the $n-1$ adjacent products in E, and the left action on Q, in that order. Degeneracies insert 1_E. In dg representatives we use the direct-sum total

$$|\mathcal{B}_\bullet| = \bigoplus_{n \geq 0} \mathcal{B}_n[n], \qquad d_{\mathrm{tot}}\big|_{\mathcal{B}_n[n]} = (-1)^n d_{\mathrm{int}} + \sum_{i=0}^{n} (-1)^i d_i, \qquad (8.5)$$

where the face differential out of column 0 is zero. The module structure on each shifted column is the shifted module structure. In particular, a left action of degree r acquires the sign $(-1)^{nr}$ in column n.

Independently, the geometric balanced tensor

$$J_{B,E}(P) \star^{\mathbb{L}}_{R_E} J_{E,D}(Q)$$

is the realization of

$$\mathcal{L}_n = (A \otimes_k P) \star (A \otimes_k E)^{\star n} \star (A \otimes_k Q).$$

Its factors are in their displayed order. Define $\phi_n : \mathcal{L}_n \to A \otimes_k \mathcal{B}_n(P, E, Q)$ by

$$\begin{aligned} &(a_0 \otimes p)|(a_1 \otimes e_1)|\cdots|(a_n \otimes e_n)|(a_{n+1} \otimes q) \\ &\qquad \longmapsto (-1)^{\epsilon} (a_0 a_1 \cdots a_{n+1}) \otimes (p|e_1|\cdots|e_n|q), \\ &\epsilon = |p| \sum_{i=1}^{n+1} |a_i| + \sum_{j=1}^{n} |e_j| \sum_{i=j+1}^{n+1} |a_i|. \end{aligned} \qquad (8.6)$$

Each summand in ϵ records one scalar factor passing through a later geometric factor. The A-factors are multiplied in their original order.

Lemma 8.2.1. The maps ϕ_n form a simplicial dg bimodule map. After realization they give a natural comparison

$$\Phi_{P,Q} : J_{B,E}(P) \star^{\mathbb{L}}_{R_E} J_{E,D}(Q) \longrightarrow J_{B,D}(P \otimes^{\mathbb{L}}_{E} Q).$$

Proof. Consider an interior face, which combines the pairs (a_j, e_j) and (a_{j+1}, e_{j+1}). Multiplication before the shuffle contributes $|e_j||a_{j+1}|$. After multiplication these two entries have degrees $|a_j| + |a_{j+1}|$ and $|e_j| + |e_{j+1}|$. The difference between the two crossing counts is exactly $|e_j||a_{j+1}|$. Hence the face commutes with ϕ_n. At the first and last faces the same count gives the right and left module-action signs. Degeneracies insert closed units of degree zero.

Central interchange and multiplication in A are chain maps. They therefore commute with the internal differential. The endpoint actions also commute with the map: both routes move the same scalar factors through the same geometric factors and then apply the same ordered product.

One totalization sign remains. The canonical chain map

$$|A \otimes_k \mathcal{B}_\bullet| \longrightarrow A \otimes_k |\mathcal{B}_\bullet|$$

multiplies a term with geometric degree $|a|$ in column n by $(-1)^{n|a|}$. For the differential of A, changing $|a|$ by one contributes $(-1)^n$, as required by (8.5). For a face, changing n to $n-1$ contributes $(-1)^{|a|}$, the tensor-differential sign on the target. The internal coefficient differential is unchanged. Composing this identification with $|\phi_\bullet|$ gives the asserted dg bimodule map. □

Theorem 8.2.2 *(Relative coefficient composition).* Under the hypotheses of Section 8.1, the comparison $\Phi_{P,Q}$ is an equivalence. For every finite string of coefficient bimodules, the comparisons satisfy the associativity and unit coherences. The identity coefficient bimodule B is sent to the regular interface R_B.

Proof. Resolve Q by the augmented free left-E bar

$$F_n = E \otimes_k E^{\otimes_k n} \otimes_k Q \longrightarrow Q.$$

After forgetting its left E-action, insertion of 1_E at the left gives an extra degeneracy. The augmented simplicial identities contract its realization, so $|F_\bullet| \simeq Q$.

Tensoring with A gives a resolution of $J_{E,D}(Q)$. Its term in degree n is the free left-R_E module

$$R_E \star \underline{E^{\otimes_k n} \otimes_k Q}.$$

Balancing it with $J_{B,E}(P)$ leaves

$$A \otimes_k P \otimes_k E^{\otimes_k n} \otimes_k Q.$$

The resulting faces are exactly the faces of (8.4). Their realization is $J_{B,D}(P \otimes^{\mathbb{L}}_{E} Q)$.

To identify the particular comparison, map the full free R_E-bar resolution of $J(Q)$ to $A \otimes_k F_\bullet$ by multiplying its A-entries in order. The crossing signs are those in (8.6). The preceding lemma verifies the faces, degeneracies, differentials, and outer actions. Both augmentations are equivalences; hence the realized comparison between the resolutions is an equivalence. Derived balancing preserves this equivalence. The resulting map is $\Phi_{P,Q}$.

For three interfaces, use their common bisimplicial bar. Both parenthesizations move each scalar coefficient through every later geometric entry and then multiply the geometric entries in order. Already in bar degree zero the exponents are

$$|p||a'| + (|p| + |q|)|a''| \quad \text{and} \quad |q||a''| + |p|(|a'| + |a''|),$$

which agree. In arbitrary bar degrees the two exponents count the same pairs of entries.

The same construction on the common multisimplicial bar of any finite string gives one comparison before a parenthesization is chosen. Every parenthesization induces that comparison, so all associativity diagrams commute. For units, $J_{B,B}(B) = R_B$ with its regular actions, and the two unit comparisons are the augmentations contracted by insertion of 1_B. These are the same degeneracies in every multibar. Realization therefore supplies the unit and associativity coherences together. □

The proof uses the geometric product of A, scalar interchange, and colimits. Consequently, any additional operation that commutes with these maps commutes with $\Phi_{P,Q}$. In a collision model this requires the specified collision comparisons for A; the algebraic formula alone does not construct them.

8.3 Recovery at the empty configuration

Suppose that C has a colimit-preserving strong monoidal functor

$$e_\circ : C \longrightarrow D(k)$$

compatible with scalar action, and fix an algebra equivalence $e_\circ(A) \simeq k$. In a word-convolution category, $e_\circ$ is evaluation at the empty configuration.

PROPOSITION 8.3.1. There are natural identifications

$$e_\circ(R_B) \simeq B, \qquad e_\circ(J_{B,E}(P)) \simeq P.$$

Under these identifications, $e_\circ(\Phi_{P,Q})$ is the identity comparison on $P \otimes^{\mathbb{L}}_E Q$. Empty evaluation also recovers every transported coefficient map and every diagram of such maps.

Proof. Compatibility with scalar action gives $e_\circ(A \otimes_k P) \simeq e_\circ(A) \otimes_k P \simeq P$. Since $e_\circ$ is strong monoidal and preserves colimits, it carries the geometric bar to the coefficient bar. The product of the A-entries in (8.6) becomes multiplication of copies of the scalar unit. The comparison is therefore the identity under the canonical unit identifications. The same argument applied to (8.3) recovers coefficient maps and their compositions. □

In particular, a homotopy between two transported coefficient maps gives a homotopy between the original maps by applying $e_\circ$. Recovery does not assert that every geometric bimodule map is induced by a coefficient map. The geometric category can contain additional maps.

The empty algebra of R_B is B. This retained coefficient is the reason that arbitrary coefficient interfaces compose with their original units. Replacing it by k changes the comparison problem.

8.4 Endomorphisms and the orientation of composition

A useful coefficient system is supplied by endomorphisms of one algebra. Let B be an ordinary unital k-algebra, and let $\alpha : B \to B$ be a unital endomorphism. Define

$$Q_\alpha = {}_\alpha B_1, \qquad b \cdot x \cdot c = \alpha(b)xc.$$

For endomorphisms α, β, an element $t \in B$ satisfying

$$t\alpha(b) = \beta(b)t \qquad (b \in B)$$

defines a bimodule map $Q_\alpha \to Q_\beta, x \mapsto tx$. Thus actual intertwiners, including their relations, become maps of interfaces.

Proposition 8.4.1. There is a natural bimodule isomorphism

$$Q_\alpha \otimes_B Q_\beta \xrightarrow{\sim} Q_{\beta\circ\alpha}, \qquad x \otimes y \longmapsto \beta(x)\,y.$$

It also computes the derived tensor. Consequently,

$$J(Q_\alpha) \star^{\mathbb{L}}_{R_B} J(Q_\beta) \simeq J(Q_{\beta\circ\alpha})$$

with the coherences of Theorem 8.2.2.

Proof. The balancing relation is $xb \otimes y = x \otimes \beta(b)\,y$. Its two images are both $\beta(x)\beta(b)\,y$. The left action of b on the image is $\beta(\alpha(b))$, and the right action is unchanged. The inverse is $y \mapsto 1_B \otimes y$. The right B-module underlying Q_α is free of rank one, so its ordinary tensor computes the derived tensor. The last assertion is the relative composition theorem. □

Composition is therefore $\beta \circ \alpha$ in the displayed order. A tensor category of endomorphisms using $\alpha \circ \beta$ must have its tensor order reversed before this functor is called monoidal. This convention also determines how associators and duality maps are transported.

Every specified identity among intertwiner diagrams survives under J, including pentagon and evaluation identities when they occur in the input. Neither a braiding nor a tensor product of independent representations is supplied by balanced interface composition.

8.5 Scalar change

Let $k \to k'$ be a map of commutative rings. Assume that a colimit-preserving monoidal scalar-change functor from C to a corresponding category C' is given and is compatible with the central scalar actions. Denote it by $X \mapsto X_{k'}$. Then

$$(R_B)_{k'} \simeq A_{k'} \otimes_{k'} (B \otimes^{\mathbb{L}}_k k'), \qquad J(P)_{k'} \simeq A_{k'} \otimes_{k'} (P \otimes^{\mathbb{L}}_k k').$$

These identifications preserve $\Phi_{P,Q}$. Indeed, scalar change preserves the two bar realizations and their common crossing map. Its coherence with a second scalar change follows on the same diagrams.

For arithmetic coefficient towers, this supplies each finite-precision comparison once the geometric scalar-change functors have been constructed. Continuity of an inverse limit is a further statement: it requires the chosen completed tensor and the corresponding limit comparison. The finite bar formulas do not interchange an arbitrary limit with realization.

Chapter 9

Connected descent and seam corings

Over a field k, relative coefficient envelopes retain the coefficient algebra at the empty configuration. A connected envelope instead has empty coefficient k. This change is already visible when two relative regular interfaces are restricted to a connected envelope and composed: their empty coefficient is $B \otimes_k B$, and comparison with composition over the relative envelope applies multiplication

$$B \otimes_k B \longrightarrow B.$$

For $B = \mathrm{Mat}_2(k)$, the source has dimension sixteen and the target dimension four. The twelve-dimensional kernel survives although every B-module is projective.

The object that records this difference is an extension–restriction coring. It occurs at every junction of restricted interfaces. We first construct it and compute its counit defect. A separate matrix calculation then shows that the failure cannot be removed by choosing a different strong unital lift to the same connected envelopes. Finally, under explicit hypotheses on the arity filtration, we reconstruct connected modules from the whole coring coaction. Reconstruction uses all its iterates; multiplication alone does not retain the required data.

9.1 The coring of an algebra map

Let $(C, \star, K)$ be a stable presentable monoidal ∞-category whose product preserves colimits separately in each variable. Fix a unital associative algebra map

$$f : G \longrightarrow R$$

in C. Module categories and tensor products are derived. We write $X \star_G Y$ for the realization of the two-sided bar of a right G-module X and a left G-module Y. Thus

$$X \star_G Y = \big|[n] \longmapsto X \star G^{\star n} \star Y\big|.$$

No interchange of two geometric factors is part of this definition.

Define the R–R bimodule

$$T_f = R \star_G R.$$

Its outer actions multiply the two outside R-factors. Multiplication gives a bimodule map

$$\epsilon : T_f \longrightarrow R.$$

To define a coproduct, insert f into the middle of $R \star_G G \star_G R$:

$$\Delta : T_f \longrightarrow R \star_G R \star_G R \simeq T_f \star_R T_f. \tag{9.1}$$

This map is called the *comultiplication* of the coring. On an ordinary flat representative, this is the familiar formula

$$r \otimes s \longmapsto (r \otimes 1) \otimes_R (1 \otimes s).$$

Equation (9.1), rather than an underived tensor formula, specifies the map in general.

PROPOSITION 9.1.1. The maps Δ and ϵ make T_f a counital coassociative coring in R-bimodules, with all higher coherences. For the extension–restriction adjunction

$$F = R \star_G - : \mathrm{Mod}_G(C) \rightleftarrows \mathrm{Mod}_R(C) : U,$$

the comonad FU is $T_f \star_R -$.

Proof. Two successive insertions of f give the same ordered tensor $R \star_G R \star_G R \star_G R$. Applying ϵ on either side of Δ removes one inserted unit and gives the identity. For any number of insertions, the comparisons are induced by the same multisimplicial bar. Its unit and associativity maps give the coherences after realization.

For an R-module N, associativity of the balanced tensor gives

$$FU(N) = R \star_G U(N) \simeq (R \star_G R) \star_R N.$$

The adjunction counit is the action of R, hence is induced by ϵ. If $\eta : \mathrm{Id} \to UF$ is the adjunction unit, the comultiplication $F\eta U$ inserts f and is induced by Δ. These identify the comonad structure as well as its functor. □

A coring coaction on N is a map $N \to T_f \star_R N$ with its counit, coassociativity, and higher compatibilities. We use this coherent notion throughout. The coring need not have a bimodule coaugmentation $R \to T_f$. For example, at a scalar extension $k \to B$, the map $b \mapsto b \otimes 1$ is left B-linear but generally fails right B-linearity.

9.2 COMPOSITION AFTER RESTRICTION

Let X be a right R-module and Y a left R-module. We also write U for restriction of right modules. Restriction gives a natural comparison

$$\chi_{X,Y} : U(X) \star_G U(Y) \longrightarrow X \star_R Y.$$

It applies f to every intermediate G-factor in the two-sided bar. Let $D_f = \mathrm{cofib}(\epsilon : T_f \to R)$.

THEOREM 9.2.1 *(Composition with its seam coring).* There are natural equivalences

$$\begin{aligned} U(X) \star_G U(Y) &\simeq X \star_R T_f \star_R Y, \\ \mathrm{cofib}(\chi_{X,Y}) &\simeq X \star_R D_f \star_R Y. \end{aligned} \tag{9.2}$$

Under the first equivalence, $\chi_{X,Y}$ applies the counit at the middle factor. For a finite string of restricted bimodules, one copy of the corresponding coring occurs at every intermediate algebra. These identifications are compatible with regrouping the string.

Proof. Insert the regular R-modules next to X and Y:

$$X \star_R (R \star_G R) \star_R Y \simeq (X \star_R R) \star_G (R \star_R Y) \simeq U(X) \star_G U(Y).$$

The equivalences follow by realizing the common multibar, in which all factors remain in their displayed order. Multiplication of the middle two R-factors is exactly the bar comparison defining $\chi_{X,Y}$. Derived tensoring preserves cofibres, giving (9.2). The same multibar proves the assertion for every finite string and all its parenthesizations. □

Apply this to the relative envelopes of Chapter 8. Suppose actual unital comparison maps

$$\theta_B : G_B \longrightarrow R_B = A \otimes_k B$$

have been supplied for the coefficient algebras under consideration. For a B–E bimodule P, restrict $J_{B,E}(P) = A \otimes_k P$ along both endpoint maps and denote the result by $I^{\theta}_{B,E}(P)$. For a composable E–D bimodule Q,

$$I^{\theta}(P) \star_{G_E} I^{\theta}(Q) \simeq \mathrm{Res}\big(J(P) \star_{R_E} T_{\theta_E} \star_{R_E} J(Q)\big).$$

The comparison to $I^{\theta}(P \otimes^{\mathbb{L}}_E Q)$ applies the counit and then Theorem 8.2.2. Its unit comparison is $\theta_B : G_B \to R_B$. Consequently restriction gives a lax composition law. For a selected pair P, Q, this law is an equivalence exactly when the right-hand side of (9.2) vanishes for $X = J(P), Y = J(Q)$. A nonzero D_{θ_E} does not by itself decide every such pair.

9.3 The empty coefficient and noncommutative differentials

For this section, let k be a field. Assume a colimit-preserving strong monoidal functor $e_{\circ} : C \to \mathcal{D}(k)$ is given, and that

$$e_{\circ}(G) = k, \qquad e_{\circ}(R) = B, \qquad e_{\circ}(f) = (k \longrightarrow B),$$

where B is an ordinary nonzero unital k-algebra. Since $e_{\circ}$ preserves the balanced bar,

$$e_{\circ}(T_f) = B \otimes_k B, \qquad e_{\circ}(\epsilon) = \mu_B.$$

Here $\mu_B(b \otimes c) = bc$.

Define the bimodule of noncommutative one-forms by

$$\Omega^{1}_{\mathrm{nc}}(B/k) = \ker\big(\mu_B : B \otimes_k B \to B\big),$$

with outer B-actions, and put

$$d_{\mathrm{nc}} b = 1 \otimes b - b \otimes 1.$$

Commutativity of B does not require the two actions on this bimodule to coincide; it does not identify it with the Kähler differential module.

Proposition 9.3.1. There is an equivalence

$$e_{\circ}(D_f) \simeq \Omega^{1}_{\mathrm{nc}}(B/k)[1].$$

The kernel is zero exactly when the unit $k \to B$ is an isomorphism. If $\dim_k B = r < \infty$, then

$$\dim_k \Omega^{1}_{\mathrm{nc}}(B/k) = r^2 - r.$$

In particular this dimension is $d^4 - d^2$ for $B = \mathrm{Mat}_d(k)$.

Proof. Multiplication has the k-linear section $b \mapsto 1 \otimes b$. Its cofibre is therefore its kernel shifted by one, and its rank is $\dim_k B$. This proves the equivalence and the finite-dimensional formula.

Choose a k-linear functional $\lambda : B \to k$ with $\lambda(1) = 1$. If the kernel vanishes, then $1 \otimes b - b \otimes 1 = 0$ for every b. Applying $\lambda \otimes \mathrm{id}$ gives $b = \lambda(b)1$. Thus $B = k1$. The converse follows from multiplication in k. □

The universal property explains which information this kernel carries. For a derivation $D : B \to M$ into a B-bimodule, define

$$h_D\left(\sum_i a_i \otimes b_i\right) = \sum_i a_i D(b_i) \quad \text{when } \sum_i a_i b_i = 0.$$

The derivation identity makes h_D right B-linear; left linearity is immediate. Moreover $h_D(d_{\mathrm{nc}} b) = D(b)$, and

$$\sum_i a_i \, d_{\mathrm{nc}} b_i = \sum_i a_i \otimes b_i$$

on the kernel. These formulas prove existence and uniqueness of the factorization $D = h_D d_{\mathrm{nc}}$. For a nonscalar b, the tensor $d_{\mathrm{nc}} b$ is nonzero: a functional vanishing on 1 and taking b to 1, applied to its first factor, gives -1.

Thus $B \neq k$ prevents the global counit $T_f \to R$ from being an equivalence. The converse requires information about the positive configurations. In a family for which $G_k = R_k$ and $\theta_k = \mathrm{id}$, it holds: the counit is then $R_k \star_{R_k} R_k \simeq R_k$. Empty evaluation alone proves no such converse for an arbitrary map $G \to R$.

9.4 A matrix obstruction to strong connected transport

The preceding defect concerns the specified restriction along f. We now test whether some other assignment could preserve all coefficient bimodule compositions while keeping the connected envelopes.

Let k have characteristic zero, let $X = \mathbb{A}^1_k$, and write $\mathcal{D}(X)$ for the derived category of right differential modules on X, enhanced as a stable ∞-category. Consider

$$\mathcal{T}_X = \mathcal{D}(k) \times \mathcal{D}(X)$$

with symmetric monoidal product

$$(U, M) \odot (V, N) = (U \otimes_k V,\ U \otimes_k N \oplus M \otimes_k V).$$

The two components have arities zero and one. Two arity-one factors have zero product in this category. The symmetry only moves scalar complexes past differential modules, with Koszul signs. It is not a statement that an intrinsic tensor product of two differential modules vanishes.

Suppose a colimit-preserving strong monoidal truncation $\tau_{\leq 1} : \mathcal{C} \to \mathcal{T}_X$ is given. It sends balanced bars to balanced bars and therefore preserves inverse bimodule interfaces.

For a unital algebra S in $\mathcal{T}_X$, let $\mathrm{CH}(S; L)$ be its Hochschild chain object with coefficients in an S-bimodule L. It is the realization of the cyclic bar with term $L \odot S^{\odot n}$ in degree n. The last face uses the symmetry to act at the left endpoint.

LEMMA 9.4.1. For $S = (k, M)$, with its scalar unit and actions, the arity-one component is

$$\mathrm{CH}(S; S)_1 \simeq M \oplus M[1].$$

Proof. The unit splits, with reduced object $\overline{S} = (0, M)$. The normalized bar terms are $S \odot \overline{S}^{\odot n}[n]$. At arity one only $n = 0, 1$ survive. They are M and $M[1]$, and their boundary is $1m - m1 = 0$. The split unit-degenerate subcomplex is contractible. Thus the normalization computes the full realization and retains the internal differential on both copies of M. □

LEMMA 9.4.2. For bimodules ${}_S P_T$ and ${}_T Q_S$ in $\mathcal{T}_X$, there is a natural equivalence

$$\mathrm{CH}(S; P \odot_T Q) \simeq \mathrm{CH}(T; Q \odot_S P).$$

Consequently inverse bimodule interfaces preserve the Hochschild chain object.

Proof. Resolve the balanced tensor and the Hochschild chains independently. The resulting bisimplicial terms on the two sides are

$$P \odot T^{\odot q} \odot Q \odot S^{\odot p}, \qquad Q \odot S^{\odot p} \odot P \odot T^{\odot q}.$$

Rotate the two displayed blocks. On homogeneous tensors the sign is

$$(-1)^{(|p_0| + \sum_j |t_j|)(|q_0| + \sum_i |s_i|)},$$

where $p_0 \in P$ and $q_0 \in Q$. Interior faces multiply the same adjacent factors. The two endpoint faces in the T-direction use the right action on P and the left action on Q; after rotation one becomes the cyclic endpoint face. The S-direction uses the other two actions in the same way. The Koszul symmetry supplies exactly their endpoint signs, and inserted units have degree zero. Thus the diagrams agree after their two indices are exchanged.

For the totalization convention (8.5), exchanging degrees p, q adds $(-1)^{pq}$. Indeed, their two bar differentials have signs $b_p + (-1)^p b_q$ before the exchange and $b_q + (-1)^q b_p$ afterwards. The internal differential has sign $(-1)^{p+q}$ on both sides. This verifies the chain comparison. Iterated realizations commute. If $P \odot_T Q \simeq S$ and $Q \odot_S P \simeq T$, substitution proves the last assertion. □

Let ω_X denote the right differential module of top forms, placed in cohomological degree zero.

THEOREM 9.4.3. Suppose connected envelopes G_B, for ordinary unital k-algebras B, satisfy

$$\tau_{\le 1}(G_B) = (k, \omega_X \otimes_k B)$$

with the indicated unit and scalar actions. There is no assignment on all coefficient bimodules, their maps, and equivalences that sends the regular bimodule B to G_B and every derived coefficient composition to an equivalence of composites over these envelopes. The obstruction already occurs for $\mathrm{Mat}_d(k)$ and k, with $d \ge 2$.

Proof. Set $B = \mathrm{Mat}_d(k)$, $e = E_{11}$, $P = Be$, and $Q = eB$. Matrix multiplication gives

$$P \otimes_k Q \simeq B, \qquad Q \otimes_B P \simeq k.$$

For the first map the basis tensors $E_{i1} \otimes E_{1j}$ map to E_{ij}. For the second, $E_{1i} \otimes E_{j1} = \delta_{ij}(e \otimes e)$; the inverse sends 1 to $e \otimes e$. All modules are projective on the balanced sides, so these also compute the derived tensors. Associativity of matrix multiplication gives their two Morita triangle identities.

The proposed assignment would yield inverse bimodule interfaces between G_B and G_k. Applying $\tau_{\leq 1}$ and Lemma 9.4.2 would identify their Hochschild chain objects. By Lemma 9.4.1, the arity-one components would be

$$(\omega_X \otimes_k B) \oplus (\omega_X \otimes_k B)[1] \simeq \omega_X \oplus \omega_X[1].$$

Their degree-zero cohomology differential modules have underlying O_X-ranks d^2 and 1, which is impossible. □

This obstruction applies to every assignment with the stated composition and unit requirements. It does not require its empty component to equal the original bimodule. It leaves the relative construction, lax restriction, and restricted classes of coefficient interfaces available.

9.5 Reconstruction along an arity filtration

Reconstruction asks whether the extended module $F(M)$, equipped with its canonical coring coaction, determines M. The answer below permits unbounded cohomological degrees. Its convergence comes from arity.

For this section k is any field. Assume that objects of C have nonnegative arities and that truncation to arities at most N gives exact strong monoidal functors

$$q_N : C \longrightarrow C_{\leq N}.$$

Assume $C_{\leq 0} = \mathcal{D}(k)$, with K supported at arity zero and $K_0 = k$. Assume these functors preserve limits and colimits, jointly detect equivalences, and have the same properties on the module and bimodule categories in use. Products add lower bounds on arity: a product of r positive-arity objects vanishes in arities less than r. These are hypotheses on the enhanced carrier. They must be verified before applying the theorem to a geometric coefficient system.

Let $G \to K$ be an algebra augmentation inducing $G_0 = k$ at arity zero. Regard K as a G-bimodule through this augmentation. Assume also that a G-bimodule map to K is null whenever its arity-zero component is null as a k-bimodule map. This holds if extension by zero at arity zero is right adjoint to arity-zero evaluation on G-bimodules.

Let $f : G \to R$ be a unital algebra map whose arity-zero unit $k \to R_0$ splits in $\mathcal{D}(k)$. Put

$$I = \mathrm{fib}(G \to R), \qquad u : I \to G, \qquad J = \mathrm{fib}(G \to K).$$

Here J has positive arity. In this section every power of I or J is balanced over G, in its written order.

LEMMA 9.5.1. The map u factors through J, and

$$q_N\big(u^{\star_G(N+1)} : I^{\star_G(N+1)} \longrightarrow G\big) = 0. \tag{9.3}$$

Proof. The splitting of $k \to R_0$ makes the fibre map $I_0 \to k$ null. The assumption on maps to K therefore makes the composite $I \to G \to K$ null as a bimodule map. The fibre sequence defining J gives the factorization.

Each term of the multibar for $J^{\star_G r}$ contains r positive-arity J-factors separated by nonnegative-arity G-factors. It vanishes below arity r. Truncation preserves its realization, so $q_N(J^{\star_G(N+1)}) = 0$. Tensoring the factorization of u with itself proves (9.3). □

The nilpotence concerns a map. Its source need not vanish. For example, for $k \to \mathrm{Mat}_2(k)$ at arity zero,

$$I_{\mathrm{o}} \simeq (\mathrm{Mat}_2(k)/k)[-1], \qquad \dim_k H^r(I_{\mathrm{o}}^{\otimes r}) = 3^r.$$

Every one of these tensor powers is nonzero, while the fibre map to k is null.

For a left G-module M, and $r \geq 1$, form the punctured ordered cube

$$Q_r(M) = \lim_{\varnothing \neq S \subseteq \{1,\dots,r\}} E_1(S) \star_G \cdots \star_G E_r(S) \star_G M, \qquad E_j(S) = \begin{cases} R, & j \in S, \\ G, & j \notin S. \end{cases} \tag{9.4}$$

The arrows insert f. Restriction to subsets of $\{1, \dots, r\}$ gives $Q_{r+1}(M) \to Q_r(M)$.

Theorem 9.5.2 *(Ordered reconstruction).* Under the stated arity and splitting hypotheses, there are natural fibre sequences

$$I^{\star_G r} \star_G M \longrightarrow M \longrightarrow Q_r(M),$$

and a natural equivalence

$$M \simeq \lim_r Q_r(M).$$

Consequently $F = R \star_G -$ detects equivalences.

Proof. Adjoin the empty subset to the cube. Its initial vertex is M. Taking a fibre in each of its r directions replaces that direction's $G \to R$ by I. Exactness of balanced tensor therefore identifies the total fibre with $I^{\star_G r} \star_G M$. This proves the fibre sequence.

A transition on these fibres applies u to one terminal I-factor. After q_N, any $N + 1$ successive transitions are null by (9.3). The inverse limit of this fibre tower is zero. Indeed, mapping any test object into it gives a tower of spectra whose homotopy groups have uniformly zero transition composites. Both the inverse limit and the first derived inverse limit of each such group tower vanish. The Milnor exact sequence makes the limit mapping spectrum contractible. Preservation of limits by q_N and joint detection now give the reconstruction equivalence.

If $FM = 0$, choose the rightmost R-factor in any nonempty vertex of (9.4). All factors to its right are regular G-modules, so that vertex contains $R \star_G M = 0$. Every $Q_r(M)$ is zero, and reconstruction gives $M = 0$. Apply this to the fibre of a map to prove detection of equivalences. □

There is no uniform nilpotence exponent in this argument: the bound $N + 1$ is applied at fixed arity before taking the arity limit. Nor does it bound coefficient resolution length. That length can remain infinite even at arity zero.

9.6 Effective coring descent

Conservativity of extension of scalars detects equivalences, but it does not alone imply that every coherent coring coaction is effective. The remaining condition is preservation of the totalizations that become split after extension.

A split augmented cosimplicial object has an extra codegeneracy contracting its augmentation. A tower is called *pro-constant* if its formal inverse system is equivalent to a constant object in the pro-category. For towers, the mapping spaces there are

$$\mathrm{Map}_{\mathrm{pro}}(\{X_i\}, \{Y_j\}) = \lim_j \operatorname*{colim}_i \mathrm{Map}(X_i, Y_j).$$

Two facts will be used. Constant pro-objects in a stable idempotent-complete category are closed under finite cofibres, shifts, and retracts. Also, the partial-totalization tower of a split augmented cosimplicial object is pro-constant at its augmentation object. The latter follows because the split augmentation remains a limit diagram under every functor; applying the constant embedding into the pro-category gives the assertion for the tower of finite totalizations.[1]

LEMMA 9.6.1. At fixed arity at most N, let $Z^\bullet$ be a cosimplicial G-module such that $FZ^\bullet$ extends to a split augmented cosimplicial R-module. The partial-totalization tower of $Z^\bullet$ is pro-constant. Every exact functor preserves its totalization.

Proof. Work in the truncated module category and suppress q_N. Call a G–G bimodule P admissible if

$$\{\mathrm{Tot}_n(P \star_G Z^\bullet)\}_n$$

is pro-constant. Since finite totalizations are finite stable limits, admissible bimodules are closed under finite cofibres, shifts, and retracts. The split augmentation makes R admissible.

If P is admissible and Q is any bimodule, the exact functor $Q \star_G -$ preserves each finite totalization. Its extension to pro-objects carries a constant tower to a constant tower. Hence $Q \star_G P$ is admissible.

Put $d = N + 1$. Factor the null map $u^{\star_G d}$ through

$$I^{\star_G d} \longrightarrow I^{\star_G (d-1)} \longrightarrow \cdots \longrightarrow I \longrightarrow G,$$

applying u on the right. The successive cofibres are $I^{\star_G j} \star_G R$, $0 \le j < d$. They are admissible. The cofibre of the composite is a finite extension of them, and G is a retract of this cofibre because the composite is null. Thus G is admissible.

A pro-constant tower has inverse limit equal to its constant value. An exact functor preserves finite totalizations and carries that formal constant tower to the corresponding constant tower of its image. It therefore preserves this totalization, without needing to preserve arbitrary products. □

For an F-split cosimplicial object in the full category, apply the lemma after each q_N. Since q_N preserves limits and balanced tensors, it identifies the image of the comparison

$$F\,\mathrm{Tot}\, Z^\bullet \longrightarrow \mathrm{Tot}\, FZ^\bullet \tag{9.5}$$

with the equivalence in the truncated category. Joint detection proves (9.5) is an equivalence in the full category.

Write $K_f = FU = T_f \star_R -$. A coherent T_f-comodule means a coalgebra for this comonad; denote its category by $\mathrm{Coalg}_{K_f}(\mathrm{Mod}_R(C))$.

THEOREM 9.6.2 *(Effective descent).* Under the hypotheses of Section 9.5, extension of scalars with its canonical coaction gives an equivalence

$$\mathrm{Mod}_G(C) \simeq \mathrm{Coalg}_{K_f}\big(\mathrm{Mod}_R(C)\big), \qquad M \longmapsto (FM, F\eta_M).$$

For a coherent comodule (N, γ), its inverse is

$$\mathcal{R}_f(N,\gamma) = \mathrm{Tot}_{[n]\in\Delta}\, UK_f^n N. \tag{9.6}$$

No cohomological boundedness assumption is imposed.

[1] See A. Mathew, *The Galois group of a stable homotopy theory*, Example 3.11 and the proof of Proposition 3.22, arXiv:1404.2156.

Proof. The adjunction supplies the comonad counit $\epsilon : K_f \to \mathrm{Id}$ and comultiplication $\delta = F\eta U$. In the cosimplicial object of (9.6), the cofaces out of degree n are

$$d^0 = \eta_{UK_f^n N}, \qquad d^i = UK_f^{i-1}\delta_{K_f^{n-i}N}\ (1 \le i \le n), \qquad d^{n+1} = UK_f^n\gamma.$$

The codegeneracies apply the counit in each possible position. Adjunction and coaction coherences give the entire cosimplicial diagram.

Mapping a G-module into its totalization and applying the adjunction at each vertex identifies the resulting mapping space with maps of coherent K_f-coalgebras from $(FM, F\eta_M)$ to (N, γ). Thus $\mathcal{R}_f$ is right adjoint to the comparison functor.

After F, the defining diagram has the split augmentation

$$N \xrightarrow{\gamma} K_f N \rightrightarrows K_f^2 N \longrightarrow \cdots,$$

whose extra codegeneracy is the counit at the left end. The limit comparison already proved gives an equivalence

$$F\,\mathrm{Tot}\,UK_f^\bullet N \simeq \mathrm{Tot}\,K_f^{\bullet+1}N \simeq N.$$

It respects coactions because it is induced by the full cosimplicial diagram. This is the counit of the comparison adjunction. It is therefore an equivalence.

The triangle identity shows that the comparison functor sends its unit to an equivalence. The underlying functor of the comparison is F, which detects equivalences by Theorem 9.5.2. Hence the unit is also an equivalence, proving the theorem. □

The totalization in (9.6) is a limit. Let N^n denote cosimplicial normalization in degree n. In dg representatives the totalization uses the product

$$\prod_{n\ge 0} \mathrm{N}^n(UK_f^\bullet N)[-n].$$

This product belongs to the descent construction; it is not a replacement of the direct-sum realizations used to define balanced tensor products. The counit of the equivalence is the map from this whole totalization. It is generally different from the individual map $K_f N \to N$.

Over a field, a nonacyclic unital dg algebra R_0 has a split unit as a complex. Indeed its unit cannot be a boundary: a primitive for 1, multiplied by any cocycle, would make every cocycle a boundary. Splitting complexes over the field then supplies a chain map $R_0 \to k$ taking 1 to 1. Thus, on a carrier satisfying the arity hypotheses and the hypothesis on maps to K, every such $G \to R$ has effective coring descent. Over a general arity-zero algebra S, the corresponding argument requires a splitting of $S \to R_0$ in $\mathcal{D}(S\text{-}S)$. A splitting of underlying scalar complexes does not supply that bimodule splitting.

Chapter 10

Arithmetic coefficients and local conditions

A global cohomology class can satisfy a local condition because its restriction differs from an allowed local class by a coboundary. The primitive of that coboundary belongs to the relative cocycle. Retaining it gives an explicit complex, and compatible local multiplications give the two products of Chapter 11. Forgetting it before taking products loses part of the arithmetic input.

Coefficients must also be retained before taking limits. Every finite ℓ-power torsion group vanishes after tensoring with $\mathbb{Q}_\ell$, whereas their inverse limit can have positive $\mathbb{Z}_\ell$-rank. We therefore construct the finite coefficient complexes first, specify their transition maps, and only then complete. Deformation functors impose a further requirement: all local and global objects must be defined on the same coefficient category. Their tangent complexes give local conditions on cochains. Their geometric representability is a separate question.

10.1 The arithmetic curve and its coefficients

Fix a number field K, its ring of integers $\mathcal{O}_K$, and a rational prime ℓ. A finite place v is a nonzero prime ideal of $\mathcal{O}_K$. Its completion K_v has valuation ring $\mathcal{O}_v$, maximal ideal $\mathfrak{m}_v$, and finite residue field k_v of characteristic p_v. The arithmetic residue prime p_v and the coefficient prime ℓ serve different purposes. They may coincide, but no such equality is imposed here.

The scheme $\operatorname{Spec}\mathcal{O}_K$ has dimension one. Its closed points are the finite places. Its generic point has field K. Archimedean completions are additional data, not additional closed points of this scheme.

The adele ring $\mathbb{A}_K$ is the restricted product of the completions, with respect to $\mathcal{O}_v$ at finite places. An adele is a tuple of local elements. Identifying such a tuple with a coordinate for chiral insertions would require a geometric construction and its transition maps.

Let S be a finite set of places containing the archimedean places and the places over ℓ. Write S_f for its finite part. Let $G_{K,S}$ be the Galois group of the maximal extension of K unramified outside S, and let G_{K_v} be the absolute Galois group of K_v.

Choose embeddings of algebraic closures defining continuous homomorphisms

$$j_v : G_{K_v} \longrightarrow G_{K,S} \qquad (v \in S_f).$$

These homomorphisms need not be injective. Strict restriction maps use the chosen j_v. Conjugate choices require cochain homotopies when the resulting complexes are compared.

Put $R_r = \mathbb{Z}/\ell^r\mathbb{Z}$, for $r \geq 1$. Complexes are cohomological, with differential of degree one and $M[1]^n = M^{n+1}$. Tensor products are over the displayed coefficient ring and use the Koszul sign rule. An ordinary tensor product denotes the algebraic tensor product. A derived or completed tensor product will be specified explicitly.

10.2 CONTINUOUS COCHAINS WITH THEIR MULTIPLICATION

Let G be profinite, R a commutative ring with trivial G-action, and M a discrete continuous $R[G]$-module. The normalized continuous cochains $C^n(G, M)$ are the continuous functions $G^n \to M$ vanishing when any argument is the identity. Set $C^0(G, M) = M$ and $C^n(G, M) = 0$ for $n < 0$.

Their differential is

$$\begin{aligned}(dc)(g_1, \dots, g_{n+1}) = {} & g_1 c(g_2, \dots, g_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i c(g_1, \dots, g_i g_{i+1}, \dots, g_{n+1}) \\ & + (-1)^{n+1} c(g_1, \dots, g_n). \end{aligned} \tag{10.1}$$

In degree zero this says $(dm)(g) = gm - m$. Continuous group cohomology is the cohomology of this complex.[1]

Suppose now that M is an associative unital R-algebra and that G acts by R-algebra automorphisms. For cochains c, c' of degrees n, m, define the ordered cup product by

$$(c \smile c')(g_1, \dots, g_{n+m}) = c(g_1, \dots, g_n)(g_1 \cdots g_n) c'(g_{n+1}, \dots, g_{n+m}). \tag{10.2}$$

No commutativity of M is needed. When the action is trivial, both action factors in (10.1) and (10.2) disappear.

PROPOSITION 10.2.1. The differential squares to zero. Under the algebra hypothesis, $C^\bullet(G, M)$ is a unital associative differential graded R-algebra. Restriction along continuous group homomorphisms, with the induced coefficient action, preserves its differential, product, and unit.

Proof. Write $d = \sum_i (-1)^i d_i$ for the faces in (10.1). For $i < j$, the identity $d_j d_i = d_i d_{j-1}$ pairs two terms of d^2 with opposite signs. The identity for the first two faces uses $g(hm) = (gh)m$. The adjacent inner faces use associativity in G. Every term is paired, so $d^2 = 0$. If an argument is the identity, the two neighboring faces cancel and all remaining terms vanish by normalization.

In the differential of a cup product, split the faces at the boundary of its two argument blocks. The faces in the first block give $(dc) \smile c'$, and those in the second give $(-1)^n c \smile dc'$. The extra faces at the boundary cancel. The action on the second factor in (10.2) makes this cancellation valid also for a nontrivial coefficient action. This proves Leibniz's rule.

For three cochains the two bracketings evaluate the same three blocks. The second value is acted on by the first block, and the third by the first two blocks. The action is by algebra automorphisms, so these expressions agree. The element 1_M in degree zero is a closed two-sided unit. Substitution of a group homomorphism in each argument respects every displayed formula. □

PROPOSITION 10.2.2. For trivial coefficients R_r, reduction gives degreewise surjections and isomorphisms

$$C^n(G, R_{r+1}) \otimes_{R_{r+1}} R_r \cong C^n(G, R_r).$$

These maps preserve the differential, cup product, and restrictions. Each module $C^n(G, R_r)$ is flat over R_r.

[1] J. S. Milne, *Class Field Theory*, version 4.03 (2020), Chapter II, §4, pp. 86–89, gives the continuous-cochain and finite-quotient conventions.

Proof. A continuous function from a compact space to a discrete space has finite image and is constant on a finite clopen partition. Lift each value from R_r to R_{r+1}, choosing the zero lift for the zero value. This preserves normalization.

A function reducing to zero has values in $\ell^r R_{r+1}$. Choosing preimages of its finitely many values shows that the kernel is $\ell^r C^n(G, R_{r+1})$. This proves the tensor assertion. All operations use only coefficient addition and multiplication.

Fix a finite clopen partition of G^n. Normalized functions constant on its cells form a finite free R_r-module. A basis consists of the characteristic functions of cells disjoint from all tuples with an identity argument. Refinement gives a filtered system whose union is all normalized continuous cochains. Filtered colimits of flat modules are flat. □

The finite models are compatible with the profinite topology. For trivial coefficients, every continuous cochain factors through $(G/U)^n$ for some open normal subgroup $U \subset G$. Indeed, its finite clopen fibers admit a finite cover by products of cosets of open subgroups. A common open normal subgroup refining those subgroups makes the function constant on the required product cosets. Normalization then holds on G/U, because a coset of the identity has the same value as an actual identity argument.

Consequently

$$C^\bullet(G, R_r) = \varinjlim_U C^\bullet(G/U, R_r),$$

with inflation as transition maps. The differential and cup product are compatible with this expression.

This flatness assertion concerns modules in individual degrees. It does not prove that an unbounded complex is K-flat, meaning that tensoring it with any acyclic complex remains acyclic. The resolution hypotheses of Proposition 3.3.1 are still needed when the coefficient bar is used to compute a derived tensor product.

10.3 Local conditions and retained primitives

Fix a discrete continuous $G_{K,S}$-module M over R. A cochain local condition at v consists of a complex L_v and a chain map

$$g_v : L_v \longrightarrow C^\bullet(G_{K_v}, M).$$

Set $A = C^\bullet(G_{K,S}, M)$, $B = \prod_{v \in S_f} C^\bullet(G_{K_v}, M)$, and $L = \prod_{v \in S_f} L_v$. Let $f = (j_v^*)_v$ and $g = (g_v)_v$. The products are finite, so they are also direct sums of complexes. Define the Selmer complex for these cochain data by

$$\begin{aligned} C^n_{\mathcal{L}} &= A^n \oplus L^n \oplus B^{n-1}, \\ D(a, c, y) &= (da, dc, f(a) - g(c) - dy). \end{aligned} \tag{10.3}$$

The symbol $\mathcal{L}$ records the chosen complexes and maps. A subspace of local cohomology alone does not specify these data.

Proposition 10.3.1. The complex $C^\bullet_{\mathcal{L}}$ is the homotopy fiber of $f - g : A \oplus L \to B$. In particular it has the exact sequence

$$\cdots \longrightarrow H^{n-1}(B) \longrightarrow H^n(C^\bullet_{\mathcal{L}}) \longrightarrow H^n(A) \oplus H^n(L) \xrightarrow{f_* - g_*} H^n(B) \longrightarrow \cdots .$$

A cocycle is a pair of global and allowed local cocycles together with a specified primitive of their difference after restriction.

Proof. The third component of D^2 is $f(da) - g(dc) - d(f(a) - g(c) - dy) = 0$. Projection onto $A \oplus L$ has kernel $B[-1]$, with differential $-d_B$. The resulting short exact sequence is the mapping-fiber sequence for $f - g$, and its connecting map is $f_* - g_*$. The cocycle equations are exactly those stated. □

Three choices exhibit the range of this definition. The zero condition $L_v = 0$ asks for a primitive of the local restriction. The full condition $L_v = C^\bullet(G_{K_v}, M)$, with g_v the identity, imposes no restriction. If every condition is full, the map $a \mapsto (a, f(a), 0)$ is a quasi-isomorphism $A \to C^\bullet_{\mathcal{L}}$: its complementary fiber is the contractible fiber of 1_B.

For a finite place, write I_v for inertia in G_{K_v}. The unramified cochain condition is

$$L_v = C^\bullet(G_{K_v}/I_v, M^{I_v}) \xrightarrow{\text{inflation}} C^\bullet(G_{K_v}, M). \tag{10.4}$$

The quotient acts on the inertia invariants, and inflation followed by their inclusion defines the map. If M is a coefficient algebra with Galois action by automorphisms, then M^{I_v} is a unital subalgebra and inflation preserves the cup product.

General local conditions are complexes. When A, L, B are strict dg algebras and f, g are algebra maps, there are additional products. For $x = (a, c, y)$ of degree n, they are

$$\mu_L(x, x') = (aa', cc', (-1)^n f(a)y' + yg(c')),$$
$$\mu_R(x, x') = (aa', cc', yf(a') + (-1)^n g(c)y').$$

Proposition 11.1.1 proves their dg identities. Chapter 11 constructs the comparison in every tensor length, including the module and bimodule maps. These conclusions apply to a local condition only after its algebra structure and the multiplicativity of g_v have been given.

If the cospan is unital, $u = (1_A, 1_L, 0)$ is the native unit of both products. For the zero local condition, the displayed triple provides no such common unit.

In either case the external unitization

$$R \oplus C^\bullet_{\mathcal{L}}, \qquad (r, x)(r', x') = (rr', rx' + r'x + xx'),$$

has augmentation $(r, x) \mapsto r$ and new unit $(1, 0)$. When u exists, $(0, u)$ is an idempotent in its augmentation ideal. It is not the new unit. The coefficient bar uses this external augmentation. Local vacua, scalar augmentations, and empty geometric cuts retain their distinct definitions.

A comparison of cochain models may respect restriction only up to homotopy. For the zero local condition, suppose algebra maps $\alpha : A \to A'$, $\beta : B \to B'$ and a degree-minus-one map $H : A \to B'$ satisfy $f'\alpha - \beta f = dH + Hd$. Then

$$(a, y) \longmapsto (\alpha(a), \beta(y) + H(a))$$

is a chain map of relative complexes. Its multiplicative defect is computed in Proposition 36.6.1. A nonzero defect requires higher comparison maps before one obtains a bar-coalgebra map. A chain homotopy alone is not that construction.

10.4 Completion before rationalization

Give $\mathbb{Z}_\ell = \varprojlim_r R_r$ its inverse-limit topology. A map $G^n \to \mathbb{Z}_\ell$ is continuous exactly when each of its reductions is continuous. Hence normalized cochains satisfy

$$C^\bullet_{\mathrm{cts}}(G, \mathbb{Z}_\ell) = \varprojlim_r C^\bullet(G, R_r).$$

The differential, cup product, and restrictions pass to this limit. For a general family of local conditions $L_{v,r}$, transition maps and coefficient base-change properties must be supplied as part of that family.

Proposition 10.4.1. Let E_r be a countable tower of complexes with degreewise surjective transition maps. There is an exact sequence

$$0 \longrightarrow \varprojlim{}^{1}{}_r H^{n-1}(E_r) \longrightarrow H^n(\varprojlim_r E_r) \longrightarrow \varprojlim_r H^n(E_r) \longrightarrow 0.$$

Here $\varprojlim^1$ is the cokernel of $1 - \text{shift}$ on the product of the indicated cohomology groups.

Proof. The map $1 - \text{shift} : \prod_r E_r \to \prod_r E_r$ is surjective in every degree. To solve $x_r - t_r(x_{r+1}) = y_r$, choose x_1 and lift $x_r - y_r$ recursively along the surjection $t_r : E_{r+1} \to E_r$. Its kernel is the inverse limit. Thus

$$0 \longrightarrow \varprojlim_r E_r \longrightarrow \prod_r E_r \xrightarrow{1-\text{shift}} \prod_r E_r \longrightarrow 0$$

is an exact sequence of complexes. Products of modules are exact, so their cohomology is the product of the cohomology groups. The resulting long exact sequence gives the assertion. □

The hypothesis holds for the coefficient cochains and their relative complexes with zero or full local conditions. It must be checked for other conditions. Even under this hypothesis, the possible $\varprojlim^1$ term prevents replacing the cohomology of the limit by the limit of the cohomology groups without further argument.

For a compatible tower of relative dg algebras P_r over R_r, let $\mathcal{B}_r$ be the coefficient bar of $R_r \oplus P_r$. It is the direct sum of its finite tensor words, with the signs of (3.2). Its coefficient completion and coproduct target are

$$\widehat{\mathcal{B}} = \varprojlim_r \mathcal{B}_r, \qquad \widehat{\mathcal{B}}\,\widehat{\otimes}\,\widehat{\mathcal{B}} := \varprojlim_r (\mathcal{B}_r \otimes_{R_r} \mathcal{B}_r). \tag{10.5}$$

Every element has finite word support at each coefficient precision. This is smaller than an unrestricted product over word lengths. The differential, coproduct, and endpoint comparisons pass to (10.5) by their compatible finite-stage formulas, as proved in Chapters 3 and 11.

Each finite-stage bar is conilpotent: sufficiently many reduced cuts kill any finite sum of words. The limit need not be conilpotent. Take a free rank-one module with basis a, where $|a| = 1$. The degree-zero element $\sum_{n\geq 1} \ell^n (sa)^{\otimes n}$ has finite support modulo every ℓ^r. Every iterated reduced coproduct has a nonzero term. Its existence depends on coefficient completion, not on a bound on geometric configurations.

Example 10.4.2. Each $R_r \otimes_{\mathbb{Z}_\ell} \mathbb{Q}_\ell$ is zero, since ℓ^r annihilates its first factor and is invertible on the second. But

$$(\varprojlim_r R_r) \otimes_{\mathbb{Z}_\ell} \mathbb{Q}_\ell = \mathbb{Q}_\ell.$$

The constant degree-zero cochains already exhibit this difference. There is no unital ring map $R_r \to \mathbb{Q}_\ell$: the relation $\ell^r 1 = 0$ would persist in the target. Thus a characteristic-zero realization cannot be constructed by rationalizing these finite coefficient algebras separately.

10.5 RESTRICTION, TRANSFER, AND TENSOR SUPPORT

Restriction and coefficient reduction are multiplicative in the models above. Additive transfer has a different behavior. If $H \subset G$ has finite index n, corestriction on degree-zero cohomology with trivial $\mathbb{Z}_\ell$-coefficients is multiplication by n. For finite groups this is the coset sum. For profinite groups the same formula uses the finite coset space.

PROPOSITION 10.5.1. If $n > 1$, corestriction with trivial $\mathbb{Z}_\ell$-coefficients is not multiplicative. There is no A_∞ morphism of these cochain algebras whose induced cohomology map is corestriction.

Proof. On the class of the degree-zero unit, multiplicativity would give $n = \mathrm{cor}(1 \cdot 1) = \mathrm{cor}(1)\,\mathrm{cor}(1) = n^2$. The ring $\mathbb{Z}_\ell$ has characteristic zero, so this fails for $n > 1$. The arity-two identity for an A_∞ morphism makes its first component multiplicative on cohomology, yielding the same contradiction. For index ℓ, reduction modulo ℓ^2 already detects the failure: $\ell \neq \ell^2 = 0$. □

Multiplicative norm operations, when constructed, have different axioms and cannot be substituted for this additive transfer without specifying their coefficient and algebra structures.

Changing the coefficient prime creates another separation. An abelian group is ℓ-primary torsion if every element is killed by some power of ℓ. For different primes, the derived tensor of two such groups vanishes.

PROPOSITION 10.5.2. If M_ℓ and M_p are respectively ℓ-primary and p-primary torsion groups, with $\ell \neq p$, then $M_\ell \otimes^{\mathbf{L}}_{\mathbb{Z}} M_p = 0$. For equal primes the corresponding assertion is false.

Proof. The resolution $0 \to \mathbb{Z} \xrightarrow{\ell^a} \mathbb{Z} \to \mathbb{Z}/\ell^a \to 0$, tensored with M_p, is acyclic: multiplication by ℓ^a is invertible on every p-primary group. Every finitely generated subgroup of M_ℓ is a finite sum of cyclic ℓ-power groups. Filtered unions and their exact tensor and Tor functors extend the calculation to M_ℓ. There is no higher Tor over $\mathbb{Z}$. For equal primes,

$$\mathbb{F}_\ell \otimes^{\mathbf{L}}_{\mathbb{Z}} \mathbb{F}_\ell \simeq \mathbb{F}_\ell \oplus \mathbb{F}_\ell[1],$$

since the differential in the same two-term resolution becomes zero. The shift puts its Tor group in cohomological degree -1. □

This calculation concerns tensor products over $\mathbb{Z}$. It neither supplies comparison maps between local geometric categories nor makes two factors with the same coefficient field disjoint.

10.6 DEFORMATION FUNCTORS ON ONE COEFFICIENT CATEGORY

Local conditions on representations supply cochain conditions by linearization. To form their global pullback, first fix a finite field k of characteristic ℓ, its Witt ring $W(k)$, and a continuous residual representation

$$\bar{\rho} : G_{K,S} \longrightarrow \mathrm{GL}_d(k).$$

Use a single category $\mathrm{Art}_{W(k)}$ of augmented simplicial Artinian local $W(k)$-algebras with residue field k. Deformation functors take values in spaces and invert weak equivalences of these coefficient algebras. A local theory over the Witt ring of a different residue characteristic is not automatically a functor on this category.

For a profinite group G with the specified residual representation, write $\mathrm{Def}_G(A)$ for its derived continuous deformation space. Concretely, it is the homotopy fiber at $\bar\rho$ of

$$\mathrm{Map}_{\mathrm{cts}}(BG, B\mathrm{GL}_d(A)) \longrightarrow \mathrm{Map}_{\mathrm{cts}}(BG, B\mathrm{GL}_d(k)),$$

using the continuous derived mapping-space model.

Here BG is the classifying space of G, and the fiber retains an identification of the reduction with $\bar\rho$. For ordinary Artinian A, objects are lifts of $\bar\rho$. Arrows are conjugations by matrices reducing to the identity. These arrows retain infinitesimal automorphisms.

Keeping a basis and forbidding those conjugations gives the framed deformation problem instead.[2]

Let $\mathrm{ad}\bar\rho = M_d(k)$, with action $g \cdot X = \bar\rho(g) X \bar\rho(g)^{-1}$. The tangent complex of a deformation functor records its linear response to square-zero coefficient extensions. With the cohomological convention here, its degrees $-1, 0, 1$ describe infinitesimal automorphisms, deformations, and obstructions.

Proposition 10.6.1. The tangent complex of Def_G at $\bar\rho$ is

$$T\mathrm{Def}_G \simeq C^\bullet(G, \mathrm{ad}\bar\rho)[1].$$

In particular the unframed first-order deformation space is $H^1(G, \mathrm{ad}\bar\rho)$, its infinitesimal automorphisms are $H^0(G, \mathrm{ad}\bar\rho)$, and the framed first-order space is $Z^1(G, \mathrm{ad}\bar\rho)$.

Proof. Over $k[\epsilon]/\epsilon^2$, write a lift as $\rho_\epsilon(g) = (1 + \epsilon c(g))\bar\rho(g)$. The representation equation becomes

$$c(gh) = c(g) + g \cdot c(h),$$

the cocycle equation in (10.1). Conjugation by $1 + \epsilon X$ changes c by $X - g \cdot X = -dX$. Quotienting gives H^1, while the stabilizer is $\ker d = H^0$. Before quotienting, the lifts form Z^1.

The same calculation applies to a simplicial square-zero module N. The kernel of $\mathrm{GL}_d(k \oplus N) \to \mathrm{GL}_d(k)$ is the additive simplicial module $M_d(N)$, since products of two elements of N vanish. Conjugation induces the adjoint action.

The continuous cosimplicial mapping model has normalized cochains $C^\bullet(G, \mathrm{ad}\bar\rho \otimes_k N)$. Passing to the classifying space shifts this linear complex by one. This identifies the linear response on square-zero modules, hence the stated tangent complex. Automorphisms remain in degree -1. □

Fix a determinant lift $\delta : G_{K,S} \to W(k)^\times$. There are two distinct meanings of fixed determinant. One may require the determinant character to have the value δ, while allowing all strict GL_d-conjugations. Alternatively, one may retain an identification of the determinant representation with δ and require arrows to preserve that identification. The second problem is the homotopy fiber of the determinant map of deformation functors. Denote it by $\mathrm{Def}^{\mathrm{or}}_{G,\delta}$.

Proposition 10.6.2. For the determinant-identified problem,

$$T\mathrm{Def}^{\mathrm{or}}_{G,\delta} \simeq C^\bullet(G, \mathrm{ad}^0\bar\rho)[1], \qquad \mathrm{ad}^0\bar\rho = \ker(\mathrm{tr} : M_d(k) \to k).$$

This holds also when ℓ divides d.

[2] S. Galatius and A. Venkatesh, *Derived Galois deformation rings*, arXiv:1608.07236, §§4–5 and 7, construct the derived continuous deformation functors and their tangent complexes. Their §9 imposes local conditions by homotopy pullbacks.

Proof. For a square-zero matrix, expansion of the determinant gives $\det(1 + \epsilon X) = 1 + \epsilon \operatorname{tr} X$. The tangent map of determinant is therefore the trace map

$$C^\bullet(G, \operatorname{ad}\bar{\rho})[1] \longrightarrow C^\bullet(G, k)[1].$$

Trace is equivariant and surjective. It is surjective on normalized cochains in every degree: lift a scalar value a to $\operatorname{diag}(a, 0, \dots, 0)$. This choice preserves continuity and normalization, though it need not be equivariant as a splitting. The kernel complex is $C^\bullet(G, \operatorname{ad}^0\bar{\rho})$, so the homotopy fiber is quasi-isomorphic to that kernel. No division by d occurs. □

For the determinant-value problem modulo all strict conjugations, the first-order quotient is instead

$$Z^1(G, \operatorname{ad}^0\bar{\rho}) \,/\, d\big(M_d(k)\big),$$

and its infinitesimal automorphisms are $H^0(G, \operatorname{ad}\bar{\rho})$. For a trivial two-dimensional representation, these automorphisms have dimension four. Preserving a determinant identification leaves the trace-zero automorphisms, of dimension three, also in characteristic two. The notation for the deformation problem must therefore specify which arrows are permitted.

10.7 The Selmer pullback and its tangent

Use the determinant-identified convention throughout this section. Write $\mathcal{D} = \operatorname{Def}^{\mathrm{or}}_{G_{K,S},\vartheta}$ and $\mathcal{D}_v = \operatorname{Def}^{\mathrm{or}}_{G_{K_v},\vartheta|_v}$. Choose pointed local deformation functors $\mathcal{D}_v^{\mathcal{L}}$ and actual morphisms $\mathcal{D}_v^{\mathcal{L}} \to \mathcal{D}_v$, all on $\operatorname{Art}_{W(k)}$. Define

$$\mathcal{D}_{\mathcal{L}} = \mathcal{D} \times^h_{\prod_{v\in S_f} \mathcal{D}_v} \prod_{v\in S_f} \mathcal{D}_v^{\mathcal{L}}. \tag{10.6}$$

The symbol $\times^h$ denotes a homotopy pullback of functors to spaces. It imposes compatibility together with its homotopy, rather than equality only on isomorphism classes.

THEOREM 10.7.1. Suppose each chosen local functor has tangent complex $L_v[1]$, and its morphism to $\mathcal{D}_v$ induces a chain map $g_v : L_v \to C^\bullet(G_{K_v}, \operatorname{ad}^0\bar{\rho})$. Then

$$T\mathcal{D}_{\mathcal{L}} \simeq C^\bullet_{\mathcal{L}}(G_{K,S}, \operatorname{ad}^0\bar{\rho})[1],$$

where the complex on the right is (10.3) with these actual maps. Geometric representability and Noetherianity are additional conditions on this formal deformation functor.

Proof. Evaluate (10.6) on every square-zero coefficient extension and take the fiber at its base point. Homotopy limits commute with homotopy limits, so this operation preserves the displayed pullback. The associated tangent spectra, and thus their complexes, give the fiber of

$$C^\bullet(G_{K,S}, \operatorname{ad}^0\bar{\rho})[1] \oplus \prod_v L_v[1] \longrightarrow \prod_v C^\bullet(G_{K_v}, \operatorname{ad}^0\bar{\rho})[1].$$

The arrow is restriction minus the chosen local map. Its mapping fiber is exactly (10.3), shifted by one. □

If each g_v is an inclusion of complexes, the quotient complex $C^\bullet(G_{K_v}, \operatorname{ad}^0\bar{\rho})/L_v$ gives an equivalent description of the same fiber. Without such inclusions the quotient notation has no supplied meaning. The mapping cone remains valid. The unramified deformation condition gives a concrete example when

both the residual local representation and $\delta|_v$ are unramified: inflate the deformation functor of G_{K_v}/I_v. Its tangent map is the inflation map of (10.4).

The tangent coefficients do not usually carry an associative product. In rank two the trace-zero matrices E_{12} and E_{21} have product E_{11}, whose trace is one. Thus $\mathrm{ad}^0\bar{\rho}$ is not an associative subalgebra of $M_2(k)$. A Selmer tangent complex therefore does not acquire the associative bar construction merely from its deformation-theoretic name. A separate coefficient algebra, and a comparison respecting its operations, are needed.

Representability, Noetherianity, perfectness, and cotangent amplitude are further conditions on the deformation problem. Obstructions in $H^2_{\mathcal{L}}$, which appear in tangent degree one, do not by themselves rule out quasi-smoothness. For a derived scheme, quasi-smoothness means that its cotangent complex is perfect of amplitude $[-1, 0]$. This permits tangent degree one.

Example 10.7.2. Let $A = k[x]/(x^2)$. The element x^2 is a non-zero-divisor in $k[x]$, so Spec A is a local complete intersection and is quasi-smooth. Its cotangent complex is

$$\mathbb{L}_{A/k} \simeq [A \xrightarrow{2x} A],$$

in degrees $-1, 0$. At $x = 0$ the differential vanishes, and the tangent has $H^1 = k$.

This example works also in characteristic two. Hence vanishing of the obstruction space is not equivalent to quasi-smoothness. Stack automorphisms require their own amplitude convention in addition to this scheme calculation.

10.8 Real places and the range of cohomology

Only finite places entered the relative product above. A theory of compact support over a number field must also specify its complexes at archimedean places, including any modified Tate-cohomology convention. At a complex place the absolute Galois group is trivial. At a real place it is C_2, the group of order two. Coefficients of characteristic two make the latter distinction unavoidable.

Proposition 10.8.1. For the trivial C_2-module $k = \mathbb{F}_2$, $H^n(C_2, k) = k$ for every $n \geq 0$.

Proof. If σ generates C_2, set $\eta = \sigma - 1$. Then $k[C_2] = k[\eta]/(\eta^2)$. A free resolution of the trivial module is

$$\cdots \xrightarrow{\eta} k[C_2] \xrightarrow{\eta} k[C_2] \xrightarrow{\eta} k[C_2] \longrightarrow k \longrightarrow 0.$$

The kernel and image of multiplication by η are both $k\eta$, so the resolution is exact. Applying $\mathrm{Hom}_{k[C_2]}(-, k)$ makes every differential zero. □

Consequently the unmodified real local cochains cannot be assigned a cohomological bound of two at the coefficient prime two. Neither a finite-place calculation nor a formal Selmer pullback supplies the missing archimedean convention. A comparison with de Rham or chiral objects at infinity must also specify its scalar field and geometric carrier.

10.9 Tame symbols and their recipients

Residues provide arithmetic operations with explicitly different targets at different places. For a field F, the Milnor group $K_2^M(F)$ is the abelian group generated by symbols $\{a, b\}$, for $a, b \in F^\times$. Its defining relations are bilinearity in the multiplicative arguments and the Steinberg relation $\{a, 1 - a\} = 0$ for $a \neq 0, 1$.

Let $v : F^\times \to \mathbb{Z}$ be a discrete valuation with residue field κ_v. Write $a = \pi^m u$ and $b = \pi^n w$, where π is a uniformizer and u, w are units. Set

$$\partial_v\{a, b\} = (-1)^{mn}\overline{w}^m\overline{u}^{-n} \in \kappa_v^\times. \tag{10.7}$$

This convention gives $\partial_v\{\pi, u\} = \bar{u}$.

PROPOSITION 10.9.1. Formula (10.7) is independent of the uniformizer and defines a homomorphism $K_2^M(F) \to \kappa_v^\times$.

Proof. Replacing π by πt replaces the unit parts by ut^{-m} and wt^{-n}. The extra powers of $\bar{t}$ cancel. Addition of valuations and multiplication of unit parts prove bilinearity. It remains to evaluate $\{a, 1 - a\}$.

If $v(a) > 0$, then $1 - a$ is a unit of residue one, so the symbol is one. If $v(a) = 0$, both arguments are units unless $v(1 - a) > 0$. In that case $\bar{a} = 1$, with the same result. If $m = v(a) < 0$, then $v(1 - a) = m$ and the ratio of their unit parts has residue -1. The symbol becomes $(-1)^{m^2+m} = 1$. Thus every Steinberg relation is respected. □

For $F = \mathbb{Q}$, the finite symbols land in $\bigoplus_p \mathbb{F}_p^\times$, where all but finitely many components are one. There is also a real sign symbol

$$h_\infty\{a, b\} = \begin{cases} -1, & a < 0 \text{ and } b < 0, \\ 1, & \text{otherwise.} \end{cases}$$

Signs make it bilinear, and a and $1 - a$ cannot both be negative, so it too respects the Steinberg relation.

THEOREM 10.9.2 *(Tate's rational-field calculation).* The combined homomorphism is an isomorphism

$$(h_\infty, (\partial_p)_p) : K_2^M(\mathbb{Q}) \xrightarrow{\sim} \{\pm 1\} \oplus \bigoplus_p \mathbb{F}_p^\times.$$

This is the classical computation of $K_2(\mathbb{Q})$, using the identification of field K_2 with its Milnor presentation.[3] The finite symbols alone omit the order-two class $\{-1, -1\}$: each finite valuation of its arguments is zero, while its real symbol is -1. The real factor is therefore necessary even before any comparison with geometric residues is attempted.

A product formula needs a common recipient. On the rational function field $F(t)$, the normed tame symbols satisfy

$$\prod_{x \in |\mathbb{P}^1_F|} N_{\kappa(x)/F}\big(\partial_x \xi\big) = 1 \quad (\xi \in K_2^M(F(t))). \tag{10.8}$$

Here every factor belongs to $F^\times$, the point at infinity is included, and only finitely many factors differ from one. This is the tame-symbol reciprocity theorem for the projective line.[4]

For example, if $\xi = \{t, u\}$, with $u \in F^\times$, the symbols at zero and infinity are u and u^{-1}. All others are one.

The finite residue fields of a number field do not come with these norm maps to a single ground field. Multiplying elements of $\mathbb{F}_p^\times$ for varying p without a specified recipient is not a reciprocity law. Furthermore, Spec O_K has no codimension-two points. Its dimension-one residue diagram cannot be relabelled as the two-step flag diagram of an arithmetic surface. The latter requires an actual surface, its flags, and the corresponding successive residue and norm maps.

[3] C. Weibel, *The K-book*, Chapter III, §6, especially Theorem 6.5.1 and the real symbol on pp. 231–234.

[4] Weibel, *The K-book*, Chapter III, Example 6.5.3, p. 236.

One can choose the incidence poset of finite subsets of finite places, with inclusions as arrows. It records which places occur together. It is distinct from the scheme configuration functor of pairwise disjoint sections of a curve. In particular it supplies neither collision differential forms nor their operation homotopies. Comparing the Steinberg and geometric Arnold relations requires a map between their complexes. Its compatibility with the relevant operations must also be proved.

10.10 Iwasawa coefficients and coalgebra length

For a procyclic group $\Gamma \cong \mathbb{Z}_\ell$, fix a topological generator γ. Its completed group ring is

$$\Lambda = \mathbb{Z}_\ell[[\Gamma]] := \varprojlim_{r,n} R_r[\Gamma/\ell^n\Gamma].$$

The choice of γ identifies this ring with a power-series ring. If Γ comes from a cyclotomic extension, this means its chosen procyclic factor. The full cyclotomic group can also have a finite factor. In $\mathbb{Z}_\ell^\times$, the standard procyclic subgroup is $1 + \ell\mathbb{Z}_\ell$ for odd ℓ, and $1 + 4\mathbb{Z}_2$ for $\ell = 2$.

Proposition 10.10.1. The map $\gamma \mapsto 1 + T$ induces a topological ring isomorphism $\Lambda \cong \mathbb{Z}_\ell[[T]]$.

Proof. The finite quotients are

$$R_r[T]\,/\,\big((1+T)^{\ell^n} - 1\big).$$

The ideals $(\ell^r, (1+T)^{\ell^n} - 1)$ are cofinal with the powers of (ℓ, T). To see one inclusion, fix a power $(\ell, T)^N$, take $r \geq N$, and increase n. For each $1 \leq j < N$, the identity

$$\binom{\ell^n}{j} = \frac{\ell^n}{j}\binom{\ell^n - 1}{j - 1}$$

gives valuation at least $n - v_\ell(j)$. Thus every coefficient of degree below N lies in the required power of ℓ.

Conversely, modulo the displayed ideal, T^{ℓ^n} belongs to $\ell R_r[T]$, because every intermediate binomial coefficient is divisible by ℓ. Hence $T^{r\ell^n} = 0$, and also $\ell^r = 0$. A sufficiently large power of (ℓ, T) therefore vanishes in each finite quotient. The two completions agree, and completion of $\mathbb{Z}[T]$ at (ℓ, T) is $\mathbb{Z}_\ell[[T]]$. □

An augmented dg Λ-algebra has the coefficient bar of Chapter 3. Any additional completion must again name its tensor target. A trace class in Hochschild homology does not, by itself, provide that algebra or its augmentation.

For a finitely generated torsion Λ-module M, define

$$\mu(M) = \operatorname{length}_{\Lambda_{(\ell)}} M_{(\ell)}.$$

The localization $\Lambda_{(\ell)}$ is a discrete valuation ring with uniformizer ℓ. This invariant concerns a module. Conilpotence concerns iterated reduced coproducts of a coaugmented coalgebra. Even for elementary ordinary Λ-coalgebras, the two conditions are independent.

Proposition 10.10.2. There is a conilpotent coaugmented Λ-coalgebra whose coaugmentation quotient has $\mu = 1$. There is also a nonconilpotent one whose quotient has $\mu = 0$.

Proof. For the first example take $C = \Lambda \oplus M$, with $M = \Lambda/(\ell)$, counit projection, and every element of M primitive: $\Delta(m) = 1 \otimes m + m \otimes 1$. Its reduced coproduct is zero, while $M_{(\ell)}$ has length one.

For the second take $C = \Lambda \oplus Mx$, with $M = \Lambda/(T)$, and set

$$\Delta(x) = 1 \otimes x + x \otimes 1 + x \otimes x, \qquad \epsilon(x) = 0.$$

The relation $Tx = 0$ is respected by this formula. The element $1 + x$ is group-like, which proves coassociativity. The counit identities follow directly. Every iterated reduced coproduct of x is a nonzero tensor power, because $M^{\otimes_\Lambda n} = M$. But T is invertible in $\Lambda_{(\ell)}$, so $M_{(\ell)} = 0$ and $\mu(M) = 0$. □

These are ordinary coalgebras over Λ. Their quotient modules are not required to be flat. They rule out using the module condition $\mu = 0$ as a definition of conilpotence in this category. A duality theorem with Iwasawa coefficients must specify its algebra and coalgebra classes, tensor, and completion. It must then identify the unit and counit maps it claims to invert.

Chapter II

Relative products and all-arity gluing

A relative cocycle consists of a cocycle and a primitive of its restriction. Multiplication therefore has a choice: use the primitive of the first input, or that of the second. The resulting products agree on cohomology, but the chain comparison contains ordered products of arbitrarily many primitives. These higher terms also change module actions. They must be retained when relative classes are composed.

We construct the comparison over an arbitrary commutative ring. Its formulas use finite sums on each tensor word and require no division. This gives an integral comparison of relative cochains, their modules, and their bimodules. Passing to an inverse limit of finite coefficient rings preserves the comparison. Passing instead to an unrestricted product over tensor lengths can destroy its continuity.

II.1 The two endpoint products

Let R be a commutative ring. All complexes are cohomological, their differentials have degree one, and tensor products use the Koszul rule. Fix a strict cospan of associative differential graded R-algebras

$$A \xrightarrow{f} B \xleftarrow{g} C.$$

The algebras may be nonunital. Define the relative complex

$$P^n = A^n \oplus C^n \oplus B^{n-1}, \qquad D(a, c, y) = (d_A a, d_C c, f(a) - g(c) - d_B y). \tag{II.1}$$

A cocycle (a, c, y) thus includes a specified primitive y of $f(a) - g(c)$. The identity $D^2 = 0$ follows from the chain-map identities for f and g. In the derived category of complexes, P is the fibre of $f - g : A \oplus C \to B$. This statement specifies its underlying complex; its multiplicative structure is the additional construction below.

For homogeneous $x = (a, c, y) \in P^p$ and $x' = (a', c', y')$, put

$$\begin{aligned} \mu_L(x, x') &= (aa', cc', (-1)^p f(a)\, y' + y\, g(c')), \\ \mu_R(x, x') &= (aa', cc', y f(a') + (-1)^p g(c)\, y'). \end{aligned} \tag{II.2}$$

The symbols L and R name these displayed choices throughout the chapter. In the relative case $C = 0$, their third components reduce to $(-1)^p f(a)\, y'$ and $y f(a')$.

Proposition II.1.1. Both (P, D, μ_L) and (P, D, μ_R) are differential graded associative algebras. If A, B, C and both maps are unital, their common unit is $e = (1_A, 1_C, 0)$. The bilinear map of degree minus one

$$K(x, x') = (0, 0, (-1)^{p+1} y\, y')$$

satisfies

$$DK + K(D \otimes 1 + 1 \otimes D) = \mu_L - \mu_R. \tag{II.3}$$

Consequently the two products induce the same multiplication on $H^*(P)$.

Proof. Write $|x'| = q$. The third component of either bracketing of the left product on x, x', x'' is

$$(-1)^{p+q} f(a) f(a') y'' + (-1)^{p} f(a) y' g(c'') + y g(c') g(c'').$$

For the right product the common third component is

$$y f(a') f(a'') + (-1)^{p} g(c) y' f(a'') + (-1)^{p+q} g(c) g(c') y''.$$

The other components are associative because A and C are. In the left Leibniz identity the two mixed terms $f(a)g(c')$ cancel; the remaining terms give the differential of the third component in (II.2). In the right identity the cancelling terms are $g(c)f(a')$. This proves compatibility with D. Substitution proves both unit identities.

The third components of the three terms on the left of (II.3) are

$$\begin{aligned} &(-1)^{p}(d_B y)\, y' - y(d_B y'), \\ &(-1)^{p}\big(f(a) - g(c) - d_B y\big)\, y', \\ &- y\big(f(a') - g(c') - d_B y'\big). \end{aligned}$$

Their sum is the difference of the two products. On cocycles this difference is the boundary $DK(x, x')$. □

The left product also has a finite interval model. Let I_R have basis e_0, e_1 in degree zero and h in degree one, with

$$d e_0 = -h, \quad d e_1 = h, \quad d h = 0, \qquad e_i e_j = \delta_{ij} e_i, \qquad e_0 h = h = h e_1,$$

and $e_1 h = h e_0 = h^2 = 0$. Its unit is $e_0 + e_1$. The evaluations $\mathrm{ev}_i : I_R \to R$ send e_i to one and the other basis elements to zero. The graded algebra is the path algebra of one arrow from 0 to 1, placed in degree one. Its differential is the graded commutator with h, so Leibniz and $d^2 = 0$ follow from $h^2 = 0$. The constant inclusion $R \to I_R$ is a quasi-isomorphism: after quotienting by $R(e_0 + e_1)$, the differential identifies two free rank-one modules.

PROPOSITION II.1.2. The map

$$(a, c, y) \longmapsto \big(a, c, f(a) e_0 + g(c) e_1 + (-1)^{p} y h\big), \qquad |(a, c, y)| = p,$$

is a strict isomorphism from (P, D, μ_L) onto the dg algebra

$$\big\{(a, c, \beta) \in A \times C \times (B \otimes_R I_R) : \mathrm{ev}_0\, \beta = f(a), \quad \mathrm{ev}_1\, \beta = g(c)\big\}.$$

Here evaluations act on the interval factor, and $b e_i$ and $b h$ denote tensors in $B \otimes_R I_R$.

Proof. Every triple in the target has the indicated unique form. Its edge coefficient after differentiation is $(-1)^{p+1}(f(a) - g(c) - d_B y)$. In a product of degrees p, q, the edge coefficient is

$$(-1)^{q} f(a) y' + (-1)^{p+q} y g(c').$$

This is $(-1)^{p+q}$ times the third component of μ_L. □

11.2 The integral bar comparison

Let $s : P \to P[1]$ have degree minus one, and write $W = sP$. Thus $|sx| = |x| - 1$; the third coordinate of $s(a, c, y)$ identifies with $y \in B$ in this degree. The tensor coalgebra is

$$T^c_R(W) = \bigoplus_{n \geq 0} W^{\otimes_R n}.$$

Its coproduct Δ cuts a word at every position, including the two ends. Its coaugmentation $\eta : R \to T^c_R(W)$ includes the empty word, and its counit ϵ projects onto that word. On the kernel of ϵ, removing the two end cuts gives the reduced coproduct. The property that a sufficiently long iteration kills each element of this kernel is called *conilpotence*; the tensor coalgebra has this property.

Define $\mathcal{B}_L$ and $\mathcal{B}_R$ to be this coalgebra with degree-one coderivations determined by

$$b_1(sx) = -sDx, \qquad b_{2,L/R}(sx, sx') = (-1)^{|x|} s\mu_{L/R}(x, x'). \tag{11.4}$$

Insertion of either component after $w_1, \ldots, w_j$ has sign $(-1)^{|w_1|+\cdots+|w_j|}$. All other components vanish, and the differential of the empty word is zero. The dg algebra identities imply $b^2_L = b^2_R = 0$.

These are the bars of the underlying nonunital algebras. Equivalently, they are the reduced bars of their unitizations $U_{L/R} = R \oplus P$, with multiplication

$$(r, p)(r', p') = (rr', rp' + r'p + \mu_{L/R}(p, p'))$$

and augmentation given by projection onto R. No augmentation of P is chosen. No flatness or boundedness assumption is needed for these coalgebras.

Theorem 11.2.1 *(Integral endpoint comparison).* There are inverse dg coalgebra isomorphisms

$$F : \mathcal{B}_L \longrightarrow \mathcal{B}_R, \qquad G : \mathcal{B}_R \longrightarrow \mathcal{B}_L.$$

Their components with output in W are

$$\begin{aligned} F_1 &= G_1 = 1_W, \\ F_n(w_1, \ldots, w_n) &= s(0, 0, y_1 \cdots y_n), \qquad n \geq 2, \\ G_n &= (-1)^{n-1} F_n, \qquad n \geq 2, \end{aligned} \tag{11.5}$$

where $w_i = s(a_i, c_i, y_i)$. Both maps preserve the coaugmentation, counit and increasing filtration by tensor length. They commute with strict maps of cospans and ordinary scalar extension. If the cospan is unital, every higher component vanishes when an input is se. In particular, the two endpoint algebras are strictly unital A_∞-isomorphic in that case.

Proof. On an input of length N, define F by summing over all partitions into consecutive nonempty blocks. Apply F_i to a block of length i, and tensor the block values in their original order. Set $F(1) = 1$. Cutting an output between blocks is equivalent to cutting the input there and partitioning its two pieces. This proves the coalgebra identity. Every sum is finite, and no output is longer than the input.

For the chain identity, set $|w_i| = q_i$ and $Q_j = q_1 + \cdots + q_j$, with $Q_0 = 0$. Write $b^{\otimes}_1$ for the tensor differential on an input word. Since

$$\big(b_1 s(a, c, y)\big)_B = d_B y - f(a) + g(c),$$

the differential of the ordered product cancels its internal $d_B y_i$ terms against $F_n b_1^{\otimes}$. For $n \geq 2$, the third component of $b_1 F_n - F_n b_1^{\otimes}$ is

$$\sum_{j=1}^{n} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} \big(f(a_j) - g(c_j) \big) y_{j+1} \cdots y_n. \tag{II.6}$$

At arity two,

$$\begin{aligned} (b_{2,L})_B &= f(a_1) y_2 - (-1)^{q_1} y_1 g(c_2), \\ (b_{2,R})_B &= -(-1)^{q_1} y_1 f(a_2) + g(c_1) y_2. \end{aligned}$$

Their difference is exactly (II.6). At arity $n \geq 3$, an interior split in $b_{2,R}(F_i, F_{n-i})$ has two purely local outputs and is zero. The two end splits give

$$g(c_1) y_2 \cdots y_n - (-1)^{Q_{n-1}} y_1 \cdots y_{n-1} f(a_n).$$

Adding these to (II.6) leaves

$$\begin{aligned} &\sum_{j=1}^{n-1} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} f(a_j) y_{j+1} \cdots y_n \\ &\quad - \sum_{j=2}^{n} (-1)^{Q_{j-1}} y_1 \cdots y_{j-1} g(c_j) y_{j+1} \cdots y_n. \end{aligned}$$

This is the third component of the source binary contribution $F_{n-1} b_{2,L}$, including its insertion signs. The other components vanish in these arities. Thus $b_R F = F b_L$ after projection to W. The two sides are coderivations relative to F, so this projection determines their equality. Explicitly, induction on input length makes their remaining difference primitive; a primitive of the tensor coalgebra with zero projection to W is zero.

Construct G by the same partition formula. On length $n \geq 2$, the component in W of FG is the local product $s(0, 0, y_1 \cdots y_n)$ times

$$\sum_{k=1}^{n} \binom{n-1}{k-1} (-1)^{n-k} = 0.$$

For GF the sign is $(-1)^{k-1}$, and the sum again vanishes. The linear components are identities. The uniqueness of coalgebra maps with prescribed components now gives $FG = GF = 1$; hence G is also a chain map.

A strict map of cospans takes an ordered product of the y_i to the ordered product of their images. Ordinary scalar extension preserves the same formulas and finite sums. Finally the local coordinate of e is zero. This proves the unit assertion. □

The comparison contains more than the binary homotopy (II.3). For example, its arity-three component is $F_3(w_1, w_2, w_3) = s(0, 0, y_1 y_2 y_3)$. Let $\tau_{L/R} : \mathcal{B}_{L/R} \to P$ be the degree-one map that desuspends the length-one part and kills every other length. Then $\tau_R F$ evaluates every higher product in (II.5). Those terms carry the change of endpoint into representations.

11.3 Transporting all module operations

For a graded R-module M, the tensor product $M \otimes_R T^c_R(W)$ is a right comodule by deconcatenation on the word factor. Denote its coaction by ρ. A right A_∞ module over (P, μ_R) is a degree-one map Q_M satisfying

$$\rho Q_M = (Q_M \otimes 1 + 1 \otimes b_R)\rho, \qquad Q_M^2 = 0.$$

It is determined by its components $\beta_n : M \otimes_R W^{\otimes_R n} \to M$ of degree one, including the differential β_0. On a word, Q_M sums the operations β_j on the module entry and the first j factors, together with $(-1)^{|m|} m \otimes b_R$ on the word. All these sums are finite. The graded maps in the module category are the graded comodule maps $T : M \otimes \mathcal{B}_R \to N \otimes \mathcal{B}_R$, with differential $Q_N T - (-1)^{|T|} T Q_M$.

In these unsuspended-module conventions a strict dg right action is encoded by

$$\beta_0(m) = d_M m, \qquad \beta_1(m; sx) = (-1)^{|m|+1} mx, \qquad \beta_n = 0 \quad (n > 1). \tag{11.7}$$

The minus sign is fixed by (11.4): on $m \otimes sx \otimes sx'$, the two action terms in Q_M^2 have opposite coefficients $(-1)^{|x|}$ and $(-1)^{|x|+1}$. On one bar factor the identity is the dg module Leibniz rule.

Strict unitality means $\beta_1(m; se) = (-1)^{|m|+1} m$ and vanishing of β_n, for $n > 1$, when a word input is se. A normalized map has the analogous vanishing in every positive word arity.

Theorem 11.3.1. Pullback along F gives an isomorphism of the dg categories of right A_∞ modules over (P, μ_R) and (P, μ_L), with inverse pullback along G. It leaves the underlying complex unchanged. Its positive-arity operations are

$$\beta^F_n(m; w_1, \dots, w_n) = \sum_{\substack{i_1 + \cdots + i_k = n \\ i_j > 0}} \beta_k\big(m; F_{i_1}(w_1, \dots), \dots, F_{i_k}(\dots, w_n)\big). \tag{11.8}$$

For unital cospans it preserves strict units and normalized module maps.

Proof. Let $C^M_F = 1_M \otimes F$ and $C^M_G = 1_M \otimes G$. Define

$$Q^F_M = C^M_G Q_M C^M_F.$$

The identity $b_R F = F b_L$ transports the comodule identity to one over b_L, and $(Q^F_M)^2 = C^M_G Q^2_M C^M_F = 0$. Projection to the length-zero module factor satisfies $\mathrm{pr}_M\, C^M_G = \mathrm{pr}_M$. Its composite with Q^F_M is therefore exactly (11.8). No extra signs occur because every F_i has degree zero.

A homogeneous comodule map $T : M \otimes \mathcal{B}_R \to N \otimes \mathcal{B}_R$ is sent to $C^N_G T C^M_F$. Conjugation preserves composition and the differential on maps $Q_N T - (-1)^{|T|} T Q_M$. Conjugation by the inverse maps reverses both constructions. This proves the assertion for the entire dg category.

A unit input in a surviving partition must be a singleton, since every higher F_i vanishes on it. The unit identities for the outer operation then give exactly these properties after pullback. The same argument applies to G. □

A strict action can acquire operations in every arity: $\beta^F_n(m; w_1, \dots, w_n) = \beta_1(m; F_n(w_1, \dots, w_n))$. The identity linear term of F therefore does not permit the module comparison to be replaced by the identity on its underlying complex.

II.4 RELATIVE BIMODULES

An interface has actions on both sides. To compare them, fix two cospans

$$A_0 \xrightarrow{f_A} A_1 \xleftarrow{g_A} A_2, \qquad E_0 \xrightarrow{f_E} E_1 \xleftarrow{g_E} E_2.$$

Let M_i be a dg A_i–E_i bimodule, and choose chain maps $\phi : M_0 \to M_1$, $\psi : M_2 \to M_1$ with

$$\phi(ame) = f_A(a)\phi(m)f_E(e), \qquad \psi(ame) = g_A(a)\psi(m)g_E(e)$$

on the respective domains. Write P_A, P_E for their relative algebra complexes, and put

$$P_M^n = M_0^n \oplus M_2^n \oplus M_1^{n-1}, \qquad D_M(m_0, m_2, v) = (dm_0, dm_2, \phi(m_0) - \psi(m_2) - dv).$$

For $x = (a_0, a_2, y) \in P_A^p$, $m = (m_0, m_2, v) \in P_M^q$, and $u = (u_0, u_2, z) \in P_E$, the endpoint actions are

$$\begin{aligned}
x \cdot_L m &= (a_0 m_0, a_2 m_2, (-1)^p f_A(a_0)v + y\psi(m_2)),\\
x \cdot_R m &= (a_0 m_0, a_2 m_2, y\phi(m_0) + (-1)^p g_A(a_2)v),\\
m \cdot_L u &= (m_0 u_0, m_2 u_2, (-1)^q \phi(m_0)z + v g_E(u_2)),\\
m \cdot_R u &= (m_0 u_0, m_2 u_2, v f_E(u_0) + (-1)^q \psi(m_2)z).
\end{aligned}$$

For each choice of endpoint these make P_M a dg bimodule for the matching products on P_A and P_E. The proof below includes the compatibility of the two actions.

The corresponding bar bicomodule is

$$\mathcal{B}^M_{L/R} = T^c_R(sP_A) \otimes_R sP_M \otimes_R T^c_R(sP_E).$$

Its left and right coactions cut before or after the middle entry. Its differential inserts the unary differentials, the algebra products, and the two actions, with the suspended conventions of (II.4) on every entry, including sP_M. In particular this middle entry is suspended, unlike the module entry in (II.7).

THEOREM II.4.1. There is a dg bicomodule isomorphism $\Phi : \mathcal{B}^M_L \to \mathcal{B}^M_R$ over the coalgebra maps F_A, F_E of Theorem II.2.1. Its component with no algebra inputs is the identity on sP_M. For $r + t \geq 1$, its component with r left and t right inputs is

$$\Phi_{r,t}(sx_1, \dots, sx_r; sm; su_1, \dots, su_t) = s(0, 0, y_1 \cdots y_r\, v\, z_1 \cdots z_t). \tag{II.9}$$

Its inverse has higher components $\Psi_{r,t} = (-1)^{r+t}\Phi_{r,t}$ and identity linear term. The maps commute with strict diagram maps and ordinary scalar extension. They preserve strict units in the algebra inputs when the cospans and bimodules are unital.

Proof. Form the triangular dg algebras

$$T_i = \begin{pmatrix} A_i & M_i \\ 0 & E_i \end{pmatrix}, \qquad \begin{pmatrix} a & m \\ 0 & u \end{pmatrix}\begin{pmatrix} a' & m' \\ 0 & u' \end{pmatrix} = \begin{pmatrix} aa' & am' + mu' \\ 0 & uu' \end{pmatrix}.$$

Their entrywise differential has the dg algebra Leibniz property because the two module actions do. The maps ϕ, ψ, together with the algebra maps, give a strict cospan $T_0 \to T_1 \leftarrow T_2$. Its relative complex

has diagonal components P_A, P_E and off-diagonal component P_M. The two endpoint products give exactly the four displayed actions. Their dg bimodule identities are thus the corresponding entries of the dg algebra identities.

In the tensor bar of this triangular relative algebra, take words with upper-left entries, then one upper-right entry, then lower-right entries. They form $\mathcal{B}^M_{L/R}$, and its differential preserves this submodule. Applying the partition formula for the triangular algebra preserves it too. The unique block containing the upper-right entry has local component $y_1 \cdots y_r v z_1 \cdots z_t$, without any interchange of factors. This proves (11.9). The inverse sign is $(-1)^{(r+t+1)-1}$.

The chain and inverse identities restrict from those of the triangular bars. Deconcatenation gives

$$\Delta_L \Phi = (F_A \otimes \Phi)\Delta_L, \qquad \Delta_R \Phi = (\Phi \otimes F_E)\Delta_R.$$

Finally, strict diagram maps preserve every ordered local product, scalar extension preserves the finite formulas, and a gluing unit has local component zero. These give the remaining assertions. □

An algebra local condition for arithmetic cochains must provide a dg algebra and a multiplicative map into the local cochains. A linear local condition may instead enter the bimodule construction once its two actions and the compatible maps are supplied. Its cone as a complex does not determine either action.

11.5 The homological meaning of the bar

The relative complex and its tensor bar have different meanings. The complex P computes the relative cohomology of the cospan. The bar computes a derived tensor of the augmentation module of $U = R \oplus P$ under the K-flatness hypothesis of Proposition 3.3.1.

Proposition 11.5.1. If P is K-flat over R, then for either endpoint product its bar represents $R \otimes^{\mathbf{L}}_U R$, where R is a left or right U-module through the augmentation.

Proof. For either endpoint product, the augmentation ideal of $U = R \oplus P$ is P, and the differential and bar signs are those of (3.2). Apply Proposition 3.3.1 to this augmented algebra. □

Degreewise flatness does not replace K-flatness for an unbounded complex. Without that hypothesis the explicit bar and the endpoint isomorphism still exist; the proposition does not identify that bar with a derived tensor.

The unital gluing case gives a useful distinction even without flatness. If P has a closed unit e, its underlying nonunital bar contracts onto the empty word. On a nonempty word c, set $h(c) = se \otimes c$, and set $h(1) = 0$. Since $b_1(se) = 0$ and $b_2(se, sx) = sx$, direct substitution gives

$$bh + hb = 1 - \eta\epsilon.$$

Thus $H^*(\mathcal{B}) = R$, although $H^*(P)$ can be much larger. Algebraically the same distinction appears in $U \cong R \times P$, via $(r, p) \mapsto (r, re + p)$. To form a reduced bar of an augmented unital algebra P itself, one instead uses its specified augmentation ideal. No such choice is implicit in the endpoint construction.

II.6 HOMOTOPY-COMMUTING COEFFICIENT MAPS

Strict maps of cospans preserve the preceding constructions. A comparison commuting only up to cochain homotopy has an additional product defect, visible already in the relative case $C = 0$. Write $P(f) = A \oplus B[-1]$ for this specialization of (II.1). Alongside $f : A \to B$, choose a dg algebra map $f' : A' \to B'$. Let $\alpha : A \to A'$ and $\gamma : B \to B'$ be dg algebra maps, and let $H : A \to B'$ have degree minus one with

$$f'\alpha - \gamma f = dH + Hd.$$

Define $T : P(f) \to P(f')$ by $T(a, y) = (\alpha(a), \gamma(y) + H(a))$.

PROPOSITION II.6.1. The map T is a cochain map. For the left endpoint products its multiplicativity defect has zero first component and local component

$$\begin{aligned}(-1)^p &(f'\alpha - \gamma f)(a)\gamma(y') \\ &+ (-1)^p f'\alpha(a)H(a') - H(aa'), \qquad |(a, y)| = p.\end{aligned}$$

It induces a strict tensorwise map of the relative bars if and only if this expression vanishes on every pair of inputs.

Proof. The local component of $D'T - TD$ is $(f'\alpha - \gamma f)(a) - dH(a) - H(da) = 0$. Expanding $\mu'_L(Tx, Tx') - T\mu_L(x, x')$ gives the displayed formula. Projection of the strict bar-map identity onto one output factor on two inputs is precisely multiplicativity; on one input it is the chain-map identity. These two identities suffice in every length because the bar differentials have only unary and binary components. □

If the defect is nonzero, higher components must be constructed in the permitted operation spaces. Closedness of an obstruction in a larger Hom complex does not provide a primitive with prescribed support, pole bounds, units or continuity. The endpoint comparison above supplies such components for its explicit algebraic problem; it does not supply them for an arbitrary homotopy-commuting square.

II.7 FINITE PRECISION AND CONTINUOUS GLUING

Fix a prime ℓ, put $R_j = \mathbb{Z}/\ell^j$, and take compatible strict cospans over the rings R_j. Write $W_j = sP_j$ and $\mathcal{B}_{L/R,j} = T^c_{R_j}(W_j)$. Define their restricted inverse limits by

$$\widehat{\mathcal{B}}_{L/R} = \varprojlim_j \bigoplus_{n \geq 0} W_j^{\otimes_{R_j} n}.$$

Each finite-precision module is discrete; the limits have the inverse-limit topology. An element has only finitely many nonzero word lengths at any fixed precision, although the number of such lengths may grow with j. The completed tensor recipient is defined here to be

$$\widehat{\mathcal{B}} \,\widehat{\otimes}\, \widehat{\mathcal{B}} := \varprojlim_j (\mathcal{B}_j \otimes_{R_j} \mathcal{B}_j). \tag{II.10}$$

This definition makes no identification with a different completed tensor product.

For a compatible tower of modules or relative bimodules, use

$$\widehat{C}(M) = \varprojlim_j (M_j \otimes_{R_j} \mathcal{B}_j), \qquad \widehat{\mathcal{B}}^M = \varprojlim_j \mathcal{B}_j^M,$$

with the same topology. Their coaction recipients are, respectively, $\varprojlim_j (C(M_j) \otimes_{R_j} \mathcal{B}_j)$ and the two limits of $\mathcal{B}_{A,j} \otimes_{R_j} \mathcal{B}_j^M$ and $\mathcal{B}_j^M \otimes_{R_j} \mathcal{B}_{E,j}$. The subscripts A, E distinguish the left and right coefficient bars.

Theorem 11.7.1. The maps F_j, G_j induce inverse continuous maps $\widehat{F} : \widehat{\mathcal{B}}_L \to \widehat{\mathcal{B}}_R$ and $\widehat{G}$. They preserve the differential and coproduct, with recipient (11.10). Compatible module and bimodule bars admit the corresponding continuous comparisons, with coaction recipients the inverse limits of their finite-precision tensor recipients.

Proof. At precision j, each element is a finite sum of words, and each word has finitely many consecutive partitions. The maps are therefore defined there and satisfy all chain, inverse and coaction identities. Strict compatibility with coefficient reduction gives the maps on inverse limits. Every identity holds after each projection, hence in the limit. Each output at precision j depends only on the input at the same precision, proving continuity. The same argument applies to $1_M \otimes F_j$, to module conjugation and to the triangular bicomodule maps. □

No interchange of cohomology with inverse limit occurs in this proof. Such an interchange would need its own hypotheses on derived inverse limits. Ordinary conilpotence can also fail in the completed object. For example, let $P = \mathbb{Z}_\ell a$, with $|a| = 1$, zero differential and zero product. The element

$$z = \sum_{n \geq 1} \ell^n (sa)^{\otimes n}$$

exists in the restricted bar. Every iterated reduced coproduct has a nonzero component, obtained by cutting a sufficiently long word. Each finite coefficient bar is conilpotent, while z is not.

Proposition 11.7.2. The map F need not extend continuously to the unrestricted product $\prod_{n \geq 0} W^{\otimes_R n}$ with discrete word coordinates.

Proof. Take the relative identity map $f : \mathbb{Z} \to \mathbb{Z}$, with $C = 0$, and let $v = s(0, 1)$. It has degree zero and satisfies $F_n(v^{\otimes n}) = v$ for every $n \geq 1$. The partial sums $z_N = \sum_{n=1}^{N} v^{\otimes n}$ converge in the product of word spaces: each coordinate eventually stabilizes. The length-one coordinate of $F(z_N)$ is Nv, which does not converge in the discrete module $\mathbb{Z}v$. Continuity of an extension would contradict this sequence. □

In the restricted ℓ-adic bar the weighted series $\sum_{n \geq 1} \ell^n v^{\otimes n}$ is defined. Its length-one image is $\ell(1 - \ell)^{-1} v$. The denominator is an ℓ-adic unit; it arises by summing the convergent coefficients, not in the definition of any Taylor component. The comparison is integral at every finite precision. An analytic realization must separately bound the higher components in its chosen seminorms and compare its completed tensors with the recipient in which the coproduct is defined.

Chapter 12

Hall correspondences and primitive kernels

A Hall product counts extensions. Its associativity comes from flags: the two bracketings forget different steps of the same filtration. Recovering a geometric operation from the count requires more data. Automorphisms determine the integration weight, and a vanishing scalar sum need not come from an acyclic complex.

The first primitive already exhibits both issues. Its coefficients on a nonsplit extension and a split extension cancel under Green's coproduct. Placing those coefficients on separate components leaves nonzero cohomology. A Fourier kernel on the extension line instead joins the two strata by a Gysin morphism. We construct that kernel, extend it to every cut of a flag, and determine what is lost when the flag is forgotten.

Quiver cohomology gives another extension product. Its Euler factors, cohomological grading and vanishing cycles must be retained before comparing it with arithmetic fields. An explicit shuffle relation will also distinguish a valid product from a proposed ordinary cooperation. The arithmetic comparison remains a problem about these operations and their maps, beyond equality of numerical invariants.

12.1 Extension counts and the tensor crossing

Let $\mathcal{A}$ be an essentially small abelian category with finite sets $\mathrm{Hom}(M,N)$ and $\mathrm{Ext}^1(M,N)$. Write $a_M = |\operatorname{Aut} M|$. Define $F^L_{M,N}$ to be the number of subobjects $N' \subset L$ satisfying $N' \simeq N$ and $L/N' \simeq M$. Thus the first index names the quotient and the second names the subobject. Let $H(\mathcal{A})$ be the free vector space over a field k on isomorphism classes u_M.

Proposition 12.1.1. The formula

$$u_M u_N = \sum_{[L]} F^L_{M,N} u_L$$

defines an associative multiplication with unit u_0. Let $K_0(\mathcal{A})$ be the abelian group generated by object classes, subject to $[L] = [M] + [N]$ for each short exact sequence. For any bicharacter $b : K_0(\mathcal{A}) \times K_0(\mathcal{A}) \to k^\times$, the product $u_M *_b u_N = b([M],[N])u_M u_N$ is also associative. Here a bicharacter is multiplicative in each additive argument.

Proof. The finite extension set leaves finitely many possible middle objects. The finite Hom set bounds the number of embeddings into each one. The coefficient of u_L in either triple product counts flags

$$0 \subset L_1 \subset L_2 \subset L$$

with successive quotients P, N, M. The two bracketings forget L_1 or L_2, so their coefficients agree. The twist factors agree because

$$b(M,N)b(M+N,P) = b(N,P)b(M,N+P).$$

The zero object has precisely the unit subobject and quotient. □

For the coproduct, assume that $\mathcal{A}$ is linear over $\mathbb{F}_q$, hereditary, and has finite-dimensional Hom and Ext spaces. Hereditary means that $\operatorname{Ext}^i = 0$ for $i > 1$. Assume also that every object has finitely many subobjects, as for finite-dimensional modules over a finite field. Then

$$\langle M, N\rangle = \dim_{\mathbb{F}_q} \operatorname{Hom}(M, N) - \dim_{\mathbb{F}_q} \operatorname{Ext}^1(M, N)$$

is additive in short exact sequences. Put $(M, N) = \langle M, N\rangle + \langle N, M\rangle$ and $v = \sqrt{q}$. Work over $\mathbb{Q}(v)$ with the twisted product $u_M * u_N = v^{\langle M,N\rangle} u_M u_N$.

THEOREM 12.1.2 *(Green's compatibility).* The coproduct and counit

$$\Delta u_L = \sum_{[M],[N]} v^{\langle M,N\rangle} \frac{a_M a_N}{a_L} F^L_{M,N}\, u_M \otimes u_N, \qquad \varepsilon(u_L) = \delta_{L,0}, \tag{12.1}$$

make this Hall algebra a braided bialgebra. For homogeneous classes α, β, the crossing is

$$c(x_\alpha \otimes y_\beta) = v^{(\alpha,\beta)}\, y_\beta \otimes x_\alpha.$$

In particular, multiplicativity of Δ uses

$$(x_\alpha \otimes y_\beta)(x_\gamma \otimes y_\delta) = v^{(\beta,\gamma)} (x_\alpha * x_\gamma) \otimes (y_\beta * y_\delta). \tag{12.2}$$

All sums in these formulas are finite.

Proof. The automorphism factors in an iterated coproduct cancel, leaving the same three-step flags in either order. This proves coassociativity.

For multiplicativity, Green's formula counts pairs $N, N' \subset L$ through their four subquotients

$$L/(N + N'), \quad N/(N \cap N'), \quad N'/(N \cap N'), \quad N \cap N'.$$

If the first and last are A, D, the groupoid of extension-square fillings contributes

$$\frac{|\operatorname{Ext}^1(A, D)|}{|\operatorname{Hom}(A, D)|} = q^{-\langle A,D\rangle}.$$

Heredity removes the degree-two obstruction to a filling.

Substituting these weights into (12.1) leaves the crossing (12.2), by Euler additivity. This is Green's extension-counting theorem with its automorphism normalization. See Ringel, *Green's theorem on Hall algebras*, Part I, §§1 and 8. The zero-object terms prove both counit identities. □

For finite vector spaces let $s = u_{\mathbb{F}_q}$. Counting lines gives

$$s * s = v(q + 1) u_{\mathbb{F}_q^2}, \qquad [s \otimes s]\Delta u_{\mathbb{F}_q^2} = v^{-1}.$$

Here $[s \otimes s]$ denotes the coefficient of that basis vector. Thus $[s \otimes s]\Delta(s * s) = q + 1$. Expanding $\Delta(s)^2$ gives $1 + q$, since the crossed term has weight $v^2 = q$. An ordinary flip would give 2. Even this smallest example fixes the tensor multiplication used by the theorem.

A hereditary category can have infinitely many subobjects, as for coherent sheaves on a curve. Its coproduct requires a specified tensor completion and locally finite products. The finite extension-square identity persists. It does not by itself define multiplication on arbitrary coefficientwise infinite sums.

The hereditary hypothesis also has content. For $R = \mathbb{F}_q[\epsilon]/(\epsilon^2)$ and $S = R/(\epsilon)$, the resolution with every differential multiplication by ϵ gives $\operatorname{Ext}^n_R(S, S) = \mathbb{F}_q$ for every $n \geq 0$. The alternating sums of Ext dimensions oscillate. The Hall product still exists, but this infinite Ext sequence does not define a finite Euler twist.

12.2 The local primitive and its Green norm

Fix a prime power Q and the category of finite-dimensional nilpotent $\mathbb{F}_Q[t]$-modules. A partition $\lambda = (\lambda_1, \dots, \lambda_l)$ names the module $M_\lambda = \bigoplus_i \mathbb{F}_Q[t]/(t^{\lambda_i})$. Write $u_\lambda = u_{M_\lambda}$ and $|\lambda| = \sum_i \lambda_i$. The length $\ell(\lambda)$ is its number of Jordan blocks. The Euler form is zero, so Green's multiplication and coproduct use the ordinary tensor product here.

Work over $\mathbb{C}$ with the positive Hermitian Green form

$$(u_\lambda, u_\mu)_G = \frac{\delta_{\lambda\mu}}{a_{M_\lambda}},$$

conjugate-linear in the first argument. The coproduct is adjoint to multiplication. For $r \geq 0$, put $e_r = Q^{r(r-1)/2} u_{(1^r)}$, with $e_0 = 1$, and set $E(z) = \sum_{r\geq 0} e_r z^r$. Subspace counting gives

$$\Delta u_{(1^r)} = \sum_{i+j=r} Q^{-ij} u_{(1^i)} \otimes u_{(1^j)}, \qquad \Delta E(z) = E(z) \otimes E(z).$$

These are formal power series, with finite-dimensional pieces in each module dimension.

Theorem 12.2.1 *(Classical Hall primitives).* The algebra is polynomial on the e_r, $r > 0$. Define p_r by

$$\log E(z) = \sum_{r\geq 1} \frac{(-1)^{r-1}}{r} p_r z^r. \tag{12.3}$$

Then

$$p_r = \sum_{|\lambda|=r} \left(\prod_{j=1}^{\ell(\lambda)-1} (1 - Q^j) \right) u_\lambda. \tag{12.4}$$

Each p_r is primitive, and the homogeneous primitives of dimension r form its one-dimensional span. Their Green norms are

$$(p_r, p_s)_G = \delta_{rs} \frac{r}{Q^r - 1}. \tag{12.5}$$

Proof. The polynomial presentation is the classical Hall theorem. Its triangular construction uses products of semisimple classes whose dimensions are the successive kernel increments of t. The leading term has the kernel filtration of M_λ. Every other term has larger kernel dimensions. In each fixed dimension the resulting triangular matrix is invertible. Commutativity follows by dualizing exact sequences, since every nilpotent Jordan module is isomorphic to its linear dual.

The coefficient formula (12.4) is the classical Newton identity in this basis. In the present normalization, it is Lemma 3.5 of Shimoji–Yanagida, *A study of symmetric functions via derived Hall algebra*, arXiv:1812.06033. Its coefficients are fixed by the vertical-strip Hall numbers, rather than by rescaling a primitive after construction. Taking the logarithm of the group-like identity for E proves primitivity. The Newton relations identify the polynomial generators e_r and p_r triangularly.

In a characteristic-zero polynomial algebra with primitive generators, a primitive polynomial f satisfies $f(X + Y) = f(X) + f(Y)$. Differentiating in each Y variable at zero makes every partial derivative of f constant. Hence f is linear in the p_r. The dimension grading gives the asserted homogeneous span.

Finally, the order of the general linear group gives

$$(E(u), E(v))_G = \sum_{r\geq 0} \frac{Q^{r(r-1)/2} (\bar{u}v)^r}{\prod_{j=1}^r (Q^j - 1)} = \prod_{j\geq 1} (1 - Q^{-j} \bar{u}v)^{-1}.$$

The product identity follows coefficientwise from $(1-t)P(Qt) = P(t)$ and $P(0) = 1$. Primitivity and adjunction make distinct primitive dimensions orthogonal and give factorial pairings for powers. Taking logarithms of this identity and using (12.3) yields (12.5). □

In dimension two, writing $S = \mathbb{F}_Q[t]/(t)$ and $J_2 = \mathbb{F}_Q[t]/(t^2)$ gives

$$u_S^2 = u_{J_2} + (Q+1)u_{S\oplus S}, \qquad p_2 = u_{J_2} - (Q-1)u_{S\oplus S}.$$

The middle Green coefficients of u_{J_2} and $u_{S\oplus S}$ are $(Q-1)/Q$ and $1/Q$. They cancel for p_2. The cancellation uses automorphism orders and a signed linear combination of classes. It does not yet specify a complex or a homotopy on an extension space.

12.3 Flag convolution and a nonacyclic primitive class

Let $\mathcal{M}_n$ be a finite skeleton of the groupoid of n-dimensional nilpotent $\mathbb{F}_Q[t]$-modules. For a characteristic-zero field k, consider

$$\mathscr{D}_n = D^b \operatorname{Fun}(\mathcal{M}_n, \operatorname{Vect}_k^{\mathrm{fd}}) \simeq \prod_{|\lambda|=n} D^b \operatorname{Rep}_k^{\mathrm{fd}}(\operatorname{Aut} M_\lambda).$$

A functor on a groupoid assigns a vector space to each object and an invertible map to each isomorphism. Its restriction to one component is a representation of that object's automorphism group. Let $\mathcal{E}_{m,n}$ be the groupoid of short exact sequences with quotient dimension m and subobject dimension n. Write p for its endpoint map and q for its middle-object map.

Pullback followed by left Kan extension defines

$$\mathscr{F} \diamond \mathscr{G} = q_! p^*(\mathscr{F} \boxtimes \mathscr{G}).$$

Left Kan extension sums over the relevant finite groupoid fiber, taking coinvariants under its stabilizers. Characteristic zero makes these finite-group coinvariants exact. The two iterated convolution functors are push–pull along the same three-step flag groupoid. Base change gives associativity. Full flags give its higher coherences.

Let δ_M be the trivial representation on the component of M, extended by zero. At L, the fiber of $\delta_M \diamond \delta_N$ is the permutation representation on subobjects counted by $F^L_{M,N}$. Taking dimensions recovers the Hall product. For the reverse functor $p_! q^*$, coinvariants of the trivial representation of a finite group have dimension one. Groupoid cardinality instead assigns the reciprocal group order.

PROPOSITION 12.3.1. The zero-differential complex

$$\mathscr{P}_2 = \delta_{J_2} \oplus \delta_{S\oplus S}^{\oplus(Q-1)}[1]$$

has Euler class p_2. After applying $p_! q^*$ and forgetting endpoint actions, its (S,S) component has

$$H^0 = k^{Q-1}, \qquad H^{-1} = k^{Q-1}.$$

It is not acyclic.

Proof. There are Q extension classes of S by S. Each has stabilizer $\operatorname{Hom}(S,S)$ of order Q. The $Q-1$ nonzero classes have middle module J_2. The remaining class is split. Ordinary Kan extension therefore gives dimensions $Q-1$ and 1. It preserves the zero differential, so the shifted split summands give exactly the two displayed cohomology groups.

Green's scalar coefficients instead cancel as $(Q-1)/Q - (Q-1)/Q = 0$. □

The two source summands lie on different connected components of $\mathcal{M}_2$. This category has no morphism between them that could provide a cancelling differential. A geometric extension space can connect the split point to nonsplit extensions. The next construction retains that connection and its integration weight at the level of complexes.

12.4 A Fourier kernel on the extension space

Fix $\mathbb{F}_q$, a prime $\ell \nmid q$, and $K = \overline{\mathbb{Q}}_\ell$. We use bounded constructible complexes with Weil structure. Thus Frobenius acts on their stalk cohomology, and its alternating trace is defined. Our Tate convention gives $K(1)$ trace q^{-1}. A cohomological shift $[1]$ changes the trace sign. The notation $Rf_!$ denotes the derived direct image with proper supports, and Rf_* the ordinary derived direct image.

Choose a nontrivial additive character $\psi : \mathbb{F}_q \to K^\times$. Its Artin–Schreier sheaf $\mathcal{L}_\psi$ is the rank-one summand of the finite additive cover selected by ψ. For a d-dimensional vector space V, $d > 0$, let $p_V : V \times (V^\vee \setminus 0) \to V$ be projection. The pairing defines

$$\mathcal{P}_V = R p_{V!} \mathcal{L}_{\psi\langle v,\xi\rangle}[1]. \tag{12.6}$$

The shift is $[1]$ in every dimension. We use unshifted Fourier integration before inserting this shift.

Theorem 12.4.1. Let $i : \{0\} \hookrightarrow V$ and $j : V \setminus 0 \hookrightarrow V$. There is a triangle

$$i_* K(-d)[-2d] \xrightarrow{\text{Gys}} K_V \longrightarrow \mathcal{P}_V \longrightarrow . \tag{12.7}$$

The first arrow is the Gysin map normalized by compact trace, and $\mathcal{P}_V \simeq R j_* K_{V\setminus 0}$. Its nonzero stalk cohomology is

$$H^0(\mathcal{P}_V)_v = K \quad (v \in V), \qquad H^{2d-1}(\mathcal{P}_V)_0 = K(-d).$$

Its trace is 1 away from zero and $1 - q^d$ at zero, while $R\Gamma_c(V, \mathcal{P}_V) = 0$.

Proof. Fourier integration over all of $V^\vee$ gives $i_* K(-d)[-2d]$. Indeed, a nonzero v supplies a nonconstant linear coordinate whose Artin–Schreier sheaf has zero compact cohomology. At $v = 0$, the coefficient is constant on $\mathbb{A}^d$. Localization at the zero covector gives (12.7), with the first arrow initially defined by this integral.

Integrate in the other order. Each $\xi \neq 0$ again supplies a nonconstant Artin–Schreier coordinate, so the entire compact cohomology vanishes. The first arrow consequently induces the trace isomorphism on compact cohomology.

Purity identifies it with the normalized Gysin generator. The localization triangle $i_* i^! K_V \to K_V \to R j_* j^* K_V$ identifies its cone. At zero, the two terms have degrees $2d$ and 0. Their cone has the two stated degrees. The odd degree $2d - 1$ contributes $-q^d$ to the trace. □

The vanishing used in this proof is a vanishing of complexes. For the Artin–Schreier cover of $\mathbb{A}^1$, its deck translations act trivially on the sole compact cohomology of the covering affine line. Every nontrivial character summand therefore vanishes. Splitting off a nonconstant coordinate proves the higher-dimensional case. This also fixes the normalization independently of a character sum. Compare Laumon's Fourier formalism, §§1.1.3 and 1.2.1.

For the extension line of S by S, the operator is

$$\begin{pmatrix} 0 & v \\ 0 & 0 \end{pmatrix}, \qquad v \in \mathbb{A}^1.$$

Its middle module is J_2 when $v \neq 0$ and $S \oplus S$ when $v = 0$. Thus the trace of $\mathcal{P}_{\mathbb{A}^1}$ gives the coefficients of p_2, and integration over the extension line is zero as a complex. The Gysin arrow supplies the information absent from the disconnected complex of Proposition 12.3.1.

The construction works for a vector bundle $E \to B$ by using $E \times_B E^\vee$ and removing the zero section of the dual. It commutes with base change. Bundle automorphisms act contragrediently on the dual and preserve the pairing. The kernel therefore carries equivariance for the endpoint gauge action. This does not yet make it an object on the stack of middle modules.

PROPOSITION 12.4.2. For the split vector group $U = \mathbb{G}_a^h$,

$$R\Gamma_c(BU, K) = K(h)[2h].$$

Its trace is q^{-h}. On a product of an extension space with BU, proper-support integration includes this tensor factor.

Proof. The smooth atlas $\operatorname{Spec} \mathbb{F}_q \to BU$ has Čech nerve U^n. Each term has ordinary cohomology K. The normalized complex of these constants has only K in degree zero. The smooth stack has dimension $-h$ and dualizing complex $K(-h)[-2h]$. Verdier duality therefore gives the displayed compact cohomology. The product assertion follows from proper-support Künneth. □

For extensions of S by S, automorphisms fixing the endpoints form $\mathbb{G}_a$. The nonsplit and split trace contributions are $(q-1)/q$ and $(1-q)/q$. The attaching map makes their compact pushforward zero before and after tensoring with $K(1)[2]$. This geometric factor recovers the reciprocal stabilizer weight that ordinary finite-group coinvariants do not supply.

12.5 EVERY CUT OF A FLAG

For a vector space E, write the unshifted Fourier transform as

$$\mathsf{F}_E(\mathcal{K}) = R\operatorname{pr}_{E^\vee!}(\operatorname{pr}_E^* \mathcal{K} \otimes \mathcal{L}_{\psi\langle x,\xi\rangle}).$$

Integrating twice gives pullback by -1 followed by $(-\dim E)[-2\dim E]$. The rank-normalized transform is $\mathsf{F}_E[\dim E]$.

Let $0 = F_0 \subset F_1 \subset \cdots \subset F_s = V$ be a flag with positive graded dimensions n_i. Define

$$\mathfrak{g} = \operatorname{End}(V), \quad \mathfrak{p} = \{x : xF_i \subset F_i\}, \quad U = \{x : xF_i \subset F_{i-1}\}, \quad \mathfrak{l} = \bigoplus_i \operatorname{End}(F_i/F_{i-1}).$$

Let $i : \mathfrak{p} \hookrightarrow \mathfrak{g}$ and $q_0 : \mathfrak{p} \to \mathfrak{l}$ be the inclusion and quotient. Put $r = \dim U = \sum_{i<j} n_i n_j$. Trace pairings identify the full matrix spaces with their duals.

PROPOSITION 12.5.1. For every constructible complex $\mathcal{K}$ on $\mathfrak{l}$,

$$\mathsf{F}_{\mathfrak{g}}(i_* q_0^* \mathcal{K}) \simeq i_* q_0^* \mathsf{F}_{\mathfrak{l}}(\mathcal{K})(-r)[-2r].$$

For rank-normalized transforms, only the Tate twist remains. The comparison commutes with base change of flags, proper forgetting of flags, and finite flag refinements.

Proof. Choose an adapted frame. Integrating the strictly upper blocks forces the corresponding lower blocks of the dual matrix to vanish. This says $U^\perp = \mathfrak{p}$ for the trace pairing. The affine integral on this

locus contributes $K(-r)[-2r]$. The remaining phase is the trace pairing on $\mathfrak{l}$. Since $\dim \mathfrak{g} = \dim \mathfrak{l} + 2r$, rank normalization removes exactly that shift.

The pairings and subbundles are intrinsic, so the calculation glues over the flag scheme. Its incidence projection to $\mathfrak{g}$ is proper. Proper-support base change commutes the projection with Fourier integration. Every refinement integrates each strictly upper block once, with the same phase. Fubini and the coherent composition of the six operations identify all parenthesizations. □

Full matrix support matters here. The Fourier transform of a skyscraper at zero is constant on the dual matrix space. It need not retain nilpotent support.

For $1 \le p < s$, set

$$U_p = \{x : x(V) \subset F_p,\ x(F_p) = 0\} \subset U, \qquad H_p = U_p^{\perp} \subset U^\vee.$$

In an adapted splitting, U_p consists of blocks $i \le p < j$.

Define

$$\Omega = U^\vee \setminus \bigcup_{p=1}^{s-1} H_p, \qquad \mathcal{P}_F = \mathsf{F}_{U^\vee}(j_! K_\Omega)[s-1],$$

where $j : \Omega \hookrightarrow U^\vee$. A covector belongs to Ω exactly when its restriction to each whole cross-cut subspace is nonzero. For $s = 1$, set $\mathcal{P}_F = K$ on $U = 0$. This is an operation unit. A vacuum at a retained position is additional data.

Theorem 12.5.2. Every cut quotient $\rho_p : U \to U/U_p$ satisfies $R\rho_{p!}\mathcal{P}_F = 0$. The kernel and these comparisons are equivariant for the flag-preserving group. Successive quotient integrations have compatible Fubini comparisons.

Proof. Integrate first along U_p. A covector nonzero on U_p gives zero compact cohomology. A covector zero on U_p belongs to H_p, where $j_! K_\Omega$ restricts to zero. Proper-support base change proves the vanishing on the quotient. The flag group preserves each U_p and its annihilator, hence preserves the kernel. Iterated integration integrates over the same sum of cut subspaces, so its comparisons agree. □

The full flag is visible even in its scalar trace. For $J \subset \{1, \dots, s-1\}$, put $S_J = \sum_{p \in J} U_p$, $r_J = \dim S_J$ and $D = \dim U$. Inclusion–exclusion and character orthogonality give

$$k_F(x) = (-1)^{s-1} \sum_J (-1)^{|J|} q^{D - r_J} 1_{S_J}(x). \tag{12.8}$$

For three one-dimensional pieces, with coordinates $(a, b, c) = (x_{12}, x_{13}, x_{23})$, this becomes

$$k_3(x) = q^3 1_{x=0} - q 1_{c=0} - q 1_{a=0} + 1.$$

A nonzero outer entry b, with $a = c = 0$, gives $1 - 2q$. A single nonzero adjacent entry gives $1 - q$. Both operators have Jordan type $(2, 1)$, so the trace remembers the flag beyond the middle module.

For four one-dimensional pieces let $\delta_{ij} = 1_{x_{ij}=0}$. Formula (12.8) gives

$$\begin{aligned} k_4 = 1 &- q(\delta_{12} + \delta_{23} + \delta_{34}) + q^2 \delta_{12}\delta_{34} \\ &+ q^3(\delta_{23}\delta_{24}\delta_{34} + \delta_{12}\delta_{13}\delta_{23}) - q^6 1_{x=0}. \end{aligned}$$

Meeting every cut is weaker than connecting the graph of labels. The two edges 13 and 24 meet every consecutive cut but form a disconnected graph.

Comparison with the scalar Hall primitive

For a complete flag in dimension n, define

$$p_n(x) = \prod_{j=1}^{\ell(\lambda(x))-1} (1 - q^j), \qquad x \in U,$$

where $\lambda(x)$ is the Jordan partition. These are the coefficients in (12.4). For functions on the dual space, use $\mathsf{F}f(x) = \sum_\xi f(\xi)\psi(\langle x, \xi\rangle)$. Its inverse has opposite phase and factor q^{-D}.

PROPOSITION 12.5.3. For each proper cut and every $x \in U$,

$$\sum_{u \in U_p(\mathbb{F}_q)} p_n(x + u) = 0.$$

Hence $\mathsf{F}^{-1}p_n$ is supported on Ω. For $n = 3$, let $i_{13} : L_{13} \hookrightarrow U$ be the line $a = c = 0$, and write $\mathcal{P} = \mathcal{P}_{\mathbb{A}^1}$. Then

$$p_3 = \operatorname{tr}(\mathcal{P}_F \oplus i_{13*}\mathcal{P}(-1)[-2]). \tag{12.9}$$

Both summands have zero proper-support image under either cut. In dual coordinates (α, β, γ),

$$p_3 = \mathsf{F}(1_\Omega - q^{-1}1_{\{\beta \neq 0\}}).$$

Proof. Fix the diagonal blocks A, C at a cut. Changing a splitting changes its cross block B by $AZ - ZC$. The cokernel is $\operatorname{Ext}^1_{\mathbb{F}_q[t]}(C, A)$, so every extension class has the same number of cross-block representatives. The Green coefficient is the sum of the primitive's middle-object coefficients over these classes, divided by $|\operatorname{Hom}_{\mathbb{F}_q[t]}(C, A)|$. Primitivity makes it zero. Fourier transformation identifies this vanishing with zero restriction to H_p.

For three blocks, $ac \neq 0$ gives type (3), a nonzero operator with $ac = 0$ gives type (2, 1), and zero gives type (1, 1, 1). Their primitive coefficients are 1, $1 - q$ and $(1 - q)(1 - q^2)$. Subtracting from k_3 gives

$$k_3 - p_3 = -q1_{L_{13}} + q^2 1_{\{0\}} = -q \operatorname{tr}(i_{13*}\mathcal{P}).$$

The twist (-1) multiplies trace by q and $[-2]$ preserves its sign. The invariant line lies in both cut subspaces. Its cut pushforward has fiber $R\Gamma_c(\mathbb{A}^1, \mathcal{P}) = 0$. Finally, summing first over α, γ gives

$$\mathsf{F}1_{\{\beta \neq 0\}} = q^2 1_{L_{13}}(q1_{b=0} - 1),$$

which proves the last formula. □

The direct sum in (12.9) realizes the scalar primitive and its cut vanishing. It supplies no induction-compatible comparison of Hall products. The trace identity also supplies no distinguished map whose cone is the outer-line summand.

12.6 The attaching maps and their contractions

The flag kernel also has a construction over the integral flag scheme. Use constructible rational Beilinson motives, with their oriented six operations and purity for regular closed immersions. These operations and realizations are the setting of Cisinski–Déglise, *Triangulated categories of mixed motives*, Theorems 14.4.1 and 15.2.1 and Chapter 17. No integral Artin–Schreier sheaf is being assumed.

Over the flag scheme, U_p and S_J are vector subbundles of U: their adapted-frame descriptions have constant rank and glue. Let $i_J : S_J \hookrightarrow U$ and $h_J = D - r_J$. Define

$$B_J = i_{J*}\mathbf{1}_{S_J}(-h_J)[-2h_J].$$

Purity identifies B_J with $i_{J*}i_J^!\mathbf{1}_U$.

For $p \notin J$, the counit of the nested closed immersion gives a face $B_J \to B_{J\cup\{p\}}$. If its codimension is c, this is the Gysin map $\mathbf{1}_{S_J}(-c)[-2c] \to \mathbf{1}_{S_{J\cup\{p\}}}$, with closed direct image understood. Composition of the counits gives a coherent commuting cube.

Place B_J in external degree $|J|$, with total graded term $B_J[-|J|]$. The face in direction p has sign

$$\epsilon(J, p) = (-1)^{\#\{j\in J : j<p\}}.$$

The total differential is $d_{\mathrm{Tot}} = (-1)^{|J|}d_{\mathrm{int}} + d_{\mathrm{cube}}$. Use a compatible complex model of the finite cube and put $\mathcal{M}_F = \mathrm{Tot}(B_\bullet)[s-1]$. The Gysin morphisms remain part of this totalization.

Proposition 12.6.1. The ℓ-adic realization of $\mathcal{M}_F$ on a finite-field fiber is $\mathcal{P}_F$. The complex realization is the same total Gysin cube, retaining the Tate markings. On the fiber over a fixed complex flag, use the right differential-module convention $\mathrm{DR}(\omega_S) = \mathbb{C}_S[\dim S]$. Its vertex is

$$(i_J)_+\omega_{S_J}[-r_J - 2h_J], \qquad \text{with Tate marking } (-h_J). \tag{12.10}$$

Proof. On $U^\vee$, the tensor product of localization fibers $[K_{U^\vee} \to K_{H_p}]$ is $j_!K_\Omega$. Its J-vertex is K_{H_J} in external degree $|J|$, where $H_J = \bigcap_{p\in J} H_p = S_J^\perp$. Fourier integration of this vertex gives B_J: the integral vanishes off S_J and contributes $(-h_J)[-2h_J]$ on it. Each restriction face becomes the Gysin face normalized by compact trace. Thus Fourier integration identifies the entire cubes, including their total differentials and final shift.

Realization preserves the six operations and fundamental classes. Applying DR to (12.10) gives $i_{J*}\mathbb{C}_{S_J}[-2h_J]$, as required. For the absolute differential module over a smooth complex base B of flags, the shift is instead $[-\dim B - r_J - 2h_J]$, because $\dim S_J = \dim B + r_J$. For a normal coordinate t, the sequence

$$0 \longrightarrow \omega \longrightarrow \omega(*t) \longrightarrow i_+\omega_{t=0} \longrightarrow 0$$

represents the codimension-one Gysin map after these shifts. Tensoring its normal-coordinate models gives higher codimension. □

The supported differential module retains every finite normal derivative. If δ is its normal generator, then

$$(\delta\,\partial_t^a)t = a\,\delta\,\partial_t^{a-1}.$$

These are finite sums of derivatives, with no product completion. The comparison identifies the constructed cube in two realizations. It does not identify their whole coefficient categories.

Theorem 12.6.2. After quotient integration in a nonempty set P of cut directions, the total Gysin cube admits homotopies h_p, $p \in P$, with

$$dh_p + h_p d = 1, \qquad h_p^2 = 0, \qquad h_p h_q + h_q h_p = 0 \quad (p \neq q).$$

They are compatible with the trace-normalized comparisons for further cut integrations.

Proof. Set $U_P = \sum_{p\in P} U_p$ and let $\rho_P : U \to U/U_P$. The pushed vertex is supported on $\overline{S}_J = \rho_P(S_J)$. Its twist and shift are determined by

$$h_J + \dim(S_J \cap U_P) = D - \dim \overline{S}_J.$$

Both this integer and the support depend only on $J \setminus P$.

For $p \in P$, affine trace identifies the pushed p-face with the identity. The remaining faces are Gysin maps of the image subbundles, with common factor $(-\dim U_P)[-2\dim U_P]$. The pushed cube is therefore equivalent to the remaining cube tensored with $[K \xrightarrow{1} K]$ in every direction of P.

Write e_J for the external label of a vertex in this tensor model. Before the final shift define

$$h_p(e_J) = \begin{cases} \epsilon(J \setminus \{p\}, p)e_{J\setminus\{p\}}, & p \in J, \\ 0, & p \notin J. \end{cases}$$

Its coefficient map is the inverse of the identity comparison.

The p-face contributes the identity to $dh_p + h_p d$. Every other face cancels with the reversed order, and the internal differential cancels because label removal changes $|J|$ by one. Removing the same label twice gives zero. Reversing two distinct removals changes the sign. This proves all three identities.

The final shift multiplies both d and h_p by $(-1)^{s-1}$. Composing affine traces gives the trace for the composite quotient. The common orientation therefore makes these homotopies compatible with further integrations. □

The omitted outer covector locus

For three one-dimensional pieces, the two binary groupings use the dual opens

$$O_L = \{\alpha \neq 0,\ (\beta,\gamma) \neq (0,0)\}, \qquad O_R = \{\gamma \neq 0,\ (\alpha,\beta) \neq (0,0)\}.$$

Their union O misses the nonempty locus $Z = \{\alpha = \gamma = 0,\ \beta \neq 0\}$ in Ω. Extending by zero to $U^\vee$, the two triangles are

$$K_{O_L\cap O_R,!} \longrightarrow K_{O_L,!} \oplus K_{O_R,!} \longrightarrow K_{O,!} \longrightarrow,$$
$$K_{O,!} \longrightarrow K_{\Omega,!} \longrightarrow K_{Z,!} \longrightarrow .$$

Fourier transform with the common shift $[2]$ preserves them. The last term has trace $q1_{b=0} - 1$, so it is nonzero. These are extension coordinates. A position-space 13|2 operation requires a separate map preserving the corresponding supports.

12.7 Descent after forgetting the flag

Assume the finite field has characteristic different from two. Let $\mathcal{N}_2 \subset \mathfrak{sl}_2$ be the nilpotent cone, with punctured inclusion j_N. The extension line maps into it by $f(v) = \left(\begin{smallmatrix} 0 & v \\ 0 & 0 \end{smallmatrix}\right)$.

THEOREM 12.7.1. There is no constructible complex $\mathcal{F}$ on $\mathcal{N}_2$ with $j_N^*\mathcal{F} \simeq K$ and $f^*\mathcal{F} \simeq \mathcal{P}_{\mathbb{A}^1}$, whose restriction to $\mathbb{G}_m$ agrees with that constant marking.

Proof. The cone is $\mathbb{A}^2/\{\pm 1\}$, and the quotient is finite étale away from zero. Characteristic-zero coefficients make invariants exact. The scalar involution preserves the orientation class, so purity gives stalk cohomology K in degree zero and $K(-2)$ in degree three for $R\,j_{N*}K$ at zero. In particular, its degree-one stalk vanishes.

An $\mathcal{F}$ as stated would give, by adjunction and base change,

$$\mathcal{P}_{\mathbb{A}^1} \longrightarrow f^* R j_{N*} K \longrightarrow R j_* K_{\mathbb{G}_m} \simeq \mathcal{P}_{\mathbb{A}^1}.$$

The composite is the identity on $\mathbb{G}_m$. Since $R j_*$ is fully faithful, it is the identity everywhere. Its degree-one stalk would factor the identity of $K(-1)$ through zero, a contradiction. □

There is a further obstruction without an open marking. Work over $\overline{\mathbb{F}}_q$ and let $G = \mathrm{GL}_n$. For a parabolic P with Levi quotient L, use

$$\mathcal{N}_L \xleftarrow{p} \mathcal{N}_P \xrightarrow{i} \mathcal{N}_n, \qquad \mathcal{N}_P = \mathcal{N}_n \cap \mathrm{Lie}\, P.$$

Parabolic restriction $\mathsf{R}_L^G = R p_! i^*$ first forgets equivariance from G to P, then identifies P- and L-equivariance on $\mathcal{N}_L$. Use its perverse-exact normalization, and fix a maximal torus $T \subset B \subset G$.

Proposition 12.7.2. If $\mathcal{F} \in D^b_G(\mathcal{N}_n, K)$ and $\mathsf{R}_T^G \mathcal{F} = 0$, then $\mathcal{F} = 0$. For $n \geq 2$, no nonzero object of this category has all proper parabolic restrictions zero.

Proof. Parabolic restriction is perverse-exact and has parabolic induction as right adjoint. See Achar–Mautner, arXiv:1207.7044, Remark 2.1 and Proposition 3.1. Every simple G-equivariant perverse sheaf is a summand of the Springer sheaf $\mathsf{I}_T^G K$. Indeed, nilpotent centralizers in GL_n are connected, so these simples are indexed by partitions. The ordinary Springer injection is a bijection because irreducible characteristic-zero representations of S_n have the same indexing.

For a simple $\mathcal{L}$, its nonzero inclusion into $\mathsf{I}_T^G K$ gives a nonzero map $\mathsf{R}_T^G \mathcal{L} \to K$ by adjunction. Exactness and finite length show that restriction kills no nonzero perverse sheaf. It commutes with perverse cohomology, so boundedness proves the assertion for $\mathcal{F}$. Transitivity factors restriction to T through successive proper cuts. □

These statements concern the ordinary nilpotent recipient and its specified restriction functors. The marked Fourier construction retains an extension or cotangent variable. Its cut integrals are different operations, so its positive vanishing theorem survives.

The failure is also visible after a proper forgetting map. Let $\widetilde{\mathcal{N}}_2$ consist of pairs (N, L) with $N(V) \subset L$ and $N(L) = 0$. Its projection $\pi : \widetilde{\mathcal{N}}_2 \to \mathcal{N}_2$ forgets L. The extension line bundle over $\mathbb{P}^1$ carries the relative kernel $\mathcal{P}$.

Proposition 12.7.3. The compact cohomology of $f^* R\pi_* \mathcal{P}$ is nonzero. Its Frobenius trace is $q(1-q)$, although integration over the original extension fiber is zero.

Proof. A regular nilpotent has one stable line with nonzero extension coordinate, giving trace 1. At zero, all $q+1$ lines are stable and each contributes $1-q$. Summing on the marked line therefore gives $(q-1) + (q+1)(1-q) = q(1-q) \neq 0$. The nonzero trace detects nonzero cohomology. Including the unipotent factor $K(1)[2]$ divides the trace by q and leaves it nonzero. □

For linear grouping itself, put $\widetilde{\mathcal{P}}_V = \mathcal{P}_V[-1]$. The inclusion of the product of punctured duals into the punctured total dual gives

$$\widetilde{\mathcal{P}}_V \boxtimes \widetilde{\mathcal{P}}_W \longrightarrow \widetilde{\mathcal{P}}_{V \oplus W}.$$

All parenthesizations include the same locus where every original covector block is nonzero, so they compose coherently. The two omitted punctured axes give the triangle

$$(\mathcal{P}_V \boxtimes \mathcal{P}_W)[-1] \longrightarrow \mathcal{P}_{V \oplus W} \longrightarrow (\mathcal{P}_V \boxtimes K_W) \oplus (K_V \boxtimes \mathcal{P}_W) \longrightarrow .$$

This follows by applying Fourier integration to their localization triangle, retaining the single shift in (12.6).

A linear map $g : V \to W$ likewise has the comparison

$$\mathsf{F}_W(Rg_!\mathcal{G}) \simeq (g^\vee)^*\mathsf{F}_V(\mathcal{G}).$$

Both sides integrate the phase $\langle g(v), \eta\rangle$. Rank normalization adds $[\dim W - \dim V]$ on the right. These linear comparisons do not construct the nonlinear Hall incidences or a vanishing-cycle comparison.

12.8 Cohomology of the extension correspondence

An extension count records the size of a fiber. Equivariant cohomology also records its characteristic classes. Even the charge-one space already distinguishes the two constructions: a one-dimensional vector space has automorphism group $\mathbb{C}^\times$, and $H^*(B\mathbb{C}^\times;\mathbb{Q}) = \mathbb{Q}[x]$, with $|x| = 2$. There is one class in every nonnegative even degree.

Let Q be a finite quiver, with vertex set I and a_{ij} arrows from i to j. For a dimension vector $d \in \mathbb{N}^I$, put

$$X_d = \bigoplus_{i,j} \mathrm{Hom}(\mathbb{C}^{d_i}, \mathbb{C}^{d_j})^{\oplus a_{ij}}, \qquad G_d = \prod_i GL_{d_i}, \qquad \mathfrak{M}_d = [X_d/G_d].$$

Fix standard subspaces of dimension d_i in $\mathbb{C}^{d_i+e_i}$. Let $X_{d,e} \subset X_{d+e}$ be the representations preserving them, and let $P_{d,e} \subset G_{d+e}$ preserve the subspaces. The two maps

$$\mathfrak{M}_d \times \mathfrak{M}_e \xleftarrow{p} [X_{d,e}/P_{d,e}] \xrightarrow{q} \mathfrak{M}_{d+e}$$

remember the subrepresentation and quotient, or forget the subspaces. The map q is proper: its fibers are closed subvarieties of products of Grassmannians. The map p retains the extension coordinates and the unipotent automorphisms of the sequence.

Write

$$\chi(d,e) = \sum_i d_i e_i - \sum_{i,j} a_{ij} d_i e_j.$$

The cohomological Hall product acts on $\bigoplus_d H^*(\mathfrak{M}_d;\mathbb{Q})$. It combines pullback along p, the normal Euler class of $X_{d,e}$, and proper flag pushforward. Its cohomological degree is $-2\chi(d,e)$. Since X_d contracts equivariantly to zero,

$$H^*(\mathfrak{M}_d;\mathbb{Q}) = \mathbb{Q}[x_{i,r} : i \in I,\ 1 \le r \le d_i]^{\prod_i S_{d_i}}.$$

Here $x_{i,r}$ are Chern roots of degree two.

THEOREM 12.8.1 *(Cohomological Hall shuffle product).* For f of charge d and g of charge e, the product is

$$f * g = \sum_{\text{vertexwise shuffles}} f(x)g(y) \frac{\displaystyle\prod_{i,j}\prod_{r=1}^{d_i}\prod_{s=1}^{e_j}(y_{j,s} - x_{i,r})^{a_{ij}}}{\displaystyle\prod_i \prod_{r=1}^{d_i}\prod_{s=1}^{e_i}(y_{i,s} - x_{i,r})}. \tag{12.11}$$

The sum is a symmetric polynomial. It defines an associative unital product. The unit is $1 \in H^*(\mathfrak{M}_0) = \mathbb{Q}$.

Proof. The normal directions to the invariant-subspace locus are maps from the subspace at i to the quotient at j, one for each arrow $i \to j$. Their equivariant Euler class is the numerator. The tangent directions of the flag variety give the denominator.

The fixed points of its maximal torus are precisely the choices of d_i roots at each vertex. Equivariant localization of the proper pushforward therefore gives (12.11). The pushforward is defined before localization, so its sum is polynomial. This is the extension-correspondence calculation of Kontsevich–Soibelman, arXiv:1006.2706, §§2.2–2.4.

For three factors, either parenthesization chooses the same ordered three-block partition at every vertex. Every pair of blocks contributes the same Euler quotient exactly once. The terms, including their degrees, agree. An empty block contributes no Euler factors and has one shuffle. This proves associativity and the unit laws. □

Suppose now that $a_{ij} = a_{ji}$. The charge shift

$$A_d = H^*(\mathfrak{M}_d; \mathbb{Q})[-\chi(d,d)]$$

makes multiplication degree zero. Thus a polynomial of degree r has cohomological degree $2r + \chi(d,d)$. Exchanging its two blocks in (12.11) gives $f * g = (-1)^{\chi(d,e)} g * f$. We first use the symmetric tensor convention whose crossing on charges d, e is $(-1)^{\chi(d,e)}$.

There is also an ordinary super convention. Put

$$\tau(d,e) = \chi(d,e) + \chi(d,d)\chi(e,e) \pmod 2$$

and choose a bilinear form ψ modulo two with $\psi(d,e) + \psi(e,d) = \tau(d,e)$. Such a form exists because τ is alternating. The product $f \star g = (-1)^{\psi(d,e)} f * g$ is supercommutative for the usual cohomological parity. Its associativity follows from bilinearity of ψ. The choice changes signs, not the graded spaces.

Example 12.8.2. For one vertex with no arrows the kernel in (12.11) is $1/(y-x)$. Let $e_r = x^r$ in charge one. Then

$$e_r * e_s = \frac{x^r y^s - x^s y^r}{y - x}, \qquad |e_r| = 2r + 1.$$

The algebra is the exterior algebra on all e_r, $r \geq 0$. Indeed, the product of $e_{r_1}, \dots, e_{r_n}$ is, up to sign, their alternant divided by the Vandermonde determinant. For strictly increasing nonnegative exponents these quotients give the Schur basis of the symmetric polynomials. Repeated exponents give zero. This proves both spanning and linear independence.

For one vertex with one loop the kernel is 1 and $|e_r| = 2r$. Products are symmetrized monomials. Their multiplicity factorials are invertible over $\mathbb{Q}$, so the algebra is the polynomial algebra $\mathbb{Q}[e_0, e_1, \dots]$. Neither example has only one generator in charge one.

12.9 Primitive fields for a symmetric quiver

The dual of the Hall product is a coproduct. In the symmetric, zero-potential case it belongs to a vertex algebra with a precise primitive description. All duals in this section are graded duals:

$$V = \bigoplus_{d,k} (A_d^{-k})^\vee.$$

Each summand is finite dimensional. The full linear dual, with its unrestricted product over degrees, is a different recipient.

Use vertex algebras with lower-truncated fields $Y(a,z)=\sum_n a_{(n)}z^{-n-1}$, vacuum 1, and translation D. They satisfy $Y(1,z)=\mathrm{id}$, $Y(Da,z)=[D,Y(a,z)]=\partial_z Y(a,z)$ and $Y(a,z)1=e^{zD}a$, together with mutual locality. For a pair of states, locality of order $N\geq 0$ is equivalent to $a_{(n)}b=0$ for $n\geq N$. The symmetric tensor convention is the charge crossing fixed above.

Let e_i denote the ith standard dimension vector. Start with states v_i of charge e_i, parity $\chi(e_i,e_i) \bmod 2$ and cohomological degree $-\chi(e_i,e_i)$. Impose locality orders $N_{ij}=\max\{0,-\chi(e_i,e_j)\}$. The principal free vertex algebra P_Q is the universal vertex algebra with these generating states and relations.

The singular products $a_{(n)}b$, $n\geq 0$, and translation form a *vertex Lie algebra*. Its axioms are the sesquilinearity, skew-symmetry and Jacobi identities of the singular part of a field. Its universal enveloping vertex algebra $U^{\mathrm{ch}}(P)$ is generated by P with these prescribed singular products and translation. The coefficient-mode construction appears in the proof.

THEOREM 12.9.1 *(Dotsenko–Mozgovoy).* For a finite symmetric quiver with zero potential and rational coefficients, V is canonically a connected cocommutative vertex bialgebra and $P_Q\simeq V$. Its coproduct is dual to the Hall product. If

$$P=\{a\in V:\Delta a=a\otimes 1+1\otimes a\},$$

then P is a vertex Lie algebra and $U^{\mathrm{ch}}(P)\simeq V$. Moreover, D has cohomological degree -2, and

$$P\simeq W\otimes\mathbb{Q}[D],\qquad W=P/DP,\qquad \dim W_d<\infty.$$

Every nonzero W_d^k has $k\equiv\chi(d,d) \pmod 2$.

After choosing homogeneous lifts of W, graded duality gives

$$\mathcal{A}\simeq \mathrm{Sym}_{\chi}(W^{\vee}\otimes\mathbb{Q}[u]),\qquad |u|=2, \tag{12.12}$$

as algebras. With the product $\star$, this is a free supercommutative algebra in the ordinary parity convention. The choice of lifts makes this last presentation noncanonical.

Proof. We recall the maps and the separate finiteness argument in Dotsenko–Mozgovoy, arXiv:2108.10338, Proposition 5.3 and Theorems 5.6–5.7. For a sequence $i_1,\dots,i_m$ of vertices with total charge d, set $N(i,j)=-\chi(e_i,e_j)$. The map from $P_Q^{\vee}$ to symmetric polynomials is

$$\xi\longmapsto \prod_{r<s}(z_r-z_s)^{N(i_r,i_s)}\big\langle \xi, Y(v_{i_1},z_1)\cdots Y(v_{i_m},z_m)1\big\rangle.$$

Its value is symmetric under simultaneous permutations of vertices and variables. The vacuum removes negative powers of the last variable. Symmetry removes them from every variable. The graded functional has finite degree support, so the expression is polynomial.

When $N(i,i)=-1$, the state is odd. Self-locality of order zero already implies self-locality of order -1.

The map is injective because coefficients of the products of generating fields span P_Q. In the lattice realization, the creation part of these products is an exponential whose coefficients are monomials in power sums. These generate the symmetric polynomial ring over $\mathbb{Q}$, proving surjectivity.

Declare the v_i primitive. Expand the coproduct by assigning each factor of the ordered field product to one of two blocks. The cross factor is exactly the Euler quotient in (12.11). Thus the comparison preserves the coproduct, not only graded dimensions.

For primitive a, b of charges d, e, compatibility of the fields and coproduct gives

$$\Delta(Y(a,z)b) = Y(a,z)b \otimes 1 + 1 \otimes Y(a,z)b \\ + e^{zD}a \otimes b + (-1)^{\chi(d,e)} b \otimes e^{zD}a.$$

The two mixed terms are regular. Hence every singular coefficient $a_{(n)}b$, $n \geq 0$, is primitive. Translation preserves primitives as well. These operations give the vertex Lie algebra P.

Positive charge makes the coalgebra connected: more than $\sum_i d_i$ positive factors annihilate its iterated reduced coproduct in charge d. The connected vertex Milnor–Moore theorem then identifies $U^{\mathrm{ch}}(P)$ with V.

For clarity, the coefficient Lie algebra of P is

$$\mathfrak{g}_P = P \otimes \mathbb{Q}[t, t^{-1}]/(D + \partial_t), \qquad [a[m], b[n]] = \sum_{j \geq 0} \binom{m}{j} (a_{(j)}b)[m + n - j].$$

Its negative part has $a[-r] = (D^{r-1}a)[-1]/(r-1)!$ for $r \geq 1$. PBW symmetrization identifies the coalgebra of the vacuum induced module with $\mathrm{Sym}_{\chi}(\mathfrak{g}_P^-)$. In particular, this coalgebra statement concerns every negative mode.

The mode presentation also has an operator T, defined on generators by $T(v_i[n]) = -v_i[n+1]$, with $[D, T] = |d|\,\mathrm{id}$ in positive charge d. Its weights are bounded below, with D raising and T lowering weight. After dividing T by $|d|$, the following elementary argument proves that D acts freely. If $Da = 0$, the finite span of $a, Ta, T^2a, \ldots$ is stable under D, T. The trace of $[D, T] = 1$ would equal its dimension and also vanish, so $a = 0$.

Choose a graded complement to DP. Induction on weight gives spanning by its D-iterates. Cancellation of the lowest power of D proves their independence.

This argument alone does not prove $\dim W_d < \infty$. The framed CoHA character identity in the cited theorem implies that $(1 + q + \cdots + q^{w \cdot d - 1})\,\mathrm{ch}(W_d)$ is a Laurent polynomial, for a framing w with $w \cdot d > 0$. The series $\mathrm{ch}(W_d)$ is bounded below and has nonnegative coefficients. The product can have finite support only if the series does. The lattice weights give the asserted parity. Finally, degreewise duality of the PBW coalgebra, with the chosen lifts of W, proves (12.12). □

The algebra conclusion is also Efimov's freeness theorem, arXiv:1103.2736, Theorem 1.1. The vertex construction explains its translation strings. The quotient P/DP has a Lie bracket induced by the zeroth product. It must not be identified with a cohomological BPS Lie algebra merely because their graded characters give the same invariants.

12.10 A potential and the perverse filtration

A potential changes the coefficients of the correspondence. Let $W \in \mathbb{C}Q/[\mathbb{C}Q, \mathbb{C}Q]$ be a finite linear combination of cyclic paths. It defines the regular function $f_d = \mathrm{Tr}(W)$ on $\mathfrak{M}_d$. The Jacobi algebra is the path algebra modulo the cyclic derivatives $\partial_a W$ for arrows a. Its representation moduli form the critical locus of f_d. Critical cohomological Hall theory uses vanishing cycles of f_d, retaining their monodromy.

Choose numbers ζ_i with positive imaginary parts. For $d \neq 0$, set

$$Z_\zeta(d) = \sum_i \zeta_i d_i, \qquad \mu_\zeta(d) = -\frac{\mathrm{Re}\, Z_\zeta(d)}{\mathrm{Im}\, Z_\zeta(d)}.$$

A representation is ζ-semistable when every nonzero proper subrepresentation has slope at most that of the full representation. Fix a slope μ. Write Λ^{ζ}_{μ} for zero together with the dimension vectors of that slope, and $\mathfrak{M}_d^{\zeta\text{-ss}}$ for the stack of semistable representations.

Require ζ to be *μ-generic*: $\chi(d,e) = \chi(e,d)$ for all $d, e \in \Lambda^{\zeta}_{\mu}$. Fix a Serre subcategory $\mathcal{S}$, closed under subobjects, quotients and extensions. Require its semistable objects to form a locally closed substack $\mathfrak{M}_d^{\zeta\text{-ss},\mathcal{S}}$. These choices enter both the Hall algebra and its primitive term.

We use rational monodromic mixed Hodge modules. This coefficient category retains the Hodge and weight filtrations together with vanishing-cycle monodromy. Put $\mathbb{L} = H_c(\mathbb{A}^1;\mathbb{Q})$ and use its monodromic square root $\mathbb{L}^{1/2}$, of cohomological degree one.

Let ϕ_f^{mon} be the perverse-normalized monodromic vanishing-cycle functor. Assume that every critical point of f_d lies over zero. Without this assumption, replace it by the sum of vanishing cycles over all critical values.

Define

$$\mathcal{A}^{\zeta,\mathcal{S}}_{W,\mu} = \bigoplus_{d\in\Lambda^{\zeta}_{\mu}} H_c\left(\mathfrak{M}_d^{\zeta\text{-ss},\mathcal{S}}, \phi^{\mathrm{mon}}_{f_d}\mathbb{Q}_{\mathfrak{M}_d^{\zeta\text{-ss}}} \otimes \mathbb{L}^{-\dim \mathfrak{M}_d^{\zeta\text{-ss}}/2}\right)^{\vee}.$$

The functor and dimension shift are taken on the ambient smooth semistable stack before restriction to $\mathcal{S}$. Stack cohomology uses equivariant finite-dimensional approximations. The dual is the degreewise dual of compactly supported cohomology. The extension correspondence and Thom–Sebastiani isomorphism define the critical Hall multiplication on this object.

Let $M_d^{\zeta\text{-ss}}$ be the coarse moduli space. Its normalized intersection complex IC_d is Verdier self-dual. On a smooth component it is $\mathbb{L}^{-\dim M_d/2}\mathbb{Q}_{M_d}$. Define the BPS sheaf to be $\phi^{\mathrm{mon}}_{f_d}\mathrm{IC}_d$ if the stable locus is nonempty, and zero otherwise.

Denote by $\mathcal{B}^{\zeta,\mathcal{S}}_{W,\mu}$ the direct sum of the duals of its compactly supported cohomology restricted to the coarse loci selected by $\mathcal{S}$. The remaining universal factor is

$$H(B\mathbb{C}^{\times})_{\mathrm{vir}} = \mathbb{L}^{1/2} \otimes H^*(B\mathbb{C}^{\times};\mathbb{Q}).$$

Its half-Tate shift is part of the normalization.

THEOREM 12.10.1 *(Davison–Meinhardt).* With these hypotheses there is a PBW isomorphism of charge-graded, cohomologically graded monodromic mixed Hodge objects

$$\mathrm{Sym}_{\tau}\left(H(B\mathbb{C}^{\times})_{\mathrm{vir}} \otimes \mathcal{B}^{\zeta,\mathcal{S}}_{W,\mu}\right) \xrightarrow{\sim} \mathcal{A}^{\zeta,\mathcal{S}}_{W,\mu}.$$

Here the symmetry is the Koszul sign multiplied by $(-1)^{\tau(d,e)}$, with τ as above on Λ^{ζ}_{μ}. The perverse associated graded of the Hall algebra is free commutative for this symmetry. After a bilinear sign modification $\psi + \psi^{\mathrm{T}} = \tau$ of multiplication, that associated graded is free supercommutative for the ordinary Koszul symmetry. The displayed PBW map concerns underlying graded objects. It need not be an algebra isomorphism for the original Hall multiplication.

This is the absolute form of Theorems A and C of Davison–Meinhardt, arXiv:1601.02479. The perverse filtration comes from the map from the semistable stack to its coarse moduli space. It is not the filtration by total dimension alone. The PBW map uses the BPS embedding and symmetrized Hall multiplication. The original algebra can therefore have nonzero commutators whose leading perverse symbols commute.

The recipient allows infinitely many cohomological degrees. For each fixed charge and weight, only finitely many cohomological degrees occur, and the weights are bounded below at fixed charge. Symmetric powers are formed by sums in this recipient. They are not unrestricted products of all cohomological degrees. The zero-potential algebra theorem (12.12) retains its stronger conclusion in its own finite symmetric-quiver setting.

12.11 An ordinary coproduct obstruction on a shuffle algebra

The preceding vertex coproduct is dual to a symmetric Hall product. A deformed shuffle multiplication poses a different compatibility problem. Its charge-one elements can already prevent an ordinary counital coproduct from being multiplicative.

Work over

$$R = \mathbb{Q}[h_1, h_2], \qquad h_3 = -h_1 - h_2, \qquad a = -(h_1^2 + h_1h_2 + h_2^2), \qquad b = -h_1h_2(h_1 + h_2).$$

Put $N(v) = \prod_i (v + h_i) = v^3 + av + b$. For $j = 0, 1$, let

$$\mathcal{A}^{(j)} = \bigoplus_{n \geq 0} R[x_1, \dots, x_n]^{S_n}, \qquad K_j(v) = v^{2j-1} N(v).$$

These are algebraic direct sums. Charge is n. All cochain degrees and parities are zero. There is no completion or inversion of parameters. The product is

$$(F *_j G)(X) = \sum_{I \sqcup J = [d+e],\ |I| = d} F(X_I) G(X_J) \prod_{i \in I, k \in J} K_j(x_k - x_i).$$

There is no factorial denominator. For $j = 0$, opposite residues cancel along each true diagonal, so the sum is polynomial. For $j = 1$ every summand is polynomial. Ordered three-block partitions prove associativity in either case. The unit is $1_0 \in A_0 = R$, distinct from the constant polynomial in charge one.

The binary image remembers the coefficient ring. Write $c = (x + y)/2$, $v = y - x$, $t = v^2$ and $B = R[c, t]$. Then $R[x, y] = B \oplus vB$, and the multiplication map is

$$\mu_j(A + vC) = 2t^j \big((t + a)A + bC\big). \tag{12.13}$$

Consequently its image is $t^j(t + a, b)$. The complex $[B^2 \xrightarrow{\mu_j} B]$ in degrees $-1, 0$ has

$$H^{-1} = B\,(b, -(t + a)), \qquad H^0 = B/t^j(t + a, b).$$

To compute the kernel, reduce $(t + a)A + bC = 0$ modulo $t + a$. The quotient $R[c]$ is a domain, so C is divisible by $t + a$. Cancellation gives the displayed generator. Multiplication by t^j adds no kernel.

The two cokernels have different parameter annihilators:

$$\operatorname{Ann}_R B/(t + a, b) = (b), \qquad \operatorname{Ann}_R B/t(t + a, b) = 0.$$

For the first, set $t = -a$. For the second, evaluation at $t = 0$ maps the quotient onto the faithful R-module $R[c]$. Thus the two binary lattices cannot be interchanged over R by an operation-preserving charge-graded equivalence.

THEOREM 12.11.1. Neither $\mathcal{A}^{(j)}$ admits an R-linear, charge-preserving, unital algebra map

$$\Delta : \mathcal{A}^{(j)} \longrightarrow \mathcal{A}^{(j)} \otimes_R^{\mathbb{L}} \mathcal{A}^{(j)}$$

with ordinary Koszul multiplication and two-sided counit given by projection to charge zero. The same holds for the subalgebra generated by charge one. No coassociativity hypothesis is needed.

Proof. Set $e_m = x^m \in A_1$. The difference of the two kernel orders gives

$$[f, g]_{*_j} = 2bt^j \frac{f(x)g(y) - g(x)f(y)}{y - x}.$$

In particular,

$$[e_0, e_3] = 2bt^j(x^2 + xy + y^2), \qquad [e_1, e_2] = 2bt^j xy,$$
$$[e_0, e_1] = 2bt^j, \qquad e_0 *_j e_0 = 2t^j(t + a).$$

They satisfy the exact relation

$$[e_0, e_3] - 3[e_1, e_2] + a[e_0, e_1] = b(e_0 *_j e_0). \tag{12.14}$$

Charge preservation and both counits force $\Delta e_m = e_m \otimes 1_0 + 1_0 \otimes e_m$. In the ordinary tensor product, mixed terms in the commutator of two even primitive elements cancel. The $(1, 1)$ component of the coproduct of the left side of (12.14) is therefore zero. The right side gives $2b\, e_0 \otimes e_0$, which is nonzero in $R[x, y]$.

Every ambient charge component is free over R, so its derived tensor is ordinary. For the charge-one generated subalgebra the same detecting component is still the free tensor $R[x, y]$. Taking cohomology preserves the contradiction. At $(h_1, h_2, h_3) = (1, 1, -2)$ its coefficient is $2b = -4$. The proof neither divides by b nor asserts persistence at $b = 0$. □

The tensor in this theorem is essential. A rational replacement can carry a compatible cooperation. For ordered blocks X, Y, set

$$Q^{(j)}_{d,e}(X, Y) = \prod_{x \in X, y \in Y} K_j(y - x), \qquad \Delta^{\mathrm{rat}}_{d,e} F = \frac{F(X, Y)}{Q^{(j)}_{d,e}(X, Y)}, \qquad r(v) = \frac{v^3 + av - b}{N(v)}.$$

Use polynomial rings localized at all spectral differences and their translates $v \pm h_i$, then take the blockwise symmetric invariants. No parameter is inverted by itself, but closed spectral loci have been removed. Take F of bidegree (d, e) and G of bidegree (d', e'). Their target product is the sum of

$$F(X_1, Y_1)G(X_2, Y_2) \prod_{x \in X_1, x' \in X_2} K_j(x' - x)$$
$$\cdot \prod_{y \in Y_1, y' \in Y_2} K_j(y' - y) \prod_{y \in Y_1, x' \in X_2} r(y - x')$$

over the two prescribed ordered splittings of X and Y. The last factor changes the interchange of the middle two blocks.

PROPOSITION 12.11.2. This target multiplication is associative and unital. The maps Δ^{rat} are multiplicative, coassociative in the corresponding three-block localizations, and counital at charge zero.

Proof. In a shuffle term, division by the total cross kernel cancels the factors between X_1 and Y_2. The remaining middle ratio is $K_j(x' - y)/K_j(y - x') = r(y - x')$, for $y \in Y_1$, $x' \in X_2$. This is exactly the displayed target product.

For three factors, either parenthesization contains the same internal kernels and the same earlier-right, later-left exchange factors. This proves associativity. Iterating cooperation divides by $Q_{12}Q_{13}Q_{23}$ in both orders. Empty products give the unit and both counits. □

For (12.14), the new mixed term satisfies

$$(1 - r(v))v(v^2 + a) = b(1 + r(v)),$$

as follows directly from $1 - r(v) = 2b/N(v)$. It supplies the term absent from the ordinary tensor calculation.

Nevertheless,

$$\Delta^{\mathrm{rat}}_{1,1}(1_2) = \begin{cases} v/N(v), & j = 0, \\ 1/(vN(v)), & j = 1, \end{cases}$$

is not polynomial. Localizing an equation that vanishes on a shifted collision annihilates that closed restriction. Extending this rational cooperation to supported coefficients remains a separate problem. Such an extension must retain the integral images (12.13) and derived collision complexes. An ordinary coefficient bialgebra and a strong coalgebra for cut convolution have different tensors. The theorem excludes the latter only when its marked comparison induces the former.

12.12 The arithmetic Hall comparison

The constructions above specify several recipients of Hall data. The scalar Hall algebra retains automorphism-weighted extension counts. The Fourier kernel retains an attaching morphism and compatible primitive contractions. Cohomological Hall theory retains characteristic classes. A potential additionally retains vanishing cycles and their monodromy. A comparison must name which of these operations it preserves.

Question 12.12.1. Construct an independently defined arithmetic Hall category and an operation-preserving functor to the intended geometric or field category. Its extension correspondences must induce the specified Hall multiplication and primitive cut maps. It must retain automorphism and Tate normalizations, place labels, substitutions and nonconsecutive collision supports. The empty unit and marked local vacuum require their own compatible maps. All comparisons must respect composition.

For a critical CoHA target, construct the arithmetic quiver, potential, stability data and normalized coefficient comparison. For a field target, construct the actual fields, translation and supported products on the proposed states.

The flag kernels solve the primitive cut problem with the flag retained. Their descent failures locate the additional datum needed by an unmarked recipient. The symmetric-quiver theorem constructs primitive fields on its graded dual. Neither statement constructs an arithmetic Hall functor or an equivalence with an independently specified arithmetic category.

The formal Euler expansion also keeps a precise scope. On $\operatorname{Re} s > 1$,

$$\log \zeta(s) = \sum_p \sum_{k \geq 1} \frac{p^{-ks}}{k}, \qquad -\frac{\zeta'(s)}{\zeta(s)} = \sum_p \sum_{k \geq 1} (\log p)\, p^{-ks}.$$

The coefficients of the first series are rational. Logarithms appear after differentiation. Neither series specifies a finite cyclic word in a path algebra. A potential requires such a cyclic class, or a specified completion and a trace map on it. A class in cyclic homology or an exponential Hodge recipient would require its own construction and comparison with the Euler series. The scalar identity supplies no canonical lift of this kind.

Chapter 13

Hecke, Adams, and Witt operations

An operation on mode indices does not determine its arithmetic meaning. Divisor substitutions, index shifts and Hecke operators act on different structures, even when their first values agree. Their composition laws separate them. Integral lattices, distinguished states and completed domains give further distinctions.

We begin with three explicit formulas. The divisor substitutions have a noncommutative algebra of boundary corrections. A second divisor formula gives a genuine linear Hecke action. The index shifts preserve the integral symmetric-function lattice and satisfy additional Frobenius congruences. Big Witt coordinates retain this integral information when ghost values lose it. Finally, the radial transform and weighted operator domains specify which comparisons survive Hilbert completion.

13.1 Three operations on mode indices

Let R be a commutative unital ring and S a finite set of species. Define the free module and its symmetric algebra by

$$M_R = \bigoplus_{s\in S,\ k\geq 1} R x_{s,k}, \qquad P_R = \mathrm{Sym}_R(M_R).$$

These objects have cohomological degree zero. Each generator has particle degree one and weight k. The unit $1 \in P_R$ is the polynomial vacuum. All polynomials have finite support.

The species index and the index of an operation are independent.

For $n \geq 1$, define two unital R-algebra endomorphisms by

$$D_n x_{s,k} = \sum_{d|(n,k)} d\, x_{s,nk/d}, \qquad \psi_n x_{s,k} = x_{s,nk}. \tag{13.1}$$

The first is the *divisor substitution*. The second is the *index shift*. The sums are finite and use integer coefficients. Thus both definitions commute with scalar extension.

For an arbitrary species set, take the union over its finite subsets. For $S = \varnothing$, both maps are the identity on R.

A third formula defines an R-linear endomorphism of M_R:

$$\mathsf{H}_n x_{s,k} = \sum_{d|(n,k)} d\, x_{s,nk/d^2}. \tag{13.2}$$

The index is integral because d divides both n and k. The squared denominator changes the composition law. We suppress the species when examining one summand.

Example 13.1.1. For a prime p, all three maps send x_1 to x_p. Their next values are

$$D_p x_p = x_{p^2} + p x_p, \qquad \psi_p x_p = x_{p^2}, \qquad \mathsf{H}_p x_p = x_{p^2} + p x_1.$$

Consequently

$$(D_p^2 - D_{p^2})x_1 = px_p, \qquad (D_p^2 - D_{p^2} - pI)x_1 = p(x_p - x_1).$$

Both differences are nonzero over $\mathbb{Z}$. The index shifts satisfy $\psi_m\psi_n = \psi_{mn}$ on every generator, hence on P_R. The linear Hecke relation will instead include the additional term pI.

Extending a linear generator map $A : M_R \to M_R$ to $\mathrm{Sym}(A) : P_R \to P_R$ preserves composition. It does not preserve addition as a function of A. Already

$$\mathrm{Sym}(2A)(x^2) = 4(Ax)^2, \qquad 2\,\mathrm{Sym}(A)(x^2) = 2(Ax)^2.$$

Moreover, every such extension fixes the vacuum. Over $\mathbb{Z}$, the putative polynomial Hecke relation

$$\mathrm{Sym}(\mathsf{H}_p)^2 = \mathrm{Sym}(\mathsf{H}_{p^2}) + pI$$

already fails on 1, where its two sides give 1 and $1 + p$. Linear operator relations and multiplicative substitutions must therefore retain their different carriers.

13.2 Composition and the boundary of a prime chain

Fix a prime p and $u \geq 1$ with $(u, p) = 1$. Write $e_r = x_{up^r}$ for $r \geq 0$, and let A_a be the restriction of D_{p^a} to this free submodule. Then $A_0 = I$ and

$$A_a e_r = \sum_{i=0}^{\min(a,r)} p^i e_{r+a-i}.$$

The lower endpoint $r = 0$ truncates the sum. Farther along the chain, the same operators act by polynomials in the forward shift. Their noncommutativity is confined to the truncated region.

THEOREM 13.2.1 *(Prime-chain composition).* For $a, b, r \geq 0$, put $[v]_+ = \max(v, 0)$ and

$$N_{a,b}(r, t) = \mathbf{1}_{t \leq r+b}\big[\min(b, r, t) - \max(0, t - a) + 1\big]_+.$$

Over every commutative coefficient ring,

$$A_a A_b e_r = \sum_{t=0}^{a+b} p^t N_{a,b}(r, t) e_{r+a+b-t}.$$

For $1 \leq a < b$, the boundary commutator is

$$[A_a, A_b]e_1 = -p^{a+1}e_b. \tag{13.3}$$

Thus, over a nonzero characteristic-zero ring, A_a and A_b commute exactly when $a = b$ or $ab = 0$.

Proof. A term of $A_a A_b e_r$ chooses integers

$$0 \leq i \leq \min(b, r), \qquad 0 \leq j \leq \min(a, r + b - i).$$

Its coefficient is p^{i+j} and its output index is $r + a + b - i - j$. Fixing $t = i + j$ leaves the conditions

$$t \leq r + b, \qquad \max(0, t - a) \leq i \leq \min(b, r, t).$$

Their number is $N_{a,b}(r,t)$, proving the first formula.

For the commutator, first use $A_b e_1 = e_{b+1} + p e_b$. Applying A_a gives successive coefficients $1, 2p, \dots, 2p^a, p^{a+1}$. In the reverse order, $A_a e_1 = e_{a+1} + p e_a$. Since $b \geq a+1$, its final coefficient is $2p^{a+1}$. All other coefficients agree. Their difference proves (13.3).

The nonzero integer p^{a+1} remains nonzero in a characteristic-zero ring. The commuting cases are immediate, and exchanging a, b covers the other order. □

For example, the entire first commutator is

$$[A_1, A_2]e_r = \begin{cases} -p^2 e_2, & r = 1, \\ 0, & r \neq 1. \end{cases}$$

For $r \geq 2$, both operators have their untruncated polynomial form. The two remaining basis vectors give the displayed boundary term.

Corollary 13.2.2 *(Independent prime coordinates).* Set $a_p = v_p(m)$, $b_p = v_p(n)$ and $r_p = v_p(k)$. Then

$$D_m D_n x_k = \sum_{(t_p)} \left(\prod_{p \mid mn} p^{t_p} N_{a_p,b_p}(r_p, t_p) \right) x_{mnk/\prod_{p\mid mn} p^{t_p}}, \qquad 0 \leq t_p \leq a_p + b_p.$$

Terms with zero coefficient are omitted. In particular, $D_m D_n = D_{mn}$ when $(m,n) = 1$. For a nonempty species set over a nonzero characteristic-zero ring,

$$\begin{aligned} D_m D_n = D_{mn} \quad &\Longleftrightarrow \quad (m,n) = 1, \\ [D_m, D_n] = 0 \quad &\Longleftrightarrow \quad \text{for every } p,\ a_p b_p = 0 \text{ or } a_p = b_p. \end{aligned}$$

Over $\mathbb{F}_\ell$, omit the condition at $p = \ell$ in both criteria.

Proof. Multiplication or division by a power of p leaves every other prime valuation unchanged. The divisor choices therefore factor over primes, giving the formula and the coprime statement. Equality on generators extends multiplicatively to P_R.

If $a_p, b_p > 0$, then

$$A_{a_p} A_{b_p} e_0 = \sum_{j=0}^{\min(a_p,b_p)} p^j e_{a_p+b_p-j}.$$

Its $j = 1$ term is absent from $A_{a_p+b_p} e_0$. Selecting the highest terms at the other primes isolates its nonzero coefficient. This proves the first necessity.

For the second, use x_p at a prime with unequal positive exponents. At other primes, both orders agree on their initial vector. Their highest terms and (13.3) again isolate a nonzero power of p.

In characteristic ℓ, the terms with positive powers of ℓ vanish, so $D_{\ell^a} = \psi_{\ell^a}$ on $P_{\mathbb{F}_\ell}$. At every other prime, the same powers of p remain nonzero. This proves precisely the stated exception. □

The index shifts interact with the divisor substitutions by

$$\psi_m D_n x_k = \sum_{d \mid (n,k)} d\, x_{mnk/d}, \qquad D_n \psi_m x_k = \sum_{d \mid (n,mk)} d\, x_{mnk/d}.$$

In characteristic zero they commute exactly when $(m, n) = 1$. Coprimality equates the divisor conditions. If a common prime exists, $k = 1$ supplies an extra term with a nonzero integer coefficient.

There is also a monoid action retaining the prime divisor maps. Define $\Theta_n = \prod_p D_p^{v_p(n)}$. Different prime maps commute, so $\Theta_m \Theta_n = \Theta_{mn}$.

For $a \geq 1$, its prime-chain values are

$$A_1^a e_r = \sum_{j=0}^{a} \binom{a}{j} p^j e_{r+a-j} \quad (r \geq 1), \qquad A_1^a e_0 = \sum_{j=0}^{a-1} \binom{a-1}{j} p^j e_{a-j}.$$

The first formula is the binomial theorem on the invariant tail. The second follows after $e_0 \mapsto e_1$. This action changes the higher operations. Its prime maps retain the Frobenius obstruction computed below.

13.3 The algebra of linear divisor operators

The prime-chain algebra admits a finite test for each proposed relation. Each test controls a finite boundary region and the entire infinite tail.

Let $U e_r = e_{r+1}$, $B e_0 = 0$ and $B e_r = e_{r-1}$ for $r \geq 1$. Then $BU = I$ and $U^i B^i$ projects onto the tail $r \geq i$. Consequently

$$A_a = U^a \sum_{i=0}^{a} p^i B^i, \qquad A_{a+1} = U A_a + p^{a+1} U^{a+1} B^{a+1}.$$

These identities place the generated algebra inside the algebra of the shift and its partial inverse. They need not generate that entire ambient algebra.

Put $q_a(z) = \sum_{i=0}^{a} p^i z^{a-i}$ for $a \geq 1$. For a word $w = Z_{a_l} \cdots Z_{a_1}$, define

$$d(w) = \sum_j a_j, \qquad q_w = \prod_j q_{a_j},$$

and

$$B_w(r, s) = \sum_{\substack{0 \leq i_j \leq a_j,\ \sum_j (a_j - i_j) = s \\ i_j \leq r + \sum_{h<j} (a_h - i_h) \text{ for each } j}} p^{\sum_j i_j}.$$

The rightmost factor acts first. For the empty word, set $d(w) = 0$, $q_w = 1$ and $B_w(r, s) = \mathbf{1}_{s=0}$.

THEOREM 13.3.1 *(Tail and boundary presentation).* Let $F = \sum_w c_w w$ be a finite element of $R\langle Z_1, Z_2, \ldots \rangle$, and set $d = \max_w d(w)$. For $F = 0$, take $d = 0$. Then $F(A_1, A_2, \ldots) = 0$ if and only if

$$\sum_w c_w q_w(z) = 0 \quad \text{in } R[z],$$
$$\sum_w c_w B_w(r, s) = 0 \quad (0 \leq r < d,\ 0 \leq s \leq d).$$

These conditions define the kernel ideal $I_{p,R}$, giving

$$R[A_1, A_2, \ldots] \simeq R\langle Z_1, Z_2, \ldots \rangle / I_{p,R}.$$

Every finite expression has a finite coefficient test. No finite generating set for the ideal is asserted.

Proof. Expanding the successive divisor choices gives $w(A)e_r = \sum_s B_w(r,s)e_{r+s}$. For $r \geq d$, every intermediate index is at least r. All choices $0 \leq i_j \leq a_j$ are then allowed. Their coefficients are exactly those of $q_w(z)$. The polynomial identity therefore tests all vectors with $r \geq d$.

The remaining equations test every earlier basis vector. Together they are precisely the kernel of evaluation $Z_a \mapsto A_a$. The kernel is a two-sided ideal, and the quotient is its image. □

Equivalently, every evaluated expression is uniquely $q(U) + E$. Here E is a finite matrix, supported in columns $r < d$ and rows $r \leq r + s \leq r + d$. Uniqueness follows by testing arbitrarily large e_r. The tail-symbol map onto $R[z]$ is surjective, since $q_1 = z + p$. Its kernel consists of the finite matrices which occur in the generated algebra. The commutator $[A_1, A_2]$ gives a nonzero example over $\mathbb{Z}$.

For finitely many primes, use a basis indexed by their valuation vectors. Word coefficients are products of the corresponding prime-chain coefficients. In each coordinate, separate the finitely many boundary values from the unrestricted tail. This gives finitely many mixed boundary tests and polynomial identities for every finite expression. Every expression in the full prime family involves only finitely many primes.

13.4 The linear Hecke law and its determinant

The partial inverse enters differently in (13.2). On M_R, define

$$U_p x_k = x_{pk}, \qquad B_p x_k = \begin{cases} x_{k/p}, & p \mid k, \\ 0, & p \nmid k. \end{cases}$$

Then $B_p U_p = I$, while $U_p B_p$ projects onto the p-divisible indices. At distinct primes all four pairs commute. The linear operators satisfy

$$\mathsf{H}_{p^r} = \sum_{j=0}^{r} p^j U_p^{r-j} B_p^j.$$

Multiplying by $U_p + pB_p$ gives

$$\mathsf{H}_p \mathsf{H}_{p^r} = \mathsf{H}_{p^{r+1}} + p\mathsf{H}_{p^{r-1}} \qquad (r \geq 1).$$

Indeed, the final backward-shift term supplies $p^{r+1}B_p^{r+1}$. Every other backward-shift term cancels a forward shift using $B_p U_p = I$, leaving $p\mathsf{H}_{p^{r-1}}$.

Proposition 13.4.1 *(Universal determinant identity).* For independent indeterminates T, d, define

$$H_0 = 1, \qquad H_1 = T, \qquad H_{r+1} = TH_r - dH_{r-1} \quad (r \geq 1).$$

Then in $\mathbb{Z}[T, d]$,

$$H_r H_s = \sum_{j=0}^{\min(r,s)} d^j H_{r+s-2j}.$$

The identity also holds after substituting any commuting pair of endomorphisms of a module over a commutative ring.

Proof. Substitute $T = u + v$ and $d = uv$. The recurrence gives $H_r = \sum_{i=0}^{r} u^i v^{r-i}$. For $r \leq s$, the coefficient of $u^i v^{r+s-i}$ in the product is

$$1 + \min(r, i, r + s - i) \qquad (0 \leq i \leq r + s).$$

The right side has one contribution for each $0 \le j \le \min(r, i, r+s-i)$, so the coefficients agree.

The substitution is injective: in lexicographic order with $u > v$, $(u+v)^a (uv)^b$ has leading monomial $u^{a+b}v^b$. These leading monomials are distinct for distinct pairs (a, b). The identity therefore holds before specialization, including $r = s$. Evaluation at commuting endomorphisms preserves it. □

COROLLARY 13.4.2. Over every commutative coefficient ring,

$$\mathsf{H}_m \mathsf{H}_n = \sum_{d \mid (m,n)} d\, \mathsf{H}_{mn/d^2}.$$

Proof. At each prime, specialize the proposition to (H_p, pI). The divisor formula factors H_n over its prime powers. Multiplication of the local identities proves the global formula. □

This is a representation of the stated linear operator algebra. The algebra generated by all U_p, B_p also retains these relations in its regular representation. Neither construction identifies its multiplication with the vertex products of a Heisenberg algebra.

13.5 SATAKE PARAMETERS AND THE RADIAL STATE

The determinant in the universal identity has a geometric normalization. Fix $K_p = \mathrm{GL}_2(\mathbb{Z}_p)$ and give it Haar volume one. The complex spherical Hecke algebra is

$$\mathcal{H}_p = C_c(K_p \backslash \mathrm{GL}_2(\mathbb{Q}_p) / K_p, \mathbb{C}),$$

The product is convolution. The two characteristic functions used below are

$$T_p = \mathbf{1}_{K_p \,\mathrm{diag}(p,1) K_p}, \qquad \mathsf{z}_p = \mathbf{1}_{K_p \,\mathrm{diag}(p,p) K_p}.$$

THEOREM 13.5.1 *(Normalized spherical Satake isomorphism).* The normalized Satake isomorphism identifies

$$\mathcal{H}_p \simeq \mathbb{C}[X^{\pm 1}, Y^{\pm 1}]^{S_2}, \qquad T_p \longmapsto \sqrt{p}(X+Y), \qquad \mathsf{z}_p \longmapsto XY.$$

At a character, put $\alpha = \sqrt{p}X$ and $\beta = \sqrt{p}Y$. Then $\alpha\beta = p\mathsf{z}_p$, using the scalar central character on the right. Trivial central character gives $\mathsf{z}_p = 1$. Temperedness is the additional condition $|X| = |Y| = 1$.

This is the convention of Gross, *On the Satake isomorphism*, Proposition 3.6, equations (3.13)–(3.14), and Section 8. In particular, trivial central character does not imply temperedness. The higher elements $H_{p^r} \in \mathcal{H}_p$ are specified by the complete symmetric Satake polynomials:

$$\sum_{r \ge 0} H_{p^r} t^r = (1 - T_p t + p\mathsf{z}_p t^2)^{-1}.$$

This follows by multiplying $(1 - \sqrt{p}Xt)$ and $(1 - \sqrt{p}Yt)$ in the Satake algebra and using injectivity. These higher elements need not be individual double-coset characteristic functions.

For a fixed pair $\alpha\beta = p$, the diagonal matrix $S_p = \mathrm{diag}(\alpha, \beta)$ gives

$$\mathrm{Tr}(\mathrm{Sym}^r S_p) = \sum_{j=0}^{r} \alpha^{r-j}\beta^j = H_r(\alpha + \beta, p).$$

This follows from the monomial eigenbasis of the symmetric power. The matrix, its scalar traces and the operators H_n are three separate representations of the parameter formulas. In a basis a, b, the line $\mathbb{C}(a+b)$ is S_p-invariant exactly when $\alpha = \beta$. Its image is $\alpha a + \beta b$, which proves the criterion.

If the pair is tempered, write

$$\{\alpha, \beta\} = \{\sqrt{p}\, e^{i\theta_p}, \sqrt{p}\, e^{-i\theta_p}\}.$$

The angle is defined modulo 2π and sign.

For any family of such angles, the product

$$L_\theta(s) = \prod_p \frac{1}{1 - 2\cos\theta_p\, p^{-s} + p^{-2s}}$$

converges absolutely and locally uniformly for $\operatorname{Re} s > 1$. Indeed, its logarithm is the absolutely convergent sum

$$\sum_p \sum_{m \geq 1} \frac{2\cos(m\theta_p)}{m} p^{-ms}.$$

On every closed smaller half-plane, its absolute values are bounded by a constant times $\sum_p p^{-\operatorname{Re} s}$.

This constructs the local-parameter Euler product on that domain. An automorphic identification or continuation beyond it requires additional arithmetic data. Replacing unitary parameters by α, β shifts the Dirichlet variable by one half.

The integral cyclic module of a tree

Fix a rooted $(p+1)$-regular tree $(\mathcal{T}_p, o)$. Use counting measure on its vertices and let S_r be the sphere of radius r about o. Its size is

$$s_0 = 1, \qquad s_r = (p+1)p^{r-1} \quad (r \geq 1).$$

The radial Hilbert space $\mathcal{R}_p$ consists of square-summable functions constant on each sphere. Its orthonormal basis is $e_r = s_r^{-1/2} \mathbf{1}_{S_r}$.

Adjacency is $(Tf)(v) = \sum_{w \sim v} f(w)$. Cauchy–Schwarz bounds its norm on the vertex Hilbert space by $p+1$, and symmetry makes it self-adjoint. Counting edges gives

$$\begin{aligned} Te_0 &= \sqrt{p+1}\, e_1, \\ Te_1 &= \sqrt{p+1}\, e_0 + \sqrt{p}\, e_2, \\ Te_r &= \sqrt{p}(e_{r-1} + e_{r+1}) \quad (r \geq 2). \end{aligned}$$

Distance defines a filtration, not a grading preserved by T.

Define monic integer polynomials by

$$R_0 = 1, \quad R_1 = x, \quad R_2 = x^2 - (p+1), \qquad R_{r+1} = xR_r - pR_{r-1} \quad (r \geq 2).$$

The recurrence gives $R_r(T)e_0 = \mathbf{1}_{S_r}$. Monicity then proves an integral cyclic-module isomorphism

$$\mathbb{Z}[x] \xrightarrow{\sim} \bigoplus_{r \geq 0} \mathbb{Z}\mathbf{1}_{S_r}, \qquad f \longmapsto f(T)e_0. \tag{13.4}$$

No prime is inverted in this statement. The normalized Hilbert basis instead uses real square roots.

THEOREM 13.5.2 *(Radial transform with its state).* Put $x(\theta) = 2\sqrt{p}\cos\theta$ for $0 \le \theta \le \pi$, and define

$$d\nu_p(\theta) = \frac{2p(p+1)\sin^2\theta}{\pi(p^2+1-2p\cos 2\theta)}\,d\theta.$$

The measure has mass one. The assignment

$$\mathcal{U}_p e_r = \frac{R_r(x(\theta))}{\sqrt{s_r}}$$

extends to a unitary $\mathcal{R}_p \xrightarrow{\sim} L^2([0,\pi],\nu_p)$. It sends e_0 to 1 and intertwines T with multiplication by x. In particular, $\|T|_{\mathcal{R}_p}\| = 2\sqrt{p}$, and

$$\langle e_0, f(T)e_0\rangle = \int_0^\pi f(2\sqrt{p}\cos\theta)\,d\nu_p(\theta)$$

for every bounded Borel function on the spectral interval.

Proof. The tridiagonal recurrence makes e_0 cyclic. After deleting its row and column, the remaining Jacobi operator has every off-diagonal coefficient equal to $\sqrt{p}$. Its first diagonal resolvent entry satisfies

$$g(z) = \frac{1}{z - pg(z)} = \frac{z - \sqrt{z^2-4p}}{2p}.$$

The branch is analytic off $[-2\sqrt{p}, 2\sqrt{p}]$ and asymptotic to z. It is selected by $g(z) \sim z^{-1}$.

Taking the Schur complement at the original root gives

$$m(z) = \langle e_0, (z-T)^{-1}e_0\rangle = \frac{1}{z-(p+1)g(z)}.$$

For $|x| < 2\sqrt{p}$, Stieltjes inversion yields

$$-\frac{1}{\pi}\operatorname{Im} m(x+i0) = \frac{(p+1)\sqrt{4p-x^2}}{2\pi((p+1)^2-x^2)}.$$

A pole outside the interval would require $g^2 = 1$ and $z = \pm(p+1)$. The chosen branch instead has $g(\pm(p+1)) = \pm p^{-1}$. At either endpoint the denominator is nonzero because $p > 1$. Thus m has continuous finite boundary values on the interval and analytic continuation across its complement.

The inversion formula gives only the displayed absolutely continuous measure. Its mass is one by $m(z) \sim z^{-1}$. Changing variables to $x = 2\sqrt{p}\cos\theta$ gives ν_p.

The spectral theorem and (13.4) imply

$$\int R_r(x)R_s(x)\,d\nu_p = \langle \mathbf{1}_{S_r}, \mathbf{1}_{S_s}\rangle = s_r\delta_{rs}.$$

The normalized polynomials are therefore orthonormal. They span all polynomials by monicity. Polynomial approximation on the compact interval proves their density in L^2, hence the asserted unitary.

The recurrence gives intertwining on finite sums, then everywhere by boundedness. The spectral support is the entire closed interval, so the operator norm is $2\sqrt{p}$. Bounded Borel functional calculus proves the state identity. □

For the Bruhat–Tits tree of $\mathrm{PGL}_2(\mathbb{Q}_p)$, vertices are homothety classes of lattices in $\mathbb{Q}_p^2$. Adjacency is represented by $pL \subset L' \subset L$ with $[L : L'] = p$. Lines in L/pL give $p+1$ neighbors. The maximal compact subgroup has volume one, so this adjacency is the Hecke operator of $\mathrm{diag}(p, 1)$. Pullback to GL_2 makes z_p act as the identity. The radial transform consequently preserves both the spherical Hecke action and its root state.

Proposition 13.5.3 *(Distance operators).* Define $\mathcal{D}_r$ by

$$(\mathcal{D}_r f)(v) = \sum_{d(v,w)=r} f(w).$$

Then $\mathcal{D}_r = R_r(T)$ and

$$H_k(T, p) = \sum_{j=0}^{\lfloor k/2 \rfloor} \mathcal{D}_{k-2j}.$$

Their root expectations satisfy

$$\langle e_0, H_k(T, p) e_0 \rangle = \begin{cases} 1, & k \text{ even}, \\ 0, & k \text{ odd}. \end{cases}$$

On $\mathcal{R}_p$, the generating series converges in operator norm for $|t| < p^{-1/2}$, and

$$\left\langle e_0, (I - tT + pt^2 I)^{-1} e_0 \right\rangle = \frac{1}{1 - t^2}.$$

Proof. Every row and column of $\mathcal{D}_r$ has s_r entries, so it is bounded. Counting the first step gives

$$T\mathcal{D}_1 = \mathcal{D}_2 + (p+1)I, \qquad T\mathcal{D}_r = \mathcal{D}_{r+1} + p\mathcal{D}_{r-1} \quad (r \geq 2).$$

Hence $\mathcal{D}_r = R_r(T)$. With $H_{-1} = H_{-2} = 0$, the recurrences give $R_r = H_r - H_{r-2}$. Telescoping proves the sum formula. Only $\mathcal{D}_0 e_0$ has a nonzero inner product with e_0, giving the expectations.

The spectral values are

$$H_k(2\sqrt{p}\cos\theta, p) = p^{k/2} \sum_{j=0}^{k} e^{i(k-2j)\theta}.$$

They include the coinciding-parameter cases $\theta = 0, \pi$. Thus $\|H_k(T, p)\| \leq (k+1)p^{k/2}$ on $\mathcal{R}_p$. This proves norm convergence in the stated disk. Multiplying the series by $I - tT + pt^2 I$ proves the inverse formula, and its state can be evaluated term by term. □

At $p = 2$, the first normalized radial polynomials are

$$1, \qquad x/\sqrt{3}, \qquad (x^2 - 3)/\sqrt{6},$$

whereas $H_2(x, 2) = x^2 - 2$. There are three two-step returns to the root. Of the four-step returns, nine return after two steps and six first reach distance two. Therefore

$$\int x^2 \, d\nu_2 = 3, \qquad \int x^4 \, d\nu_2 = 15, \qquad \int H_2 \, d\nu_2 = 1, \qquad \int R_2 \, d\nu_2 = 0.$$

The distinction persists before taking a spectral integral.

There is also a distinction between two cyclic Hecke representations. Give the free complex mode space the Hermitian form $\langle x_k, x_l \rangle = k\delta_{kl}$ and complete it. Then $U_p^* = pB_p$, and $\mathsf{H}_p = U_p + pB_p$ is bounded and self-adjoint. At its unit vector x_1,

$$\langle x_1, \mathsf{H}_p^2 x_1 \rangle = p, \qquad \langle e_0, T^2 e_0 \rangle = p + 1.$$

The first value follows from $\mathsf{H}_p^2 x_1 = x_{p^2} + p x_1$. Thus the common Hecke recursion does not give an intertwiner preserving these two specified states.

Finite sets of primes

For a finite prime set F, tensor the radial maps to obtain

$$\mathcal{U}_F : \widehat{\bigotimes}_{p \in F} \mathcal{R}_p \xrightarrow{\sim} L^2\left([0, \pi]^F, \prod_{p \in F} \nu_p \right).$$

It sends $\bigotimes_p e_{r_p}$ to the product of the normalized radial polynomials. It preserves each local Hecke operator and sends the tensor root state to integration against the product measure. The integral cyclic lattices are the finite tensor products of the sphere-sum lattices.

Adjoining a prime uses $v \mapsto v \otimes e_0$ on the tree side and $f \mapsto f \otimes 1$ on the spectral side. These isometries commute with $\mathcal{U}_F$ and preserve the states. Their algebraic union therefore has an isometric comparison, which extends to its Hilbert completion. Each finite-support Hecke operation acts on its own natural factors. No bound uniform over all primes is required or asserted.

13.6 The integral symmetric-function lattice

The index shifts already form a monoid action on P_R. Their integral Frobenius property depends on the lattice. For one species over $\mathbb{Z}$,

$$\psi_p x_1 - x_1^p = x_p - x_1^p \notin p P_{\mathbb{Z}}.$$

The two monomials remain distinct after reduction modulo p. We now construct the larger lattice on which the same rational operations satisfy the required congruences.

Inside $P_{\mathbb{Q}}$, define $h_0 = 1$ and

$$H(t) = \sum_{r \geq 0} h_r t^r = \exp\left(\sum_{k \geq 1} \frac{x_k t^k}{k} \right), \qquad \Lambda = \mathbb{Z}[h_1, h_2, \ldots].$$

The coefficients are defined formally, one degree at a time. Differentiation gives Newton's recursion

$$r h_r = \sum_{k=1}^{r} x_k h_{r-k}.$$

It expresses x_r as an integral polynomial in $h_1, \ldots, h_r$. Conversely, $h_r = x_r/r$ plus a polynomial in earlier x_k over $\mathbb{Q}$.

Thus the h_r are algebraically independent and

$$P_{\mathbb{Z}} \subsetneq \Lambda, \qquad P_{\mathbb{Q}} = \Lambda \otimes \mathbb{Q}.$$

For instance, $h_2 = (x_1^2 + x_2)/2$ does not belong to $P_{\mathbb{Z}}$. We call Λ the *Hall lattice*. For several species, take its finite tensor products.

To identify its standard operations, specialize $x_k = z_1^k + \cdots + z_N^k$. Then $H(t) = \prod_{i=1}^{N}(1 - z_i t)^{-1}$, so h_r is the complete symmetric polynomial of degree r. These symmetric polynomials stabilize when zero variables are adjoined. Every fixed weight is detected once N is sufficiently large. Substitution $z_i \mapsto z_i^n$ therefore preserves Λ and induces $\psi_n x_k = x_{nk}$.

In characteristic p, the same substitution is the Frobenius map on integer symmetric polynomials modulo p. Hence

$$\psi_p(f) \equiv f^p \pmod{p\Lambda} \qquad (f \in \Lambda). \tag{13.5}$$

Special lambda operations

The full integral structure includes operations beyond their rational power sums. We specify the convention explicitly. For two finite alphabets $X = (z_i)$ and $Y = (w_j)$, let $e_n(X)$ denote the elementary symmetric polynomial. There are universal integer polynomials P_n and $Q_{m,n}$ determined by

$$e_n(\{z_i w_j\}_{i,j}) = P_n(e_1(X), \dots, e_n(X); e_1(Y), \dots, e_n(Y)),$$

and

$$e_m(\{z_{i_1} \cdots z_{i_n} : i_1 < \cdots < i_n\}) = Q_{m,n}(e_1(X), \dots, e_{mn}(X)).$$

The fundamental theorem of symmetric polynomials gives their integral coefficients and stability as the alphabets grow.

Definition 13.6.1. A *special λ-ring* is a commutative unital ring A with operations $\lambda^n : A \to A$ for $n \geq 0$. Writing $\lambda_t(a) = \sum_{n \geq 0} \lambda^n(a) t^n$, their identities are

$$\lambda^0(a) = 1, \qquad \lambda^1(a) = a, \qquad \lambda_t(a + b) = \lambda_t(a)\lambda_t(b), \qquad \lambda_t(1) = 1 + t,$$

together with the product and composition identities given by P_n and $Q_{m,n}$ above. Its *Adams operations* are the integral coefficient operations in

$$-t\frac{(\lambda_{-t}(a))'}{\lambda_{-t}(a)} = \sum_{n \geq 1} \psi_n(a) t^n.$$

Here the prime means formal differentiation in t.

The alphabet identities show that each Adams operation is a unital ring endomorphism and $\psi_m \psi_n = \psi_{mn}$. They also give the Frobenius congruences. These are identities of universal integer polynomials, so they remain valid after evaluation in every special λ-ring. The ordinary symmetric functions give such a structure on Λ. Their Adams operations are precisely the index shifts above.

Theorem 13.6.2 *(Torsion-free Adams criterion).* Let the additive group of A be torsion-free. A family of unital ring endomorphisms ψ_n determines a unique special λ-structure if

$$\psi_1 = I, \qquad \psi_m \psi_n = \psi_{mn}, \qquad \psi_p(a) \equiv a^p \pmod{pA} \quad \text{for every prime } p.$$

This is Wilkerson's criterion, as stated in Borger, *The basic geometry of Witt vectors, I*, Section 1.17. Over a $\mathbb{Q}$-algebra its reconstruction takes the form

$$\lambda_t(a) = \exp\left(\sum_{n \geq 1} \frac{(-1)^{n-1} \psi_n(a) t^n}{n}\right).$$

Over $\mathbb{Z}$, the shifts therefore give the special structure on Λ, but fail the necessary congruence on $P_{\mathbb{Z}}$. This failure concerns the specified shifts. For example, the different maps $x_k \mapsto x_k^n$ give commuting Frobenius lifts on $P_{\mathbb{Z}}$. They define the structure in which each variable is a line element, meaning $\lambda_t(x_k) = 1 + x_k t$.

Example 13.6.3 *(The torsion hypothesis).* On $\mathbb{F}_p$, let every ψ_n be the identity. These ring maps commute and satisfy all the displayed Frobenius congruences. At p, this uses $a^p = a$. At other primes q, the ideal $q\mathbb{F}_p$ is the whole ring.

They cannot come from a special λ-structure. Such a structure would give

$$1 = \lambda_t(0) = \lambda_t(p \cdot 1) = \lambda_t(1)^p = (1+t)^p = 1 + t^p,$$

which is false in $\mathbb{F}_p[[t]]$. Thus commuting Frobenius lifts alone do not replace the full integral operations on a ring with additive torsion.

PROPOSITION 13.6.4 *(Divisor substitutions on the Hall lattice).* Every D_n preserves Λ, and

$$D_n H(t) = \prod_{d|n} \psi_n H(t^d). \tag{13.6}$$

Nevertheless D_p is not a Frobenius lift on this lattice:

$$D_p h_p = \psi_p h_p + \psi_p h_1 \equiv h_p^p + h_1^p \not\equiv h_p^p \pmod{p\Lambda}.$$

Proof. In $P_{\mathbb{Q}}[[t]]$, set $k = dj$ in the logarithm to obtain

$$\sum_{k\geq 1} \frac{D_n x_k}{k} t^k = \sum_{d|n} \sum_{j\geq 1} \frac{x_{nj}}{j} t^{dj}.$$

Exponentiation gives (13.6). Every factor has integral Hall coefficients, proving preservation of Λ. For $n = p$, only the two stated contributions have degree p. Apply (13.5) to them. The term h_1^p is nonzero in the polynomial ring $\Lambda/p\Lambda$. □

In particular, the equality $D_{p^a} = \psi_{p^a}$ on $P_{\mathbb{F}_p}$ does not imply equality after reducing Λ. The inclusion $P_{\mathbb{Z}} \subset \Lambda$ is not an identification of their integral coordinates or reductions.

There is a useful comparison which does preserve the algebraic images. Define a triangular substitution on P_R by

$$C_n x_{s,k} = \sum_{d|(n,k)} d\, x_{s,k/d}.$$

Its leading term is $x_{s,k}$, and every other mode index is smaller. Induction therefore constructs an integral polynomial inverse on every generator, over every coefficient ring.

The same logarithmic calculation gives

$$C_n H(t) = \prod_{d|n} H(t^d).$$

Its coefficient of t^r is h_r plus an integral polynomial in $h_1, \ldots, h_{r-1}$. Thus C_n is also an automorphism of the Hall lattice.

Direct evaluation on the generators now proves

$$D_n = \psi_n C_n, \qquad D_n(P_R) = \psi_n(P_R), \qquad D_n(\Lambda) = \psi_n(\Lambda). \tag{13.7}$$

Equal images do not identify the two actions or their composition laws. Nor does the triangular inverse have to survive a Hilbert completion.

13.7 Big Witt coordinates and the cofree construction

The previous exponential formulas live first over $\mathbb{Q}$. Big Witt coordinates give integral formulas before any scalar extension. For a commutative ring R, put $W(R) = \prod_{r\geq 1} R$ as a set. Associate to $a = (a_r)$ the series

$$A_a(t) = \prod_{r\geq 1}(1 - a_r t^r)^{-1} \in 1 + tR[[t]]. \tag{13.8}$$

Each coefficient involves finitely many factors. Its coefficient of t^r is a_r plus a polynomial in earlier coordinates. Induction therefore gives a natural bijection $W(R) \simeq 1 + tR[[t]]$ over every ring.

The *ghost components* are

$$w_n(a) = \sum_{r|n} r\, a_r^{n/r}, \qquad t\frac{A_a'(t)}{A_a(t)} = \sum_{n\geq 1} w_n(a) t^n.$$

The derivative identity follows by differentiating the factors. It involves no division by an integer in R.

Proposition 13.7.1. If the additive group of R is torsion-free, the ghost map is injective. Over $\mathbb{F}_p$, the nonzero vector with $a_p = 1$ and all other coordinates zero has every ghost equal to zero. Its series is $(1 - t^p)^{-1} \neq 1$.

Proof. If two vectors agree below n, equality of their nth ghosts gives $n(a_n - b_n) = 0$. Torsion-freeness gives equality at n, and induction proves injectivity. For the stated vector over $\mathbb{F}_p$, the only possible ghost contribution is p when $p \mid n$. It vanishes, although the coefficient of t^p in the series is one. □

We construct the ring operations on the series themselves. Write $E_r(a) = (1 - at^r)^{-1}$. Witt addition is ordinary multiplication of series: $A +_W B = AB$. Its zero is the series 1, and its negative is A^{-1}.

Witt multiplication, denoted $\odot$, is determined by

$$E_r(a) \odot E_s(b) = \left(1 - a^{s/g} b^{r/g} t^l\right)^{-g}, \qquad g = (r,s), \quad l = \operatorname{lcm}(r,s), \tag{13.9}$$

and distributivity over Witt addition. For two arbitrary coordinate products, multiply these factors over all pairs (r,s). Since $l \geq r, s$, each coefficient uses finitely many pairs. The construction is therefore a universal integral polynomial operation.

Theorem 13.7.2 *(The big Witt ring).* These operations make $W(R)$ a natural commutative unital ring. Its multiplicative unit is $E_1(1)$. Every $w_n : W(R) \to R$ is a ring homomorphism.

Proof. Logarithmic differentiation makes each ghost additive under series multiplication. For one factor,

$$w_n(E_r(a)) = \begin{cases} r a^{n/r}, & r \mid n, \\ 0, & r \nmid n. \end{cases}$$

The ghost of (13.9) is $g l\, a^{n/r} b^{n/s}$ when $l \mid n$, and zero otherwise. Since $gl = rs$, this is the product of the two ghosts. Distributivity then proves multiplicativity for arbitrary series.

It remains to verify the ring identities without assuming injectivity on the given coefficient ring. Fix a coefficient degree and regard the finitely many input coordinates as independent variables over $\mathbb{Z}$. This polynomial ring is torsion-free, so its ghosts are injective. Commutativity, associativity, distributivity and the unit law hold on ghosts, hence on these universal coordinate polynomials. Specializing their integer coefficients proves the identities over every R. □

The Teichmüller element is $[a] = E_1(a)$. It satisfies $[a] \odot [b] = [ab]$, but need not preserve addition in R. For $m \geq 1$, define Verschiebung by $V_m A(t) = A(t^m)$. It is additive for $+_W$. Define Frobenius by its values on the coordinate factors:

$$F_m E_r(a) = \left(1 - a^{m/g} t^{r/g}\right)^{-g}, \qquad g = (m, r), \tag{13.10}$$

and extend by products of series. A coefficient through degree N uses only $r \leq mN$, so this also defines an integral operation coefficientwise.

PROPOSITION 13.7.3 *(Frobenius and Verschiebung).* Each F_m is a natural unital ring endomorphism of $W(R)$, and

$$w_n(F_m a) = w_{mn}(a), \qquad w_n(V_m a) = \begin{cases} m\, w_{n/m}(a), & m \mid n, \\ 0, & m \nmid n. \end{cases}$$

Their identities over every coefficient ring include

$$F_m F_n = F_{mn}, \qquad V_m V_n = V_{mn}, \qquad F_m V_m = mI,$$
$$F_m V_n = g V_{n/g} F_{m/g}, \qquad g = (m, n).$$

The integer multiple means repeated Witt addition. In particular, $F_m[a] = [a^m]$.

Proof. For a single factor, (13.10) has nth ghost $r a^{mn/r}$ precisely when $r \mid mn$. This proves the Frobenius formula. Substituting t^m in the logarithmic derivative proves the Verschiebung formula. The ring-map property and all displayed identities follow on ghosts. Each operation was already constructed by universal integer polynomials. The torsion-free universal-ring argument from the theorem therefore proves the identities before specialization to arbitrary R. □

Plethysm and the full comonad

The ring $\Lambda = \mathbb{Z}[h_1, h_2, \ldots]$ represents the series functor:

$$W(R) \simeq \mathrm{Hom}_{\mathrm{Ring}}(\Lambda, R), \qquad f \longmapsto \sum_{n \geq 0} f(h_n) t^n.$$

The values $f(h_n)$ are series coefficients, not the Witt coordinates a_n. They are related by the triangular integral bijection (13.8). The power sum $x_n \in \Lambda$ evaluates to w_n.

We need the integral composition operation on Λ. For $h \in \Lambda$, write its specialization to a finite alphabet as an integer sum of monomials, $h(X) = \sum_M c_M M$. Define

$$\sum_{n \geq 0} (h_n \circ h)(X) t^n = \prod_M (1 - Mt)^{-c_M}.$$

Negative multiplicities are allowed, using the inverse formal series. The coefficients are integral symmetric polynomials and stabilize when zero variables are added.

Extend $g \mapsto g \circ h$ as a ring homomorphism from Λ. This operation is *plethysm*. Its unit is $h_1 = x_1$.

Plethysm is associative. One way to check this precisely is to embed Λ in $\mathbb{Q}[x_1, x_2, \ldots]$. The defining formula gives $x_n \circ h = \psi_n(h)$, where $\psi_n x_k = x_{nk}$ and rational coefficients are fixed. These substitutions commute and satisfy $\psi_n(g \circ h) = (\psi_n g) \circ h$. Evaluating a polynomial in the x_n therefore proves $(f \circ g) \circ h = f \circ (g \circ h)$. Since the operation was constructed integrally, the equality lies in Λ.

Theorem 13.7.4 *(Cofree special lambda rings).* The functor W is right adjoint to the forgetful functor from special λ-rings to commutative rings. Its counit and comultiplication are

$$\varepsilon_R(f) = f(h_1), \qquad (\Delta_R f)(g)(h) = f(h \circ g). \tag{13.11}$$

Thus $\Delta_R : W(R) \to W(W(R))$. It satisfies both counit identities and $\Delta_{W(R)}\Delta_R = W(\Delta_R)\Delta_R$. Its outer ghosts are $w_n(\Delta_R f) = F_n f$ as elements of $W(R)$.

Proof. For $f \in W(R)$ and $g \in \Lambda$, define the operation $g(f) \in W(R)$ by $g(f)(h) = f(h \circ g)$. For fixed g, the right side is a ring homomorphism in h, by the definition of plethysm. The universal symmetric-polynomial identities for sums and products show that $g \mapsto g(f)$ is a ring homomorphism into $W(R)$. These identities are exactly the series addition and multiplication constructed above. Associativity of plethysm supplies composition of the operations. Taking the elementary symmetric operations therefore makes $W(R)$ a special λ-ring.

Let A be a special λ-ring and $\phi : A \to R$ a ring map. For $a \in A$, evaluation of symmetric operations gives the map

$$\widehat{\phi}(a)(g) = \phi(g(a)) \qquad (g \in \Lambda).$$

The sum and product identities make $\widehat{\phi} : A \to W(R)$ a ring map. The composition identities make it a λ-ring map. Its counit is ϕ, since $h_1(a) = a$.

Conversely, the counit determines a λ-ring map into $W(R)$. Applying it after the operation g recovers evaluation at g. This proves the natural adjunction.

Applying this construction to the identity on the underlying ring of $W(R)$ gives the stated Δ_R. The equalities $h_1 \circ g = g$ and $h \circ h_1 = h$ prove the two counit identities separately. Evaluating the two coassociativity maps on three elements of Λ reduces them to the two associations of the same plethysm. Finally, $h \circ x_n = \psi_n(h)$. Evaluation of the outer power sum x_n in (13.11) therefore gives precisely the coefficient action F_n. □

Equivalently, a special λ-structure on a ring A is a ring map $\eta : A \to W(A)$ satisfying

$$\varepsilon_A \eta = I, \qquad \Delta_A \eta = W(\eta)\eta.$$

Indeed, its coordinates define the complete symmetric operations. The fact that η is a ring map gives their sum and product identities. The second displayed equality gives composition, and the first fixes the degree-one operation. Inverting the complete symmetric series at $-t$ recovers the elementary operations of Definition 13.6.1. The converse follows by evaluation of those operations.

The two universal constructions have different variances:

$$\mathrm{Hom}_{\lambda\text{-Ring}}(\Lambda, A) \simeq A, \qquad \mathrm{Hom}_{\lambda\text{-Ring}}(A, W(R)) \simeq \mathrm{Hom}_{\mathrm{Ring}}(A, R).$$

The first says that Λ is free on one distinguished element. The second is the cofree property of W. On rings with additive torsion, the full map η and its composition identity retain data which its ghost operations can lose. Borger's descent interpretation uses this integral structure and its forgetful functor. It does not create an arithmetic comparison from a rational index-shift formula.

13.8 PRODUCTS, GRADINGS, AND ALGEBRAIC COMPLETIONS

The polynomial ring has a primitive Hopf structure over R:

$$\Delta x_{s,k} = x_{s,k} \otimes 1 + 1 \otimes x_{s,k}, \qquad \epsilon(x_{s,k}) = 0, \qquad \mathcal{S}(x_{s,k}) = -x_{s,k}.$$

Here $\mathcal{S}$ denotes the antipode. Each of D_n, ψ_n and C_n preserves this structure. Their generator images are primitive, and the identities of algebra maps can be checked on generators. They also preserve the unit, augmentation and particle degree.

On the Hall lattice, the same coproduct is

$$\Delta h_r = \sum_{i+j=r} h_i \otimes h_j.$$

Preservation follows from the rational power-sum identity and the torsion-free integral inclusion. This is the ordinary symmetric-function Hopf structure. An arithmetic extension correspondence would require its own comparison.

PROPOSITION 13.8.1 *(Weights and completions).* For a nonempty species set and any nonzero coefficient ring, D_n and ψ_n are injective on P_R. For $n > 1$, neither is surjective. The index shift sends weight w to weight nw. The divisor substitution sends weight w into weights between w and nw. Both act on the finite-weight quotients and continuously on

$$\widehat{P}_R^{\mathrm{wt}} = \prod_{w \geq 0} P_{R,w}.$$

They also extend to the coefficient-adic completion $\varprojlim_j P_{\mathbb{Z}}/\ell^j P_{\mathbb{Z}}$ for every prime ℓ.

Proof. Let f have highest nonzero weight w. The highest-weight term of $D_n f$ is ψ_n applied to the weight-w component, and it has weight nw. Index substitution is injective on the monomial basis, so this component cannot vanish over a nonzero coefficient ring. This proves injectivity of both maps. For $n > 1$, the same highest-weight argument excludes a preimage of x_1.

Every term of $D_n x_k$ has weight between k and nk. Multiplication proves the weight bounds on monomials. Thus the ideal of weights greater than W is preserved. Its quotient has finite rank for a finite species set. An output through weight W depends only on inputs through weight W, which proves continuity on the weight completion.

Finally, the integral maps preserve every ideal $\ell^j P_{\mathbb{Z}}$. Their compatible quotient maps give the coefficient-adic extensions. □

A finite subalgebra generated by modes $k \leq N$ is not invariant when $n > 1$: the highest term of $D_n x_N$ is x_{nN}. The finite-weight quotient is a different construction. The coefficient-adic completion is also different from the weight product. In monomial coordinates, its coefficients lie in $\mathbb{Z}_\ell$, with only finitely many nonzero coefficients modulo each ℓ^j. The unrestricted weight product imposes no such decay.

Other symmetric-function operations give different preservation laws. For one species over $\mathbb{Q}$, the internal coproduct is the algebra map $\delta x_k = x_k \otimes x_k$. It is preserved by ψ_n. For D_n with $n > 1$, the image of x_n contains both x_{n^2} and $n x_n$. The tensor square of that image has cross terms absent from $\delta(D_n x_n)$, so D_n does not preserve δ.

For a partition λ with multiplicities m_k, write $x_\lambda = \prod_k x_k^{m_k}$ and $z_\lambda = \prod_k k^{m_k} m_k!$. The internal product is the bilinear operation

$$x_\lambda * x_\mu = \delta_{\lambda\mu} z_\lambda x_\lambda.$$

Neither family preserves it for $n > 1$. Indeed, $x_1 * x_1 = x_1$, whereas $x_n * x_n = n x_n$. These nonvanishing obstructions use characteristic zero. They do not transfer unchanged to a torsion coefficient ring.

13.9 Oscillator intertwiners and vertex products

For one species, define polynomial operators

$$a_{-k} f = x_k f, \qquad a_k f = k \partial_{x_k} f \quad (k \geq 1), \qquad a_0 = 0.$$

They obey $[a_k, a_{-l}] = k \delta_{kl}$, with central element acting as one. Different species commute. The Hall pairing is $\langle x_\lambda, x_\mu \rangle = \delta_{\lambda\mu} z_\lambda$. Over $\mathbb{C}$, its Hermitian version is positive and makes a_k the adjoint of a_{-k} on polynomials.

The substitutions intertwine creation by x_k with creation by its image. Their annihilation intertwiners require a separate calculation. For the index shifts, differentiation gives

$$\psi_n a_{-k} = a_{-nk} \psi_n, \qquad a_{nk} \psi_n = n \psi_n a_k, \qquad a_j \psi_n = 0 \quad (n \nmid j). \tag{13.12}$$

Sending both positive and negative modes to their index multiples would multiply the commutator by n. Over $\mathbb{Q}$, the assignments

$$a_{-k} \longmapsto a_{-nk}, \qquad a_k \longmapsto a_{nk}/n$$

instead define a central-charge-one Heisenberg embedding. It is intertwined by ψ_n, but does not preserve the Hall adjoint.

Proposition 13.9.1 *(An integral annihilation lift).* Fix $n \geq 1$. Define integers $c_{k,i}$ in increasing order of i by

$$c_{k,i} = 0 \quad (n \nmid i), \qquad c_{k,nj} = k \delta_{kj} - \sum_{\substack{d \mid (n,j) \\ d > 1}} d \, c_{k,nj/d}.$$

The polynomial derivations

$$\mathcal{A}_k^{(n)} = \sum_{i \geq 1} c_{k,i} \partial_{x_i}$$

are well-defined and commute. They satisfy

$$\mathcal{A}_k^{(n)} (D_n x_j) = k \delta_{kj}, \qquad \mathcal{A}_k^{(n)} D_n = D_n a_k.$$

Together with multiplication by $D_n x_j$, they give a central-charge-one oscillator representation.

Proof. Every term on the right of the recursion has smaller index. It therefore defines all coefficients integrally. Each polynomial uses finitely many variables, so only finitely many derivatives contribute to its image. Constant-coefficient derivations commute.

Substituting (13.1) into the first identity gives exactly the recursion. The chain rule proves the second identity on all polynomials. Commuting a derivation past multiplication by $D_n x_j$ gives its constant derivative $k \delta_{kj}$, proving the oscillator relations. □

Over $\mathbb{Q}$, the lift can be written $\mathcal{A}_k^{(n)} = \sum_i (c_{k,i}/i) a_i$. Integrality concerns the polynomial derivation, not these coefficients in the fixed annihilation modes. The lift is generally not adjoint-preserving. Both unscaled substitutions send x_1 to x_n, whose squared norm is n. Creation by x_n and its Hall adjoint therefore have commutator n, rather than one. This obstructs the specified adjoint-preserving assignment when $n > 1$.

PROPOSITION 13.9.2 *(The vertex obstruction).* Over $\mathbb{Q}$ or $\mathbb{C}$, neither D_n nor ψ_n is an endomorphism of the usual Heisenberg vertex algebra for $n > 1$. Both remain polynomial algebra and primitive Hopf endomorphisms.

Proof. The standard translation operator satisfies $\partial x_k = k x_{k+1}$. Every vertex homomorphism preserves it, since $\partial v = v_{(-2)}1$. Here

$$\partial \psi_n x_1 = n x_{n+1}, \qquad \psi_n \partial x_1 = x_{2n},$$

and

$$\partial D_n x_1 = n x_{n+1}, \qquad D_n \partial x_1 = x_{2n} + 2\mathbf{1}_{2|n} x_n.$$

The values differ for every $n > 1$. This argument does not require preservation of a chosen conformal vector.

The same failure is visible in the singular products. Writing $a(z) = Y(x_1, z)$, one has

$$Y(x_n, z) = \frac{\partial_z^{n-1} a(z)}{(n-1)!}, \qquad Y(x_n, z) Y(x_n, w) \sim \frac{(-1)^{n-1}(2n-1)!}{((n-1)!)^2 (z-w)^{2n}}.$$

Differentiate $a(z)a(w) \sim (z-w)^{-2}$ to obtain this coefficient. For $n > 1$, the higher pole cannot be the image of the original central second-order pole under a vacuum-preserving vertex map. The polynomial and Hopf assertions were proved above. □

For a finite species set, the index shifts nevertheless give a vacuum-preserving action of $\mathbb{N}^\times$ on the underlying vector space. This means endomorphisms with $\psi_1 = I$ and $\psi_m \psi_n = \psi_{mn}$. It does not assert an action by vertex endomorphisms. The divisor family fails even that monoid law in characteristic zero.

13.10 HILBERT CLOSURES AND A WEIGHTED THRESHOLD

Fix a nonempty finite species set and complete the complex polynomial space in the Hermitian Hall form. It is the symmetric Hilbert Fock space $\mathcal{F} = \bigoplus_{j \geq 0} \mathcal{F}^{(j)}$, with squared monomial norms $\prod_{s,k} k^{m_{s,k}} m_{s,k}!$. Its one-particle space has $\|x_{s,k}\|^2 = k$. The map $\psi_n/\sqrt{n}$ is an isometry there.

Each divisor summand $x_k \mapsto d\mathbf{1}_{d|k} x_{nk/d}$ has norm $\sqrt{nd}$. Its nonzero basis images are orthogonal with that constant norm ratio. Consequently, for $d_n = D_n|_{M_\mathbb{C}}$,

$$\|d_n\| \leq \sum_{d|n} \sqrt{nd}.$$

Both maps are bounded on one particle and on every fixed particle sector after taking symmetric tensor powers.

PROPOSITION 13.10.1 *(Closed full-Fock operators).* For $A = d_n$ or $A = \psi_n|_{M_\mathbb{C}}$, the polynomial operator $\mathrm{Sym}(A)$ is closable. Its closure is $\Gamma(A) = \bigoplus_{j \geq 0} \mathrm{Sym}^j(A)$, with domain

$$\mathrm{Dom}\,\Gamma(A) = \left\{ (v_j) \in \mathcal{F} : \sum_{j \geq 0} \|\mathrm{Sym}^j(A) v_j\|^2 < \infty \right\}.$$

For $n > 1$, both closures are unbounded. For the index shift, the domain condition is exactly $\sum_j n^j \|v_j\|^2 < \infty$.

Proof. A direct sum of bounded sector maps on the displayed domain is closed. Finite particle truncation approximates a vector and its image. Within each retained sector, finite-mode polynomials approximate both, since the sector map is bounded. Thus polynomials are a core and the direct sum is precisely their closure.

For the index shift, each sector map multiplies norms by $n^{j/2}$. Both substitutions send x_1^j to x_n^j, giving

$$\frac{\|D_n x_1^j\|}{\|x_1^j\|} = \frac{\|\psi_n x_1^j\|}{\|x_1^j\|} = n^{j/2}.$$

This proves unboundedness for $n > 1$ and the stated domain formula. □

The normalized substitution $\widetilde{\psi}_n x_{s,k} = n^{-1/2} x_{s,nk}$ gives a different positive result. It is an isometry on every particle sector and their Hilbert direct sum. It is also a complex polynomial Hopf map and a monoid action. Sending both a_{-k} and a_k to their index multiples divided by $\sqrt{n}$ preserves the Heisenberg relations and Hall adjoints. Equation (13.12), with this normalization, shows that $\widetilde{\psi}_n$ intertwines the resulting embedding. The normalization changes the integral structure and still fails ordinary translation for $n > 1$.

The kernel created by completion

The triangular automorphism C_n in (13.7) has a bounded one-particle extension. For $B_d x_k = \mathbf{1}_{d|k} x_{k/d}$, one has

$$c_n = C_n|_M = \sum_{d|n} dB_d, \qquad \|c_n\| \le \sum_{d|n} \sqrt{d}, \qquad c_n = \prod_{p|n} c_{p^{v_p(n)}}.$$

The norm estimate uses $\|B_d\| = d^{-1/2}$. The factorization follows from $B_d B_e = B_{de}$.

Theorem 13.10.2 *(One-particle kernel and range).* The operator c_n is a bounded surjection on the completed one-particle space. The divisor operator has closed range

$$\operatorname{Ran} d_n = \overline{\operatorname{span}}\{x_{nk} : k \ge 1\} = \operatorname{Ran}(\psi_n|_M), \qquad \ker d_n = \ker c_n.$$

For $n > 1$, this kernel is infinite-dimensional on the full one-species space. On a prime chain $e_r = x_{up^r}$ and for $a \ge 1$,

$$c_{p^a} = \sum_{j=0}^{a} p^j B^j, \qquad \ker c_{p^a} = \operatorname{span}_{\mathbb{C}} \left\{ \sum_{r \ge 0} (\zeta/p)^r e_r : \zeta^{a+1} = 1,\ \zeta \ne 1 \right\}.$$

The prime-chain kernel has dimension a. For $n = 1$, the operators are the identity and the kernels vanish.

Proof. On the chain, $\|e_r\|^2 = up^r$ and $\|B\| = p^{-1/2}$. For each stated root, the geometric vector has squared norm $u \sum_{r \ge 0} p^{-r} = u/(1 - p^{-1})$. It is a B-eigenvector with eigenvalue ζ/p, so c_{p^a} kills it. Conversely, a kernel vector $\sum_r b_r e_r$ satisfies

$$\sum_{j=0}^{a} p^j b_{r+j} = 0 \qquad (r \ge 0).$$

Its first a coefficients determine all the others. The distinct roots ζ/p give independent solutions by the Vandermonde determinant, exhausting this solution space.

Let $Ue_r = e_{r+1}$, so $BU = I$ and $\|U\| = \sqrt{p}$. For $\lambda = \zeta/p$, the operator

$$R_\lambda = U(I - \lambda U)^{-1}$$

is a bounded right inverse of $B - \lambda$. Indeed, $(B - \lambda)U = I - \lambda U$ and $\|\lambda U\| = p^{-1/2} < 1$. The inverse is a norm-convergent Neumann series.

Factor

$$c_{p^a} = p^a \prod_{\substack{\zeta^{a+1}=1 \\ \zeta \neq 1}} (B - \zeta/p).$$

Multiplying the right inverses in reverse order, with factor p^{-a}, gives a bounded right inverse of c_{p^a}. Its norm bound is independent of u. It therefore extends over the orthogonal sum of all prime chains. The finite product over prime factors proves surjectivity of c_n.

The factorization $d_n = \psi_n c_n$ and the scaled isometry $\psi_n|_M$ prove the range and kernel assertions. For $n > 1$, choose one nontrivial prime-power factor. Its kernel vectors on infinitely many disjoint prime chains are independent. The other factors commute with it, so all these vectors lie in $\ker c_n$. □

The polynomial inverse has a different domain. For example,

$$C_p^{-1} e_r = \sum_{j=0}^{r} (-p)^j e_{r-j}, \qquad \frac{\|C_p^{-1} e_r\|^2}{\|e_r\|^2} = \sum_{j=0}^{r} p^j.$$

Cancellation in $(I + pB)\sum_{j=0}^{r}(-pB)^j e_r = e_r$ proves the first formula. Orthogonality proves the second.

More generally, the polynomial inverse of C_n is not closable on this Hilbert space when $n > 1$. Choose $0 \neq v \in \ker c_n$ and finite truncations $v_N \to v$. Then $y_N = c_n v_N \to 0$, while $C_n^{-1} y_N = v_N \to v \neq 0$. The graph closure contains $(0, v)$ and cannot be an operator graph. The same argument applies to the algebraic inverse of d_n on its polynomial image.

These one-particle kernels also lie in $\ker \Gamma(d_n)$. By contrast, $\Gamma(\psi_n|_M)$ is injective, since each particle sector is a nonzero scalar multiple of an isometry. The polynomial maps remain injective throughout. No extension of polynomial multiplication to all Hilbert vectors is asserted.

The exact weighted boundary

Retain a prime chain $e_r = x_{up^r}$ and its finite linear span D. For $s \geq 0$, define

$$\mathcal{H}_s = \left\{ \sum_{r \geq 0} b_r e_r : \sum_{r \geq 0} (up^r)^{1+2s} |b_r|^2 < \infty \right\}.$$

If $Ee_r = up^r e_r$, this is $\mathrm{Dom}(E^s)$ in $\mathcal{H}_0$, with norm $\|E^s v\|_0$. Since $E \geq 1$, this norm is equivalent to its graph norm. Write $\mathcal{H}_{s,\geq a}$ for the closed tail spanned by e_r, $r \geq a$. Its codimension is a.

THEOREM 13.10.3 *(Weighted inverses).* Fix $a \geq 1$. The same polynomial maps c_{p^a} and d_{p^a} extend boundedly to every $\mathcal{H}_s$, with the following properties.

(i) For $0 \le s < 1/2$, c_{p^a} is onto $\mathcal{H}_s$, and d_{p^a} is onto $\mathcal{H}_{s,\ge a}$. Their common kernel has basis

$$g_\zeta = \sum_{r\ge 0} (\zeta/p)^r e_r, \qquad \zeta^{a+1} = 1, \quad \zeta \ne 1.$$

Their polynomial inverses are not closable.

(ii) For $s = 1/2$, both maps are injective. Their ranges are dense, proper and nonclosed in $\mathcal{H}_s$ and $\mathcal{H}_{s,\ge a}$, respectively. Their inverses on these actual ranges are closed and unbounded. They are the graph closures of the polynomial inverses.

(iii) For $s > 1/2$, c_{p^a} is boundedly invertible on $\mathcal{H}_s$, and d_{p^a} is a bounded isomorphism onto $\mathcal{H}_{s,\ge a}$. These inverses extend the polynomial inverses.

For $a = 0$, both maps are the identity for every s.

Proof. Set $b = p^{s+1/2}$, $q = p^{1/2-s}$ and $Q_a(z) = 1 + z + \cdots + z^a$. The vectors $f_r = e_r/(u^{s+1/2}b^r)$ form an orthonormal basis. Let $Vf_r = f_{r+1}$ and $L = V^*$. The raw shifts become $U = bV$ and $pB = qL$, so

$$c_{p^a} = Q_a(qL), \qquad d_{p^a} = b^a V^a Q_a(qL). \tag{13.13}$$

This proves boundedness with bounds $\sum_{j=0}^a q^j$ and $b^a \sum_{j=0}^a q^j$.

The isometry V^a identifies the space with its tail. It therefore suffices to analyze $Q_a(qL)$.

For $q > 1$, its kernel recurrence has distinct characteristic roots ζ/q, with $\zeta^{a+1} = 1$ and $\zeta \ne 1$. All resulting geometric sequences are square-summable. In raw coordinates, they are the stated g_ζ, with

$$\|g_\zeta\|_s^2 = \frac{u^{1+2s}}{1 - p^{2s-1}}.$$

The recurrence and Vandermonde argument prove that they form a basis.

Each $L - \zeta/q$ has bounded right inverse $V(I - (\zeta/q)V)^{-1}$, by its Neumann series. Factoring $Q_a(qL)$ and composing these right inverses in reverse order gives a bounded right inverse G for c_{p^a}. Then

$$d_{p^a}(b^{-a} G L^a) = V^a L^a,$$

the projection onto the tail. This proves both surjectivity assertions. Finite truncations of a nonzero kernel vector prove nonclosability of the polynomial inverses, as above.

At $q = 1$, kernel sequences are combinations of the periodic sequences ζ^r. A nonzero periodic sequence is not square-summable, so the kernel vanishes. The constant coefficient of Q_a is one. Its formal reciprocal acts on D, since L is locally nilpotent there. Thus $c_{p^a}(D) = D$, and the range is dense.

Fix one root $\zeta \ne 1$ and, for $N > a$, set

$$v_N = N^{-1/2} \sum_{r=0}^{N-1} \zeta^r f_r.$$

Its norm is one. The first $N - a$ coefficients of $Q_a(L)v_N$ vanish. At most a coefficients remain, each bounded by $(a+1)/\sqrt{N}$. Therefore

$$\|Q_a(L)v_N\| \le \frac{\sqrt{a}(a+1)}{\sqrt{N}} \longrightarrow 0.$$

An injective bounded operator with closed range is bounded below, by the bounded inverse theorem on its range. The sequence excludes this possibility. The dense range is consequently proper and nonclosed. Equation (13.13) gives the same conclusion inside the tail for d_{p^a}.

The inverse of an injective bounded operator on its range has closed graph: interchange the coordinates of the original closed graph. Here these inverses are unbounded by the preceding sequence.

For any $x \in \mathcal{H}_s$, choose $x_N \in D$ with $x_N \to x$. Boundedness gives $c_{p^a} x_N \to c_{p^a} x$. Hence $(c_{p^a} x_N, x_N) \to (c_{p^a} x, x)$ in the inverse graph. The same argument applies to d_{p^a}. This proves that the polynomial inverses have precisely these graph closures.

Finally, for $q < 1$, the identity $(1 - z)Q_a(z) = 1 - z^{a+1}$ gives

$$c_{p^a}^{-1} = (I - qL)(I - (qL)^{a+1})^{-1}, \qquad \|c_{p^a}^{-1}\| \le \frac{1+q}{1-q^{a+1}}.$$

The inverse is a norm-convergent Neumann series. On the tail, the inverse of d_{p^a} is $c_{p^a}^{-1} b^{-a} L^a$. Both agree with the polynomial inverses on finite vectors. □

All these bounded maps retain the common finite domain D as a core. Their polynomial formulas do not change with s. The completed kernels and inverses change because the allowed coefficient decay changes. In particular, excluding g_ζ from $\mathcal{H}_s$ at $s \ge 1/2$ does not remove its kernel class in $\mathcal{H}_0$.

13.11 Operations and states in the arithmetic comparison

The positive radial state belongs to its specified Hecke representation. A phase average on oscillator states gives a different operator, even when it uses the same measure. To see this directly, take two species with polynomial space $\mathbb{C}[a_k, b_k : k \ge 1]$ and the Hermitian Hall norm. The monomial $\prod_k a_k^{r_k} b_k^{s_k}$ has charge $m = \sum_k (r_k - s_k)$.

Let V_θ multiply its charge space by $e^{im\theta}$. These are unitary operators on the Hilbert completion. The strong average

$$A_p = \int_0^\pi V_\theta \, d\nu_p(\theta)$$

is a contraction. Its eigenvalue in charge m is $c_m = \int_0^\pi e^{im\theta} \, d\nu_p$.

Symmetry about $\pi/2$ gives

$$c_1 = i \int_0^\pi \sin\theta \, d\nu_p \in i\mathbb{R}_{>0}.$$

Thus this phase average cannot be unitarily intertwined with the self-adjoint adjacency operator while retaining the specified operators. The obstruction concerns this comparison, not every arithmetic realization.

The energy convention also matters. For species labeled by primes, integer mode weight k and arithmetic energy $k \log p$ define different diagonal operators. The integral monomial lattice survives both gradings, although the real energy operator need not preserve it.

The full oscillator partition function is $\prod_{k \ge 1} \zeta(k\beta)$ for $\beta > 1$. Keeping only mode one instead gives $\zeta(\beta)$. That subspace is not preserved by the index shifts or divisor substitutions. The operator domains and direct occupation sums establishing these statements are given in Section 28.7.

For comparison, on $\ell^2(\mathbb{N}_{>0})$ let $\mu_n \delta_N = \delta_{nN}$ and $H_{\mathrm{BC}} \delta_N = \log N \, \delta_N$. These commuting isometries satisfy

$$[H_{\mathrm{BC}}, \mu_n] = \log n \, \mu_n$$

on finite-support vectors. They move δ_1 to δ_n. The index substitutions instead fix their polynomial vacuum, and their arithmetic energy satisfies $H\psi_n = n\psi_n H$. A vacuum- and energy-preserving identification cannot equate these two specified actions for $n > 1$.

Question 13.11.1 *(Marked arithmetic realization).* Construct an arithmetic trace carrier independently of these local models, with its coefficient theory, integral form, selected trace class and functional. Construct its operations and an intertwiner with a specified local or restricted tensor-product representation. The map must preserve the distinguished vector, the functional, the determinant normalization and every chosen operation. For a Hilbert comparison, specify the domains, adjoints and completed tensor product. For a vertex comparison, retain translation and all singular products.

For example, the unramified comparison of Conjecture 27.9.1 requires the actual maps Φ, Q, Q_p, normalized local vectors and compatible linear functionals. An arbitrary family of Satake pairs does not construct those arithmetic objects or maps. Neither the root-state identity nor the Witt ghost formulas identify a full Weil functional.

There is also an immediate operation obstruction to some proposed maps. In characteristic zero, an injective intertwiner cannot identify the divisor family with commuting Adams operations or a commuting semigroup of isometries. Equation (13.3) would map a nonzero vector to zero. A quotient, a restricted domain or a different operation system remains a separate possibility with its own kernel and comparison calculation.

Chapter 14

Hall fields on curves

A torsion sheaf on a curve splits into its parts at closed points. Hall multiplication and the Green form split with it. This elementary decomposition produces operators whose exchange coefficients count points over every finite extension of the ground field. The coefficient depends on the normalization of both operators. Keeping the Hall creators and their Green adjoints gives a mass series. Changing their normalization gives the curve zeta function.

We follow these operators into three recipients. Polynomial Hall states carry local Heisenberg fields, and finite power covers retain their residue maps. Collective counting modes instead lead to fields with finitely many multiplicative collision divisors after reciprocal normalization. The unchanged Green exchange has a meromorphic difference equation and a positive coherent state. Derived intersections of the collision divisors explain why their scalar equations and supported differential modules require different comparisons.

Prime-indexed Macdonald spaces separate the choice of local parameters from a geometric Hall realization. A final nilpotent-coefficient example constructs the scalar kernel and its finite-jet comparison, then locates the missing critical Hall map.

14.1 Closed points and Green adjunction

Let C be a smooth projective geometrically connected curve over $\mathbb{F}_q$. For a closed point x, write $d_x = [k(x) : \mathbb{F}_q]$ and $Q_x = q^{d_x}$. A choice of parameter and coefficient field identifies the completed local ring with $\mathbb{F}_{Q_x}[[t]]$. Its finite-length modules are the finite nilpotent $\mathbb{F}_{Q_x}[t]$-modules. The resulting Hall algebra is independent of this presentation. The presentation names its Jordan partitions.

Use complex coefficients. For a prime power Q, let H_Q have basis u_M indexed by nilpotent modules and put $a_M = |\operatorname{Aut} M|$. The product and positive Hermitian form are

$$u_M u_N = \sum_L F^L_{M,N} u_L, \qquad \langle u_M, u_N \rangle_G = \frac{\delta_{MN}}{a_M},$$

where $F^L_{M,N}$ counts submodules of type N with quotient M. The form is conjugate-linear in its first argument. The torsion Euler form is zero. Thus the Green coproduct is adjoint to this product without an Euler twist.

The local primitive theorem, with its normalization fixed in Theorem 12.2.1, gives

$$\begin{aligned} H_Q &= \mathbb{C}[p_1, p_2, \ldots], \qquad \Delta p_r = p_r \otimes 1 + 1 \otimes p_r, \\ p_r &= \sum_{|\lambda|=r} \prod_{j=1}^{\ell(\lambda)-1} (1 - Q^j) u_\lambda, \qquad \langle p_r, p_s \rangle_G = \delta_{rs} \frac{r}{Q^r - 1}. \end{aligned} \tag{14.1}$$

In particular the coefficient of the indecomposable module of length r in p_r is one.

The elementary generating series gives another way to see the normalization. Put

$$e_r = Q^{r(r-1)/2} u_{1^r}, \qquad E(t) = \sum_{r \geq 0} e_r t^r, \qquad e_0 = 1.$$

Subspace counting gives $\Delta u_{1^r} = \sum_{i+j=r} Q^{-ij} u_{1^i} \otimes u_{1^j}$, so E is group-like.

Products of semisimple classes are triangular in the Jordan basis. The successive kernel dimensions specify a filtration lowered by t. Equality with these dimensions forces the kernel filtration itself. Its coefficient is one. Other terms have larger kernel dimensions. This proves the polynomial presentation in each finite Hall degree.

The logarithm then gives the primitive generators through

$$\log E(t) = \sum_{r \geq 1} \frac{(-1)^{r-1}}{r} p_r t^r.$$

Since $|\mathrm{GL}_r(\mathbb{F}_Q)| = Q^{r(r-1)/2} \prod_{j=1}^{r} (Q^j - 1)$, their norms can also be read from

$$\langle E(u), E(v) \rangle_G = \sum_{r \geq 0} \frac{Q^{r(r-1)/2} (\bar{u} v)^r}{\prod_{j=1}^{r} (Q^j - 1)} = \prod_{j \geq 1} (1 - Q^{-j} \bar{u} v)^{-1}.$$

The last equality follows from $(1 - t) P(Qt) = P(t)$ and $P(0) = 1$.

Primitivity and Hopf adjunction give factorial norms for powers of a primitive. Taking logarithms gives (14.1).

PROPOSITION 14.1.1. On the polynomial domain, multiplication M_r by p_r has Green adjoint

$$D_r = \frac{r}{Q^r - 1} \partial_{p_r}, \qquad [D_r, M_s] = \delta_{rs} \frac{r}{Q^r - 1} I.$$

The inverse pairing, completed by nonnegative Hall weight, is

$$\sum_{\lambda} u_\lambda \otimes a_\lambda u_\lambda = \exp\left(\sum_{r \geq 1} \frac{Q^r - 1}{r} p_r \otimes p_r \right). \tag{14.2}$$

Proof. The adjoint of multiplication by a primitive is a derivation. Its value on p_s is the scalar $\delta_{rs} r/(Q^r - 1)$, which determines the derivation on H_Q. Iterating adjunction makes the monomials orthogonal, with

$$\left\| \prod_r p_r^{m_r} \right\|_G^2 = \prod_r m_r! \left(\frac{r}{Q^r - 1} \right)^{m_r}.$$

Sum each monomial tensored with its dual to obtain the exponential. The Hall basis gives the left side of (14.2). Each weight space is finite dimensional, so both expressions define the same completed tensor. □

The torsion Hall space of C is the algebraic tensor product

$$\mathcal{F}_C = \bigotimes_{x \in |C|}{}' H_{q^{d_x}}, \qquad \deg p_{x,r} = r d_x.$$

The prime means that a tensor is the vacuum 1 at all but finitely many points. Hom and extension groups between different supports vanish, so products and Green forms factor.

There are finitely many closed points of bounded degree. Hence each weight space is finite dimensional.

Define, for $n > 0$,

$$N_n = \sum_{d_x \mid n} d_x = \#C(\mathbb{F}_{q^n}),$$
$$A_{-n} = \sum_{d_x \mid n} d_x M_{x,n/d_x}, \qquad B_n = \sum_{d_x \mid n} d_x D_{x,n/d_x}.$$

All sums are finite. A point of degree d has exactly d geometric points over $\mathbb{F}_{q^n}$ when $d \mid n$, and none otherwise. Operators at different points commute. Therefore

$$[B_n, A_{-m}] = \delta_{nm} \frac{nN_n}{q^n - 1} I, \qquad B_n = A_{-n}^{*G}.$$

Two positive modes commute, as do two negative modes.

14.2 Three normalizations of the exchange

For the unchanged creators and Green adjoints set

$$\Gamma_-(w) = \exp\left(\sum_{n>0} \frac{A_{-n} w^n}{n}\right), \qquad \Gamma_+^G(z) = \exp\left(\sum_{n>0} \frac{B_n z^{-n}}{n}\right).$$

These are coefficientwise series in the independent formal variables w, z^{-1}. Each coefficient is an operator on $\mathcal{F}_C$. Creation may equivalently be evaluated in the completion by weight. Annihilation is locally finite on every polynomial state.

Theorem 14.2.1. Put

$$K_G(t) = \exp\left(\sum_{n>0} \frac{N_n t^n}{n(q^n - 1)}\right), \qquad Z_C(t) = \exp\left(\sum_{n>0} \frac{N_n t^n}{n}\right).$$

Then

$$\Gamma_+^G(z)\Gamma_-(w) = K_G(w/z)\Gamma_-(w)\Gamma_+^G(z), \tag{14.3}$$
$$K_G(qt) = Z_C(t) K_G(t),$$
$$Z_C(t) = \prod_x (1 - t^{d_x})^{-1}, \qquad K_G(t) = \prod_{j \geq 1} Z_C(q^{-j} t).$$

The last product uses convergent logarithmic coefficients at the fixed numerical value $q > 1$.

Proof. The commutator of the two exponents is the central series $\sum_{n>0} N_n (w/z)^n / [n(q^n - 1)]$. Formal conjugation of the exponentials proves (14.3). Subtracting the logarithms at qt and t proves the difference equation. Writing $n = r d_x$ in $\log Z_C$ gives $\sum_x \sum_{r>0} t^{r d_x}/r$, the logarithm of the Euler product. Finally $1/(q^n - 1) = \sum_{j \geq 1} q^{-jn}$ proves the product for K_G in each logarithmic coefficient. □

There are two ways to obtain Z_C itself as an exchange factor. First keep the creators and replace B_n by $J_n = (q^n - 1) B_n$. The corresponding annihilation vertex is

$$\Gamma_+^\zeta(z) = \Gamma_+^G(z/q)\Gamma_+^G(z)^{-1} = \exp\left(\sum_{n>0} \frac{J_n z^{-n}}{n}\right). \tag{14.4}$$

It has exchange factor $Z_C(w/z)$ with $\Gamma_-(w)$. Its modes are no longer the Green adjoints of the fixed creators.

Second use the positive real square root and put

$$\widehat{A}_{-n} = \sqrt{q^n - 1}\, A_{-n}, \qquad \widehat{B}_n = \sqrt{q^n - 1}\, B_n.$$

They remain Green adjoints and satisfy $[\widehat{B}_n, \widehat{A}_{-m}] = \delta_{nm} n N_n I$. Their half-vertices again exchange by $Z_C(w/z)$, with both operators changed. Locally this is the adjoint pair

$$a_{-r} = \sqrt{Q^r - 1}\, M_r, \qquad a_r = \frac{r}{\sqrt{Q^r - 1}}\, \partial_{p_r}.$$

All three constructions have a common polynomial domain. No everywhere-defined operator on the Green Hilbert completion has been asserted. The dilation $z \mapsto z/q$ in (14.4) is a spectral change of variable. Absolute Frobenius is the different map $z \mapsto z^q$.

An independent oscillator polynomial space $\mathbb{C}[u_{x,r} : x \in |C|, r > 0]$ is identified with $\mathcal{F}_C$ by $u_{x,r} \mapsto p_{x,r}$. This preserves weight, multiplication and vacuum. It sends multiplication by $u_{x,r}$ to $M_{x,r}$ and $r\partial_{u_{x,r}}$ to $(q^{rd_x} - 1)D_{x,r}$. Thus it intertwines the one-sided normalized modes and all formal coefficients of their half-vertices. Specified residue operations require their own comparison below.

Example 14.2.2. For $C = \mathbb{P}^1$, $N_n = q^n + 1$ and $Z_C(t) = ((1 - t)(1 - qt))^{-1}$.

For the smooth projective cubic

$$E/\mathbb{F}_2 : \quad y^2 + y = x^3 + x + 1,$$

the first four point counts are $1, 5, 13, 25$. The equation $y^2 + y = b$ has two solutions exactly when $\mathrm{Tr}_{\mathbb{F}_{2^n}/\mathbb{F}_2}(b) = 0$. For $n = 1, 2, 3, 4$ there are respectively $0, 2, 6, 12$ such values of x, and the projective curve has one point at infinity. Consequently

$$Z_E(t) = 1 + t + 3t^2 + 7t^3 + 15t^4 + O(t^5).$$

These counts determine the exchange through degree four. The full formula $Z_E(t) = (1 - 2t + 2t^2)/((1 - t)(1 - 2t))$ also uses the classical rationality and degree-two numerator theorem for an elliptic curve.

An elementary modification

The full Hall algebra of coherent sheaves contains line bundles as well as torsion sheaves. Fix a rational point x and a line bundle L. Extensions of $\mathcal{O}_x$ by L have middle sheaf $L \oplus \mathcal{O}_x$ or $L(x)$: the extension space is one dimensional and all nonzero classes give $L(x)$.

In the split sheaf the relevant copies of L are the graphs of the q maps $L \to \mathcal{O}_x$. In $L(x)$ there is the unique subobject $L(x)(-x) = L$. Conversely $\mathrm{Ext}^1(L, \mathcal{O}_x) = 0$, and the split middle sheaf has its unique torsion subobject. Hence

$$u_{\mathcal{O}_x} u_L = q\, u_{L \oplus \mathcal{O}_x} + u_{L(x)}, \qquad u_L u_{\mathcal{O}_x} = u_{L \oplus \mathcal{O}_x}.$$

With $v = \sqrt{q}$, twist multiplication by $u_A * u_B = v^{\chi(A,B)} u_A u_B$. Here $\chi(\mathcal{O}_x, L) = -1$ and $\chi(L, \mathcal{O}_x) = 1$, so

$$[u_{\mathcal{O}_x}, u_L]_* = v^{-1} u_{L(x)}.$$

On $\mathbb{P}^1$, summing over its $q+1$ rational points gives

$$\left[\sum_x u_{O_x}, u_{O(n)}\right]_* = (v+v^{-1})u_{O(n+1)}.$$

This operation retains the elementary modification. A presentation of a quantum loop algebra requires its other generators and relations. An arithmetic trace comparison additionally requires its category, state and functional.

14.3 Local fields on every polynomial Hall state

Return to one point, with residue cardinality Q. Set $h_{-r} = M_r$, $h_r = (Q^r-1)D_r = r\partial_{p_r}$ for $r>0$, and $h_0 = 0$. Thus

$$[h_r, h_s] = r\delta_{r+s,0}I, \qquad h_r^{*G} = (Q^r-1)h_{-r} \quad (r>0).$$

Define a derivation T by $T(p_r) = r\,p_{r+1}$ and define

$$H(z) = \sum_{r\in\mathbb{Z}} h_r z^{-r-1}.$$

For a polynomial monomial set

$$Y(p_{r_1}\cdots p_{r_l}, z) =: \prod_{j=1}^{l} \frac{\partial_z^{r_j-1}H(z)}{(r_j-1)!} :, \qquad Y(1,z) = I. \tag{14.5}$$

Normal ordering places creation modes to the left. This defines the field on every state. Positive modes act locally finitely on a polynomial input, and the creation series has a lower bound on its powers of z.

Proposition 14.3.1. The fields (14.5), with vacuum 1 and translation T, give the free Heisenberg vertex algebra on H_Q. Every finite ordered product has a common normally ordered Wick expression, with rational contractions and finite poles along pairwise diagonals. Every nesting expands that expression and retains its nonconsecutive contractions.

Proof. Commuting an annihilator past a creator gives the scalar $r\delta_{rs}$. Summing gives $(z-w)^{-2}$ in the expansion $|w|<|z|$. For fixed polynomial states, commute each annihilator through later creators. The terms are indexed by partial matchings of the elementary factors. Matched factors contribute the appropriate derivatives of $(z-w)^{-2}$ and unmatched factors remain normally ordered. There are finitely many matchings and derivative orders, so one rational denominator clears every term.

Regrouping partitions the same matchings according to the blocks joined by their edges. Both nested expansions are therefore expansions of the same rational expression. Empty matchings give the vacuum identities.

Directly, $[T, h_m] = -mh_{m-1}$, which proves translation covariance. The two expansions of each contraction differ by a derivative of the formal delta distribution. A finite power of $z-w$ kills the commutator. These identities prove locality and associativity for all the fields in (14.5). □

Hall multiplication is represented by creation modes: multiplication by p_r is h_{-r}. It need not agree with the vertex (-1)-product on composite states. For example,

$$(p_1^2)_{(-1)}p_1 = p_1^3 + 2p_3, \qquad (p_1^2)p_1 = p_1^3.$$

The additional term is the constant coefficient of $2z^{-2}\sum_{r>0} p_r z^{r-1}$ in $:H(z)^2:\,p_1$.

Finite power covers

At a closed point of degree d, pull back the current density along $s = z^d$ on $\mathbb{G}_m$:

$$J_x(z) = dz^{d-1} H_x(z^d), \qquad J_n^x = \begin{cases} d\, h^x_{n/d}, & d \mid n, \\ 0, & d \nmid n. \end{cases}$$

The map is finite étale over $\mathbb{C}$ on the torus. Its extension across zero is ramified, so the domain matters. The common contraction is

$$\frac{d^2 z^{d-1} w^{d-1}}{(z^d - w^d)^2} = \sum_{\zeta^d = 1} \frac{\zeta}{(z - \zeta w)^2}. \tag{14.6}$$

Differentiate in w the identity $\sum_{\zeta^d=1} (z - \zeta w)^{-1} = dz^{d-1}/(z^d - w^d)$ to obtain this formula. Different point colors commute.

The coefficient of z^{rd-1} in $J_x(z)1$ is $d p_{x,r}$. Products of such creation coefficients recover all finite-support Hall states. Normal products and derivatives have the pulled-back Wick expansions. Derivative orders a, b give pole order at most $a + b + 2$ at each divisor $z = \zeta w$. This is a bound for each specified input. The states have no common finite derivative bound.

Fields, quasi-modules and residue maps

For a complex vector space W write $\mathcal{E}(W) = \mathrm{Hom}(W, W((z)))$. A subset is *quasi-local* if, for each pair of its fields, a nonzero polynomial in their two coordinates annihilates the commutator. It is *quasi-compatible* if each finite ordered product becomes a map to $W[[z_1, \dots, z_m]][z_1^{-1}, \dots, z_m^{-1}]$ after multiplication by a finite product of nonzero two-variable polynomials. Formula (14.6) proves quasi-locality of the point-labeled fields on $\mathcal{F}_C$. Their finite Wick expressions prove quasi-compatibility.

Li's reconstruction theorem gives a vertex algebra *of fields* from a quasi-local subset of $\mathcal{E}(W)$, including its closure under any chosen subgroup of dilations. Evaluation gives a faithful quasi-module on W.[1]

Concretely, if $p(z_1, z)$ clears the product, then

$$Y_{\mathcal{E}}(a(z), u)b(z) = \iota_{z,u}\big(p(z+u, z)^{-1}\big)\, p(z_1, z) a(z_1) b(z)\big|_{z_1 = z+u}. \tag{14.7}$$

The symbol $\iota_{z,u}$ means expansion in $\mathbb{C}((z))((u))$. Clearing first makes the substitution defined. The theorem makes its coefficients independent of the clearing polynomial and proves closure and the vertex identities. Substitution at $z_1 = \alpha z + u$ gives the dilation operations. The original Hall space is the quasi-module, and has not been identified with this vertex algebra of fields.

For finitely many point colors, the pole group is generated by finitely many roots of unity. The whole point-labeled construction is their filtered union: each operation uses finitely many denominators and colors.

There are also actual supported residue maps on the power-cover sector. Start with the Heisenberg fields of Proposition 14.3.1. At the collision of two positions, with $u = s_i - s_j$, the map on states and a multiplier f is

$$r_{ij}(f; \dots, a, \dots, b, \dots) = \mathrm{pp}_u\big(f Y(a, u) b\big).$$

[1] H. Li, *A new construction of vertex algebras and quasi modules for vertex algebras*. arXiv:math/0404110, Theorems 4.9 and 5.4. The closure includes the identity field. Faithfulness here follows from its inclusion in $\mathcal{E}(W)$.

Here pp_u retains the negative powers of u. The other states stay at their positions. Regular functions act on principal parts by their finite normal Taylor expansions. For example, for $t \neq 0$ and $r, \ell \geq 1$,

$$(u-t)^{-\ell}[u^{-r}] = (-1)^{\ell} \sum_{m=0}^{r-1} \binom{\ell+m-1}{m} t^{-\ell-m}[u^{m-r}].$$

This retains the spectator poles and every finite normal derivative.

Translation covariance makes the maps horizontal for the state connection $\partial_s + T$. Residues of disjoint pairs commute. For three positions, the three iterated principal parts come from the same rational Wick expression. The principal-parts relation between its three collision channels is their residue identity. Thus one has the full residue diagram, including its attachments, before taking a cover. These statements concern the polynomial Heisenberg states with their finite pole bounds.

Pull back this diagram along

$$(\mathbb{G}_m)^n \longrightarrow (\mathbb{G}_m)^n, \qquad (z_1, \dots, z_n) \longmapsto (z_1^d, \dots, z_n^d).$$

Finite étale base change preserves its right differential modules, residue maps and their relations. The diagonal $s_i = s_j$ pulls back to the divisors $z_i = \zeta z_j$, with their actual intersections and pulled-back attachments. Pullback of the current density is exactly (14.6). The cut tensor here excludes $z_i^d = z_j^d$ across a cut. It would change if only $z_i = z_j$ were excluded.

For finitely many colors, use the independent local factors and their labeled elementary insertions. Their finite Wick matchings give the corresponding coefficient diagrams. Composite fields at a retained root use (14.7). This supplies an operation comparison for this specified cover sector. It leaves a field presentation of an arbitrary geometric cut object as a separate question.

14.4 Collective counting fields

Sum the point-labeled currents coefficientwise:

$$J(z) = \sum_x J_x(z) = \sum_{n \in \mathbb{Z}} J_n z^{-n-1}, \qquad J_{-n} = A_{-n}, \quad J_n = (q^n - 1)B_n \quad (n > 0).$$

Set $J_0 = 0$. A fixed mode involves only points whose degrees divide its nonzero index, so it acts on the polynomial Hall space. On a fixed input only finitely many positive modes act nontrivially. The commutators are

$$[J_n, J_{-m}] = \delta_{nm} n N_n I \qquad (n, m > 0).$$

Proposition 14.4.1. A linear operator T on this mode representation can satisfy $[\mathsf{T}, J_n] = -nJ_{n-1}$ for all integers n only if $N_{n+1} = N_n$ for every $n \geq 1$.

Proof. Apply $[\mathsf{T}, -]$ to $[J_{n+1}, J_{-n}] = 0$ and use Jacobi. The resulting equality is

$$0 = -(n+1)[J_n, J_{-n}] + n[J_{n+1}, J_{-n-1}] = n(n+1)(N_{n+1} - N_n)I.$$

The coefficient field has characteristic zero. □

For $\mathbb{P}^1$, the difference $N_{n+1} - N_n = q^n(q-1)$ is nonzero. Thus the unchanged collective current has no ordinary vertex translation. The degree derivation $L_0(p_{x,r}) = r d_x p_{x,r}$ does satisfy $[L_0, J(z)] = (z\partial_z + 1)J(z)$. It implements dilation.

Reciprocal normalization

Write a rational counting function with constant term one as

$$Z(t) = \prod_{\lambda \in \Lambda} (1 - \lambda t)^{-\epsilon_\lambda}, \qquad \epsilon_\lambda \in \mathbb{Z},$$

with finitely many nonzero parameters. Its current contraction is

$$C(z, w) = \frac{1}{zw} (t\partial_t)^2 \log Z(t) = \sum_{\lambda \in \Lambda} \frac{\epsilon_\lambda \lambda}{(z - \lambda w)^2}, \qquad t = w/z. \tag{14.8}$$

This follows by twice differentiating each $-\log(1 - \lambda t)$.

For the curve, the classical rationality theorem gives

$$Z_C(t) = \frac{\prod_{i=1}^{2g} (1 - \alpha_i t)}{(1 - t)(1 - qt)}.$$

The numerator parameters α_i occur in the current contraction as well as $1, q$. They must therefore occur among its allowed collision gains. Poles of the current contraction are not determined just by poles of Z_C.

The full Laurent field needs both orders of a contraction. The expression (14.8) need not be symmetric under z, w interchange, so quasi-locality of each J_x alone does not establish quasi-locality of the infinite sum. Rationality and reciprocal eigenvalue pairing give a different collective field.

Choose $\sqrt{q} > 0$ and define

$$\widetilde{J}_{-n} = A_{-n}, \qquad \widetilde{J}_n = q^{-n/2}(q^n - 1) B_n, \qquad c_n = q^{-n/2} N_n.$$

These formulas use $n > 0$. Set $\widetilde{J}_0 = 0$.

The signed multiset

$$\widetilde{\Lambda} = \{q^{-1/2}, q^{1/2};\ \alpha_1/q^{1/2}, \dots, \alpha_{2g}/q^{1/2}\}$$

has signs $+, +, -, \dots, -$. The pairing $\alpha \leftrightarrow q/\alpha$ makes this multiset invariant under inversion. This uses reciprocal duality. No assertion about the absolute values of the α_i is needed.

THEOREM 14.4.2. The field $\widetilde{J}(z) = \sum_n \widetilde{J}_n z^{-n-1}$ has the symmetric rational contraction

$$\widetilde{C}(z, w) = \sum_{\lambda \in \widetilde{\Lambda}} \frac{\epsilon_\lambda \lambda}{(z - \lambda w)^2}.$$

Its commutator is annihilated by $\prod_{\lambda \in \widetilde{\Lambda}} (z - \lambda w)^2$. Its dilates generate a quasi-local system, and hence a vertex algebra of fields with faithful quasi-module $\mathcal{F}_C$.

Proof. Inversion invariance and

$$\frac{\lambda}{(w - \lambda z)^2} = \frac{\lambda^{-1}}{(z - \lambda^{-1} w)^2}$$

give symmetry. The coefficient of $z^{-n-1} w^{n-1}$ in the forward expansion is $n c_n$. Inversion invariance gives the same constants in the reverse expansion.

Their difference is

$$\sum_\lambda \epsilon_\lambda \partial_w \big(z^{-1} \delta(\lambda w / z) \big), \qquad \delta(t) = \sum_{m \in \mathbb{Z}} t^m.$$

Each summand is killed by $(z - \lambda w)^2$. Every finite set of dilates has a finite set of these factors. The quasi-local reconstruction theorem therefore applies. □

Translation in this vertex algebra acts on its fields through (14.7). The Hall space is a quasi-module, and its new positive modes also differ from J_n. Thus the theorem imposes no impossible translation on the unchanged representation in Proposition 14.4.1. The collective modes retain the counting sequence. Individual closed-point labels remain in the separate fields J_x.

The point-labeled and aggregate rational fields together are quasi-compatible. For a fixed point of degree d, their mixed contraction uses only $n \in d\mathbb{Z}$. Its coefficients are finite combinations of n times geometric progressions. It therefore sums to a rational function. Aggregate contractions use (14.8) and its rescalings.

Wick expansion clears a finite common denominator in every finite ordered product. Li's nonlocal reconstruction then gives a nonlocal vertex algebra of fields and a faithful Hall quasi-module.[2]

Pairwise quasi-locality of this combined set has not been assumed. The native Green current has an infinite-product kernel. It uses the analytic recipient below.

A finite-dimensional trace comparison

For a finite-dimensional graded vector space $H = \bigoplus_i H^i$ and a grading-preserving endomorphism F, graded symmetry gives

$$\sum_{n\geq 0} \operatorname{str}(F; \operatorname{Sym}^n H)t^n = \prod_i \det(1 - tF|H^i)^{(-1)^{i+1}}.$$

Indeed, after extending scalars and triangularizing, an even eigenvector contributes $(1 - \alpha t)^{-1}$. An odd eigenvector generates an exterior algebra and contributes $1 - \alpha t$. Multiply the factors and descend the coefficients. Jordan off-diagonal entries do not change the traces.

The two even eigenvalues $1, q$, in degrees zero and two, reproduce the series of $\mathbb{P}^1$. A more discriminating example is $y^2 = x^3 - x$ over $\mathbb{F}_5$, which has seven affine points and one point at infinity. The matrices

$$F = \begin{pmatrix} 0 & -5 \\ 1 & -2 \end{pmatrix}, \qquad H = \begin{pmatrix} 1 & -1 \\ -1 & 5 \end{pmatrix}$$

satisfy $F^t H F = 5H$. The leading principal minors of H are $1, 4$, so H is positive definite. This particular operator has eigenvalues of modulus $\sqrt{5}$ and determinant polynomial $1 + 2t + 5t^2$.

Identifying it with a geometric Frobenius representation still requires the cohomological realization. The point count and positive matrix alone do not construct it.

14.5 Gain equations and their derived intersections

Let k have characteristic zero and let $G \subset k^\times$ be a subgroup containing the chosen collision gains. Work on $X = (\mathbb{G}_m)^n$, with coordinate ring $S = k[z_1^{\pm 1}, \dots, z_n^{\pm 1}]$. For a finite oriented graph Γ, including repeated edges, an edge $e = (i, j, \lambda_e)$ names the equation $f_e = z_i - \lambda_e z_j$. A component is *balanced* if the oriented product of gains around every cycle is one. Reversing an edge replaces its gain by its inverse.

The scalar derived intersection is the Koszul complex

$$K_\Gamma = (S \otimes \Lambda(\xi_e : e \in E(\Gamma)), d), \qquad |\xi_e| = -1, \qquad d\xi_e = f_e.$$

For pole coefficients one instead inverts a finite collection of nonzero f_e. The union of these localization rings records functions with finitely many allowed poles. It does not assert that an infinite arrangement is a finite-type scheme.

[2] H. Li, *Nonlocal vertex algebras generated by formal vertex operators*. arXiv:math/0502244v2, Theorem 2.20. Quasi-compatibility is Definition 2.10.

THEOREM 14.5.1. Suppose Γ has n vertices, e edges and c components. If all components are balanced, a spanning forest gives

$$K_\Gamma \simeq k[y_1^{\pm 1}, \dots, y_c^{\pm 1}] \otimes \Lambda(\eta_1, \dots, \eta_{e-n+c}), \qquad |\eta_j| = -1, \quad d\eta_j = 0.$$

If a component is unbalanced, K_Γ is contractible.

Proof. Removing leaves of a spanning forest eliminates one coordinate at each step by a nonzero scalar multiple of its neighbor. Its $n - c$ equations form a regular sequence, with quotient the torus on the root coordinates. In a balanced component, every remaining equation is a constant linear combination of forest equations. Subtract this combination from its exterior generator. The resulting invertible triangular change splits off one closed generator for each extra edge.

An unbalanced cycle instead leaves $(1 - \lambda)\, y$ with $\lambda \neq 1$ and y invertible. Thus its equations generate the unit ideal. If $\sum_e g_e f_e = 1$, then exterior multiplication by $\beta = \sum_e g_e \xi_e$ satisfies $d(\beta \wedge -) + \beta \wedge d = 1$. This contracts the complete complex. □

For the balanced triangle,

$$f_1 = z_1 - \lambda z_2, \quad f_2 = z_2 - \mu z_3, \quad f_3 = z_1 - \lambda\mu z_3 = f_1 + \lambda f_2,$$
$$\eta = \xi_3 - \xi_1 - \lambda \xi_2, \qquad d\eta = 0.$$

Quotient by the forest equations and send ξ_1, ξ_2 to zero. The image of η is a nonzero exterior generator, so it cannot have been a boundary. If the third gain is instead $\nu \neq \lambda\mu$, the explicit primitive of the unit is

$$\beta = \frac{\xi_3 - \xi_1 - \lambda \xi_2}{(\lambda\mu - \nu) z_3}, \qquad d\beta = 1.$$

The forest basis computes the cohomology. Equation operations belong to the unreduced complex. A ring map $S \to S'$ and a matrix $U = (u_{te})$ satisfying $f_e \mapsto \sum_t u_{te} f'_t$ give the cochain map $\xi_e \mapsto \sum_t u_{te} \xi'_t$. Composition is matrix multiplication with coefficient substitution.

For a clustering $\alpha : I \twoheadrightarrow J$ and scales $\gamma_i \in G$, the substitution $z_i = \gamma_i y_{\alpha(i)}$ gives

$$f_{ij,\lambda} \longmapsto \gamma_i \big(y_{\alpha(i)} - \lambda \gamma_j \gamma_i^{-1} y_{\alpha(j)} \big).$$

The exterior generator has the same factor γ_i. An internal zero equation retains its exterior generator. An internal unit equation contracts. An equation that becomes zero cannot remain inverted, so a collision requires its restriction complex.

The divided exponential chart

In this spectral coefficient family, regard q as a formal variable. For gains q^a, with integers a, introduce a formal parameter $\hbar$ and use $q = e^{\hbar}$, $z_i = e^{\hbar x_i}$. In $k[x_1, \dots, x_n][[\hbar]]$ the divided equation is

$$\frac{e^{\hbar x_i} - e^{\hbar(x_j + a)}}{\hbar} = (x_i - x_j - a) U_{ij,a}(\hbar), \qquad U_{ij,a}(0) = 1.$$

The quotient denotes a power series, with no inversion of $\hbar$.

Rescaling the exterior generator by the unit $U_{ij,a}^{-1}$ gives the affine equation. A forest quotient is $k[y_1, \dots, y_c][[\hbar]]$, which is flat over $k[[\hbar]]$. Balanced cycles retain the excess exterior factors. An

unbalanced cycle telescopes to a nonzero integer, so its complex contracts. After inverting $\hbar$, this is the pulled-back multiplicative arrangement up to units.

The special fiber is the shifted arrangement $x_i - x_j = a$. Undivided equations would all reduce to zero. This constructs a family of spectral coefficient arrangements. Extending Green operators across $\hbar = 0$ further requires a lattice and a normalization, since $q^n - 1$ becomes $\hbar$ times a unit. No family of arithmetic curves is supplied by the coordinate substitution.

Scalar operations on the pole ring

Fix colors α and rational kernels $K_{\alpha\beta}(z, w)$ with finitely many allowed gain poles. For functions on two ordered lists of colors define

$$(f \diamond g)(z_1, \dots, z_{m+n}) = f(z_1, \dots, z_m)\, g(z_{m+1}, \dots, z_{m+n}) \prod_{i \le m < j} K_{\alpha_i \alpha_j}(z_i, z_j).$$

This is an associative product, with the empty list as unit: either bracketing of three blocks includes each cross-block factor exactly once. Summing over order-preserving shuffles gives an associative product on symmetric colored functions.

For graded colors, include the Koszul permutation sign. Both bracketings have the same three-block shuffles and signs.

Inverse exchanges may require gains from zeros as well as poles of the original kernels. The scalar construction then uses the enlarged group. A Hall comparison must also supply the maps of coefficients, orientations and any numerator conditions required by its recipient. The scalar product proves none of these from an equality of kernels.

14.6 Supported coefficients with excess

For one regular equation f, the scalar Koszul complex and the localization complex have different purposes. The latter is $L_f = [S \to S[f^{-1}]]$ in degrees 0, 1. Its map is horizontal for the usual left differential action. Localization gives

$$L_f \otimes^{\mathbb{L}}_S L_f \simeq L_f :$$

tensor the triangle $L_f \to S \to S[f^{-1}]$ with L_f and use the acyclicity of $L_f \otimes_S S[f^{-1}]$. In contrast, $S/(f) \otimes^{\mathbb{L}}_S S/(f)$ has a nonzero degree-minus-one Tor class.

For $f = z_i - \lambda z_j$, $i \neq j$, the Koszul complex $[S \xrightarrow{f} S]$ in degrees -1, 0 cannot admit a differential-module enhancement with the same object of $D(S)$. Such an enhancement would give its cohomology $S/(f)$ the stated S-action and a left differential action. But f acts by zero, whereas $[\partial_{z_i}, f] = 1$ would force their commutator to be the identity on this nonzero quotient.

We construct a supported recipient that also retains the excess. For a balanced graph let $V = k^{E(\Gamma)}$, with basis ξ_e, and view the equations as linear forms on $A_0 = k^n$. Put

$$F : V \longrightarrow A_0^*, \quad F(\xi_e) = f_e, \qquad W = \operatorname{im} F, \quad E = \ker F, \quad T_\Gamma = W^\perp.$$

Here E denotes the space of equation relations. If $r = \dim W$ and $c = \dim T_\Gamma$, then $r = n - c$ and $Z = T_\Gamma \cap X \cong (\mathbb{G}_m)^c$.

Let $L = \det T_\Gamma^*$ be its constant tangent density line. The density-valued scalar source is $\mathcal{K}_\Gamma = L \otimes K_\Gamma$, with

$$H^{-p}(\mathcal{K}_\Gamma) = \omega_Z \otimes_k \Lambda^p E, \qquad \omega_Z = \mathcal{O}_Z \otimes_k L.$$

These cohomology identifications are independent of a forest: wedge closed vectors of E with a degree-zero class. A forest splitting proves that this map is an isomorphism.

All complexes are cohomological. $C[m]^j = C^{j+m}$ with differential $(-1)^m d_C$.

Normal derivatives and the ordinary module

For $i : Z \hookrightarrow X$ define the right differential module

$$\mathcal{N} = i_+\omega_Z = i_*\big(\omega_Z \otimes_{\mathcal{D}_Z} \mathcal{D}_{Z\to X}\big), \qquad \mathcal{D}_{Z\to X} = \mathcal{O}_Z \otimes_{i^{-1}\mathcal{O}_X} i^{-1}\mathcal{D}_X.$$

It lies in cohomological degree zero.

Choose complementary linear coordinates $(u_1, \dots, u_r, y_1, \dots, y_c)$ with $Z = (u = 0)$, and set $\tau = dy_1 \wedge \cdots \wedge dy_c$. On the actual open chart its sections have the normal form

$$\mathcal{N} = \bigoplus_{\alpha\in\mathbb{N}^r} \mathcal{O}_Z\, \delta_{\tau,\alpha}, \qquad \delta_{\tau,\alpha} = \left[\frac{du_1 \wedge \cdots \wedge du_r \wedge \tau}{\prod_j u_j^{\alpha_j+1}}\right]. \tag{14.9}$$

The brackets denote local cohomology in degree r, placed in degree zero in $\mathcal{N}$. The residue of $du_1 \wedge \cdots \wedge du_r/(u_1 \cdots u_r)$ is one. Equivalently, $\delta_{\tau,\alpha} = \delta_{\tau,0}\partial_u^\alpha/\alpha!$. Thus

$$\begin{aligned} \delta_{\tau,\alpha} u_j &= \delta_{\tau,\alpha-e_j}, \qquad & \delta_{\tau,\alpha}\partial_{u_j} &= (\alpha_j+1)\delta_{\tau,\alpha+e_j}, \\ (b\delta_{\tau,\alpha})\partial_{y_j} &= -\partial_{y_j}(b)\delta_{\tau,\alpha}. \end{aligned} \tag{14.10}$$

The first expression is zero if $\alpha_j = 0$.

These formulas follow from $(a\Omega)\partial = -\partial(a)\Omega$ for a constant top form Ω. They satisfy the right Weyl relation $(m\partial_{u_i})u_j - (mu_j)\partial_{u_i} = \delta_{ij}m$. Every section has finite normal order. All finite orders occur. No infinite normal-derivative tail is introduced.

A constant change $u' = Au$ preserves the normalized order-zero residue and transforms derivatives by $\partial_{u'_i} = \sum_j (A^{-1})_{ji}\partial_{u_j}$. Both numerator density and denominator must transform. A tangent change $y' = By$ multiplies the density by $\det B$. These rules follow by testing the fractions against normal polynomials: $\delta_{\tau,\alpha}$ extracts the coefficient of u^α with its tangent density.

If $I = (f_e)$, the actual support complex is

$$C_I(\omega_X) = \bigotimes_{e\in E(\Gamma)} [S \longrightarrow S[f_e^{-1}]] \otimes_S \omega_X.$$

It has only $H^r = \mathcal{N}$. For forest equations this is the tensor product of the one-variable principal-parts calculation.

A redundant $f \in I$ adds no cohomology. Localization of the supported finite jets at f is zero. Thus tensoring with $[S \to S[f^{-1}]]$ changes the complex by an acyclic cone. For a zero equation, the localization is zero and the extra factor is just S in degree zero. Therefore $C_I(\omega_X)[r] \simeq \mathcal{N}$, including repeated equations.

There is a scalar cochain map

$$\varepsilon : \mathcal{K}_\Gamma \longrightarrow \mathrm{Res}_S \mathcal{N}, \qquad \tau a \longmapsto a|_Z \delta_{\tau,0},$$

which is zero on positive exterior length. Normal annihilation makes it S-linear and a cochain map. It includes ω_Z as the normal socle, the part killed by I.

Every degree-zero morphism from $\mathcal{K}_\Gamma$ to this ordinary target kills negative cohomology. More generally, $\mathcal{N}[m]$ has cohomology only in degree $-m$. It cannot receive both a nonzero vacuum class in degree zero and a nonzero excess class in degree -1. Replacing complexes by resolutions, changing density by a unit, or retaining more normal derivatives leaves this degree argument unchanged.

A derived supported complex

Let $D = \Gamma(X, \mathcal{D}_X)$. Define

$$\mathcal{P}_\Gamma = L \otimes_k \Lambda(V \oplus T_\Gamma) \otimes_k D, \qquad |V| = |T_\Gamma| = -1. \tag{14.11}$$

For $v \in V$ and $t \in T_\Gamma$ put $\mathsf{a}(v) = F(v)$ and $\mathsf{a}(t) = \partial_t$. On an ordered wedge the differential is

$$d(\tau \otimes a_1 \wedge \cdots \wedge a_m \otimes Q) = \sum_{j=1}^{m} (-1)^{j-1} \tau \otimes a_1 \wedge \cdots \widehat{a}_j \cdots \wedge a_m \otimes \mathsf{a}(a_j) Q.$$

Multiplication by $\mathsf{a}(a_j)$ is on the left of Q. The differential is right D-linear.

The operators commute because $[\partial_t, F(v)] = F(v)(t) = 0$, so $d^2 = 0$. The tangent exterior factors impose the Spencer relations.

There is an actual S-linear cochain map

$$j_\Gamma : \mathcal{K}_\Gamma \longrightarrow \operatorname{Res}_S \mathcal{P}_\Gamma, \qquad \tau a\, v_1 \wedge \cdots \wedge v_p \longmapsto \tau \otimes (v_1 \wedge \cdots \wedge v_p) \otimes a. \tag{14.12}$$

Functions commute with the $F(v_i)$, which proves its cochain equation. The scalar source is not being given a differential action by this map.

Theorem 14.6.1. There are canonical right D-module isomorphisms

$$H^{-p}(\mathcal{P}_\Gamma) \cong \Lambda^p E \otimes_k \mathcal{N}.$$

On cohomology, j_Γ includes $\omega_Z \otimes \Lambda^p E$ at normal order zero. This inclusion is injective and its right D-span is the whole group. It retains the vacuum, every excess class and, by differentiation, every finite normal descendant.

Proof. Choose V_0 complementary to E and a basis of T_Γ. The closed factor ΛE splits off. The remaining right Koszul complex uses the commuting operators $u_1, \dots, u_r, \partial_{y_1}, \dots, \partial_{y_c}$.

Filter D by differential order, assigning weight zero to normal exterior generators and one to tangent exterior generators. Its symbol complex is the commutative Koszul complex of

$$u_1, \dots, u_r, p_{y_1}, \dots, p_{y_c} \quad \text{in } S[p_1, \dots, p_n].$$

This is a regular sequence. To solve a negative-degree cycle, lift a boundary for its leading symbol and subtract it. The filtration degree decreases and is bounded below in every cochain degree, so the process terminates.

The degree-zero quotient is

$$L \otimes_k D \Big/ \left(\sum_i u_i D + \sum_j \partial_{y_j} D \right).$$

Normal ordering identifies it with the transfer module $i_+\omega_Z$: the tangent density relations remove tangent derivatives and the normal derivatives give (14.9). Wedging with closed elements of E gives a

canonical map $\Lambda^p E \otimes H^0(\mathcal{P}_\Gamma) \to H^{-p}(\mathcal{P}_\Gamma)$. The splitting proves that it is an isomorphism, removing the choice of complement from the conclusion. Formula (14.12) sends the source to the normal socle. The jet basis proves injectivity, and right normal differentiation generates the entire target cohomology. □

Projection in exterior degree zero defines a right D-linear map $\pi : \mathcal{P}_\Gamma \to \mathcal{N}$ by $\pi(\tau \otimes Q) = \delta_{\tau,0} Q$. Its cochain equation is exactly the normal and tangent annihilation of $\delta_{\tau,0}$. Thus $\pi j_\Gamma = \varepsilon$. If $E \neq 0$, π is not a quasi-isomorphism: it kills the negative excess.

Universal differential induction is a further useful recipient,

$$\mathcal{U}_\Gamma = \mathcal{K}_\Gamma \otimes_S D = L \otimes \Lambda V \otimes D.$$

Normal ordering makes D free as a left S-module. Induction therefore preserves the scalar cohomology and is functorial for every S-linear equation map, including matrices with variable coefficients and unchanged density. Inclusion of tangent exterior degree zero gives $\mathcal{U}_\Gamma \to \mathcal{P}_\Gamma$. The latter complex imposes the tangent relations while retaining the excess.

In one normal coordinate, let $A = k[u]$ and $E_u = A[u^{-1}]/A$. Left-to-right conversion gives $(u^{-n} \otimes du)\partial_u = n u^{-n-1} \otimes du$. Thus $\delta_m = u^{-m-1} \otimes du$ agrees with (14.10), and $[D \xrightarrow{u\cdot} D]$ in degrees -1, 0 is its free right D-resolution. This compares the supported normal coefficient resolutions without changing their derivative actions.

Supported dual functionals

The lost excess still has a supported dual functional. On the linear normal chart, with $B = \mathcal{O}_Z$, one has

$$H^p \operatorname{RHom}_S(\mathcal{K}_\Gamma, \mathcal{N}) \cong B \otimes_k \Lambda^p E^*, \qquad 0 \le p \le \dim E. \tag{14.13}$$

All other degrees vanish.

To compute it, the bounded free source allows ordinary Hom. Its degree-p differential is $-(-1)^p \phi d$. Rescaling the dual basis in degree p by $(-1)^{p(p+1)/2}$ gives the normal cochain Koszul differential.

For one normal variable this is $[\mathcal{N} \xrightarrow{u} \mathcal{N}]$ in degrees 0, 1. Multiplication by u is surjective, with kernel $B\delta_0$. The right inverse $R\delta_m = \delta_{m+1}$ satisfies $uR = 1$ and $Ru = 1 - \iota p$, where p extracts δ_0.

These homotopies are B-linear. The socle inclusion is S-linear and a quasi-isomorphism. Tensoring the normal contractions, with their cochain signs, leaves the socle and ΛE^*. The density line cancels, proving (14.13).

For the triangle the functional

$$\ell(dy\,\xi_3) = \delta_{dy,0}, \qquad \ell(dy\,\xi_1) = \ell(dy\,\xi_2) = 0$$

is closed and evaluates nontrivially on $dy\,\eta$. A Hom boundary evaluates to zero on that closed class. It therefore defines a nonzero map $\mathcal{K}_\Gamma \to \mathcal{N}[1]$, which kills the degree-zero vacuum. Derivative order and cohomological degree remain different gradings.

Keeping differential-module maps adds the tangent de Rham complex. On $Z = (\mathbb{G}_m)^c$ the bounded free complex (14.11) gives

$$\operatorname{RHom}_D(\mathcal{P}_\Gamma, \mathcal{N}) \simeq (\Omega^\bullet(Z), d_{\mathrm{dR}}) \otimes_k \Lambda(E^*), \qquad |E^*| = 1.$$

The same normal contractions commute with tangent differentiation. The tangent Spencer dual has differential $-d_{\mathrm{dR}}$ after the preceding degree normalization. Multiplying tangent degree a by $(-1)^a$ gives d_{dR}. The resulting degree-m cohomology is $\bigoplus_{a+p=m} H^a_{\mathrm{dR}}(Z) \otimes \Lambda^p E^*$.

Indeed $d(y^j) = j\, y^j\, d\log y$ contracts every nonzero Laurent weight. Weight zero leaves 1, $d\log y$, and tensoring gives $H^\bullet_{\mathrm{dR}}(Z) = \Lambda^\bullet\langle d\log y_1, \dots, d\log y_c\rangle$.

Equation operations and tangent connections

Suppose $F : V \to A_0^*$ and $F' : V' \to A_0^*$ have the same image, and let $U : V \to V'$ be constant with $F = F'U$. The assignments

$$v \longmapsto Uv, \qquad t \longmapsto t, \qquad Q \longmapsto Q, \qquad \tau \longmapsto \tau$$

define a right D-linear map $\mathcal{P}_F \to \mathcal{P}_{F'}$. The normal differentials agree by $F = F'U$, and constant coefficients commute with tangent differentiation. Thus the map is a cochain map and the square with the two maps j commutes strictly. It acts on cohomology as $\Lambda^p(U|_E) \otimes I_{\mathcal{N}}$, so it intertwines the excess action and composes by matrix multiplication. It may kill an excess class when $U|_E$ does.

An invertible linear coordinate map gives the same comparison on open domains that it actually identifies. It pulls back the density, sends tangent vectors by the inverse coordinate map, and transforms every normal derivative by the chain rule. These operations compose strictly. Diagonal scalings and coordinate permutations preserve the torus. An arbitrary invertible linear map need not preserve it.

For example, in the triangle take $\lambda = 2$, $\mu = 4$ and $u = z_1 - 2z_2$, $v = z_2 - 4z_3$, $y = z_3$. Under

$$z_1 = 4w_1, \qquad z_2 = \tfrac{1}{2}w_2, \qquad z_3 = w_3,$$

put $u' = w_1 - \frac{1}{4}w_2$, $v' = w_2 - 8w_3$, $y' = w_3$. The equations give $u = 4u'$, $v = \frac{1}{2}v'$ and $\eta \mapsto 4\eta'$, where $\eta' = \xi_3' - \xi_1' - \frac{1}{4}\xi_2'$.

The density-normalized jets transform by

$$\delta_{dy,(m,n)} \longmapsto 4^{-m}2^{n}\delta_{dy',(m,n)}.$$

Indeed the normal Jacobian is 2 and the denominator factor is $4^{m+1}(1/2)^{n+1}$. The vacuum is unchanged. Omitting the Jacobian would already multiply it by $1/2$.

The tangent connection restricts variable equation operations. On the same triangle let an equation automorphism fix ξ_1, ξ_2 and send

$$\xi_3 \longmapsto (1 - y)\xi_1 + \lambda(1 - y)\xi_2 + y\xi_3.$$

It fixes the equations and sends η to $y\eta$.

In supported cohomology, however, $m = \eta\delta_{dy,0}$ satisfies $m\partial_y = 0$ whereas $(ym)\partial_y = -m \neq 0$. No right D-linear cochain map on the fixed $\mathcal{P}_\Gamma$ can induce this action. Homotopies do not change the induced cohomology map.

Raw induction $\mathcal{U}_\Gamma$ remains functorial for this scalar equation map. Removing its free tangent derivatives while retaining the map requires additional connection data.

Equation symmetries can give a second obstruction, even when determinants are unchanged. Repeat the third triangle edge and put $\eta_i = \xi_{i+2} - \xi_1 - \lambda\xi_2$, $i = 1, 2$. Fix the forest generators and act by $\eta_1 \mapsto t\eta_1$, $\eta_2 \mapsto t^{-1}\eta_2$. This automorphism fixes the equations, ambient coordinates, normal quotient and tangent density, and has determinant one.

If a target assigns it the identity at $t = 2$, a natural homogeneous comparison kills both excess classes. Their images would have to equal twice and half themselves. Equation, tangent and normal determinant twists leave this argument unchanged. The invariant top wedge is not killed by this argument.

For the ordinary module on the split torus, $\mathrm{End}_D(\mathcal{N}) = k$. An endomorphism sends its normal socle generator to $b\delta_{\tau,0}$. The normal relations force the socle, and the tangent relations force every derivative of b to vanish. Right normal differentiation then determines the whole map.

Consequently a coherent action of the full $\mathrm{SL}(E)$ for $\dim E = 2$ on any single shift $\mathcal{N}[m]$ is a character to $k^\times$, and is trivial. To see this last assertion directly, conjugation by $\mathrm{diag}(2, 1/2)$ makes every upper or lower elementary unipotent a commutator. These unipotents generate $\mathrm{SL}_2(k)$.

Thus this naturality obstruction applies to the ordinary target with its full equation action. A derived target carrying ΛE has the nontrivial excess action instead.

With three copies of the third edge, a cyclic permutation is even. A natural comparison with identity target action kills the nonzero difference $\xi_3 - \xi_4 = (1 - \sigma)\eta_1$.

A nontransverse clustering

Again take the gains 2, 4, 8 and restrict to

$$\iota_Y : Y = (\mathbb{G}_m)^2 \longrightarrow X, \qquad (x, y) \longmapsto (2x, x, y).$$

This is $u = 0$, and $g = x - 4y$ is the surviving normal coordinate. The three equations become $(0, g, 2g)$. Writing $\zeta = \xi_1$ and $\eta = \xi_3 - \xi_1 - 2\xi_2$, one gets

$$\iota_Y^* K_\Gamma = K(g) \otimes \Lambda(\zeta, \eta).$$

The excess η is inherited. ζ is created by this nontransverse restriction.

Let $\mathcal{N}_X$ have normal coordinates (u, v) and let $\mathcal{N}_Y$ have normal coordinate $g = v$, both with density dy along the common stratum. For the derived pullback of underlying modules,

$$\mathcal{O}_Y \otimes^{\mathbb{L}}_{\mathcal{O}_X} \mathrm{Res}\, \mathcal{N}_X \simeq \mathcal{N}_Y[1]. \tag{14.14}$$

This convention is an $\mathcal{O}$-module pullback, rather than a dimension-normalized differential inverse image. Resolve $\mathcal{O}_Y$ by $[\mathcal{O}_X \xrightarrow{u} \mathcal{O}_X]$. After tensoring, multiplication by u is surjective on $\mathcal{N}_X$ and has kernel $\bigoplus_{n\geq 0} k[y^{\pm 1}]\delta_{dy,(0,n)}$. The residual v, ∂_v, y, ∂_y actions are exactly those of $\mathcal{N}_Y$, proving (14.14) and retaining every finite v-descendant.

Under the derived pullback of ε, the new class $dy\,\zeta$ maps to minus the supported vacuum in degree -1. Indeed, if $d\theta = u$ is the resolution generator, then $dy(\xi_1 - \theta)$ is a closed lift and maps to $-\theta\delta_{dy,0}$. The inherited $dy\,\eta$ already maps to zero before restriction, so still maps to zero. Thus inherited excess and a new Tor class have different images. No evaluation of a distribution on its singular support has been used.

Changing the third gain to 16 gives $d(\xi_3 - \xi_1 - 2\xi_2) = -8z_3$. The primitive $-(\xi_3 - \xi_1 - 2\xi_2)/(8z_3)$ of the unit remains a primitive after this clustering, with $z_3 = y$. Both scalar complexes contract and both supports are empty.

Contact differentials and the geometric comparison

A meromorphic coefficient map also needs its contact differential. Let $C, \mathcal{L}, J$ be cochain complexes, let $W : C \to \mathcal{L}$ be a cochain map, and suppose a supported extension has graded form $\mathcal{L} \oplus J$ and differential

$$d(a, s) = (d_{\mathcal{L}} a, d_J s + Ra), \qquad d_J R + R d_{\mathcal{L}} = 0.$$

Its pullback along W has the actual differential

$$E_W = C \oplus J, \qquad d(c, s) = (d_C c, d_J s + RWc).$$

The map $(c, s) \mapsto (Wc, s)$ is a cochain map because $d_J RW + RW d_C = 0$. A map to the localized component alone omits this term.

With two independent normals, the localization complex has both faces and their corner:

$$S \longrightarrow S[f^{-1}] \oplus S[g^{-1}] \longrightarrow S[(fg)^{-1}], \qquad d_0(a) = (a, a), \quad d_1(b, c) = c - b.$$

The sign makes $d_1 d_0 = 0$ and determines the corresponding connecting signs in the supported extension.

The maps ε, j_Γ and the supported dual functional now have different, explicit meanings. An independently specified geometric coefficient recipient must still receive a map from $\mathcal{P}_\Gamma$ preserving the required excess representation, tangent connection and vacuum density. For noninvertible root substitutions, it must give the transfer or supported correspondence and its action on the changing excess. Compatibility is required with successive substitutions, regular/localized/supported triangles and field attachments.

The variable equation map and (14.14) are concrete tests. The ordinary target cannot satisfy the excess requirement. The constructed derived coefficient target meets it for the constant equation and invertible coordinate operations above.

14.7 The analytic Green difference equation

Let $q > 1$ and let $Z(t)$ be rational with $Z(0) = 1$. The product

$$K(t) = \prod_{j \geq 1} Z(q^{-j} t)$$

defines a meromorphic function on $\mathbb{C}$, regular at zero with $K(0) = 1$. On a compact set, its tail factors are $1 + O(q^{-j})$ uniformly. Sufficiently far along the tail they have neither zeros nor poles. The product and its derivatives therefore converge normally there. The finite initial product is rational.

Reindexing gives $K(qt) = Z(t)K(t)$. The normalized holomorphic solution near zero is unique: the quotient of two such solutions has $H(qt) = H(t)$, and each positive-degree Taylor coefficient is killed by $q^n - 1$. For torsion Hall data this is the analytic function with formal expansion K_G.

Let $D_Z \subset \mathbb{C}^\times$ be the finite set of zeros and poles of Z, and put $U = \mathbb{C}^\times \setminus q^{\mathbb{Z}} D_Z$. Define

$$Z_n(t) = \begin{cases} \prod_{j=0}^{n-1} Z(q^j t), & n > 0, \\ 1, & n = 0, \\ \prod_{j=n}^{-1} Z(q^j t)^{-1}, & n < 0. \end{cases}$$

Then $Z_{m+n}(t) = Z_m(q^n t) Z_n(t)$. These factors also define the rank-one rational difference module with relation $\sigma e = Z(t)e$, where $\sigma f(t) = f(qt)\sigma$. Evaluation $e \mapsto K$ is a solution in meromorphic functions.

Proposition 14.7.1. The action $(t, v) \mapsto (q^n t, Z_n(t)v)$ descends the trivial line on U to a holomorphic line on $U/q^{\mathbb{Z}}$. The connection $d - d \log K$ descends with it, and K is a nowhere-zero horizontal section. For $Z(t) = ((1 - t)(1 - qt))^{-1}$ this analytic trivialization cannot be obtained from a rational function.

Proof. The action of $q^{\mathbb{Z}}$ on $\mathbb{C}^\times$ is free and properly discontinuous: logarithmic radius changes by $\log q$. Its zero/pole orbits are locally finite. Every Z_n is a holomorphic unit on U, so the cocycle gives transition isomorphisms. In logarithmic coordinates the quotient is $\mathbb{C}/(2\pi i \mathbb{Z} + \log q\, \mathbb{Z})$ with finitely many points removed.

The difference equation gives $q^*(d \log K) = d \log K + d \log Z$, the connection transformation. The product has no zeros or poles on U, and the same equation makes K the stated section.

If a rational R satisfied $R(qt)/R(t) = Z(t)$, write $r_b = \operatorname{ord}_b R$. The divisor of its ratio has order $r_{qb} - r_b$ at b. Its sum on each nonzero q-orbit is zero because the divisor of R has finite support. For the displayed Z, the orbit $q^{\mathbb{Z}}$ instead has two simple poles, at $1, q^{-1}$, and no zeros. Its sum is -2, a contradiction. □

Thus this line with connection is analytically trivial on the punctured elliptic quotient. The rational difference equation has not produced nontrivial monodromy there. Nor is the quotient by $q^{\mathbb{Z}}$ a quotient by every Frobenius ratio: a larger gain group need not act properly discontinuously.

Between polynomial Hall states, any finite product of the native Green half-vertices has a matrix element equal to a finite Laurent polynomial times factors $K(w/z)$. Normal ordering gives one factor for each annihilation–creation pair. The remaining matrix element is finite because its two test states have finite weight. The product construction continues these expressions meromorphically away from their locally finite pole divisors. Both bracketings give the same expression, proving associativity on these matrix elements. This domain statement asserts no boundedness of an unsmeared half-vertex on the entire Green Hilbert space.

14.8 HALL MASS AND POSITIVE STATES

Put $h_m = \sum_{|\lambda|=m} u_\lambda$, $h_0 = 1$, and $\mathcal{H}_Q(t) = \sum_{m\ge 0} h_m t^m$. The group-like Hall series satisfies

$$\mathcal{H}_Q(t) = \exp\left(\sum_{r\ge 1} \frac{p_r t^r}{r}\right). \tag{14.15}$$

Indeed the coefficient of $u_M \otimes u_N$ in $\Delta \sum_L u_L$ is

$$\sum_L \frac{a_M a_N}{a_L} F^L_{M,N} = \frac{|\operatorname{Ext}^1(M,N)|}{|\operatorname{Hom}(M,N)|} = 1.$$

The first equality is orbit–stabilizer for extension classes, and the last uses the zero torsion Euler form. Hence $\mathcal{H}_Q$ is group-like and its logarithm is primitive. In degree r it is a multiple of p_r.

Its indecomposable coefficient is $\sum_{j=1}^{r} (-1)^{j-1}\binom{r-1}{j-1}/j = 1/r$: each composition of r gives the unique corresponding flag in the indecomposable module. The normalization of p_r proves (14.15).

In the nonnegative weight completion set

$$v_s = \prod_x \mathcal{H}_{q^{d_x}}(s^{d_x}) = \sum_{[M]} s^{\deg M} u_M, \qquad \deg M = \sum_x d_x \operatorname{length} M_x.$$

The sum ranges over finite-support torsion objects. Their Green squared norm is a_M^{-1}.

THEOREM 14.8.1. Suppose $N_n \le C_0 q^n$. For $0 \le r < 1$,

$$K_G(r) = \sum_{[M]} \frac{r^{\deg M}}{a_M} = \exp\left(\sum_{n\ge 1} \frac{N_n r^n}{n(q^n-1)}\right) < \infty.$$

Thus v_s belongs to the Green Hilbert completion for $|s|^2 = r < 1$, with squared norm $K_G(r)$. For $0 < r < 1$ the weights $\mu_r(M) = r^{\deg M}/(a_M K_G(r))$ form a probability measure. For $0 < r < q^{-1}$,

$$\frac{\mu_{qr}(M)}{\mu_r(M)} = \frac{q^{\deg M}}{Z_C(r)}, \qquad \mathbb{E}_{\mu_r}[q^{\deg M}] = Z_C(r). \tag{14.16}$$

Proof. The factorial primitive norms give

$$\|\mathcal{H}_Q(s)\|_G^2 = \exp\left(\sum_{r\ge 1} \frac{|s|^{2r}}{r(Q^r-1)}\right).$$

Multiply over the closed points and write $n = rd_x$. The resulting logarithm is the one in the theorem. The growth assumption bounds its summands by a constant times r^n/n, so it converges for $r < 1$. Orthogonality in the Hall basis gives the mass sum. At real nonnegative r, partial products and partial sums increase to their common finite limit.

For $r < q^{-1}$, both series converge. Subtracting their logarithms gives

$$\frac{K_G(qr)}{K_G(r)} = Z_C(r).$$

Substitution into the two densities proves their likelihood ratio. Summing proves the expectation. □

A finite map $C \to \mathbb{P}^1$ gives the required growth bound by bounding every geometric fiber by its degree. This argument uses no spectral purity. At $r = 0$ the measure is concentrated on the zero object.

Local independence and finite support

Write $K_x(r) = \sum_\lambda r^{d_x|\lambda|}/a_\lambda(q^{d_x})$. The local measures $r^{d_x|\lambda|}/(a_\lambda K_x(r))$ are independent and their product gives μ_r. It introduces no infinite-support objects almost surely, since

$$\sum_x \Pr(M_x \ne 0) = \sum_x (1 - K_x(r)^{-1}) \le \sum_x \log K_x(r) = \log K_G(r) < \infty.$$

The first Borel–Cantelli lemma leaves only finitely many nonzero local factors almost surely. Independence is present in the construction, though this last implication does not require it.

The unit vector $\Psi_s = K_G(|s|^2)^{-1/2} v_s$ defines

$$\omega_s(P) = \langle \Psi_s, P\Psi_s\rangle_G$$

on finite polynomials in finitely many creators and Green annihilators. Every selected mode has a finite coherent parameter, so every such moment exists. The mean is

$$D_{x,m} v_s = \frac{s^{md_x}}{q^{md_x}-1} v_s.$$

Normal ordering gives all correlations from this mean and the unchanged Green commutators. In particular $\omega_s(P^{*G}P) \ge 0$. Infinite smearings require their own test functions and convergence domain.

The degree Hamiltonian and the ordinary trace

Let $L_0 u_M = (\deg M) u_M$ with its closed self-adjoint domain, specified by square summability after multiplication by $\deg M$. Its nonnegative integer eigenvalues have the finite Hall weight multiplicities. Equation (14.16) becomes the quadratic-form expectation

$$\|q^{L_0/2}\Psi_s\|_G^2 = Z_C(|s|^2), \qquad q|s|^2 < 1.$$

This requires the form domain of q^{L_0}. Membership in the smaller operator domain has not been assumed. The degree spectrum has been specified independently of zeta zeros.

The ordinary Gibbs trace instead counts orthonormal states once:

$$\operatorname{Tr}_{\mathcal{F}_C}(e^{-\beta L_\circ}) = \prod_{x,r\geq 1}(1-e^{-\beta r d_x})^{-1} = \prod_{r\geq 1} Z_C(e^{-\beta r}), \qquad \beta > \log q.$$

Its logarithm is $\sum_{n\geq 1} N_n/[n(e^{\beta n}-1)]$, which converges under the growth assumption. The Gibbs density is positive and trace class. In contrast, $K_G(r) = \prod_{j\geq 1} Z_C(q^{-j}r)$ is the automorphism-weighted mass and the norm of a coherent vector. The Green norm of the unnormalized basis does not insert automorphism weights into the ordinary trace. Neither positive functional has been identified with the complete signed Weil functional.

A stochastic extension product

For fixed torsion objects M, N, choose an extension class uniformly in $\operatorname{Ext}^1(M,N)$. Its middle term has law

$$P(L \mid M,N) = \frac{|\operatorname{Ext}^1(M,N)_L|}{|\operatorname{Ext}^1(M,N)|} = \frac{a_M a_N}{a_L} F^L_{M,N}.$$

The weights sum to one because the torsion Euler form is zero. In the rescaled basis $v_M = a_M u_M$, Hall multiplication reads $v_M v_N = \sum_L P(L \mid M,N) v_L$. Consequently

$$\sum_L P(L \mid M,N)P(K \mid L,P) = \sum_L P(L \mid N,P)P(K \mid M,L).$$

Both sides are $a_M a_N a_P / a_K$ times the same three-step flag count. Higher regroupings are the same higher flag counts, so this gives all finite stochastic associativity identities. An enhanced primitive object still requires its cochain or sheaf-level comparison.

14.9 Prime-indexed Macdonald and Hall constructions

The decomposition by closed points suggests a comparison with symmetric functions at each prime. This construction has two independent choices: the set of tensor factors and the parameters inside each factor. A single pair of parameters cannot equal several distinct pairs simultaneously. This elementary fact does not prohibit a family of Macdonald spaces or a map of their underlying algebras. The relevant obstruction appears only after specifying which gradings and operations the map must preserve.

Pairings and the degree obstruction

Let $K = \mathbb{Q}(q_p, t_p : p \text{ prime})$ be the field of rational functions in algebraically independent variables q_p, t_p. Each rational function involves finitely many variables. Put $\Lambda_{(p)} = K[p_1^{(p)}, p_2^{(p)}, \dots]$, with $\deg p_r^{(p)} = r$. For a partition λ, let $m_r(\lambda)$ be the number of parts equal to r, and set

$$p_\lambda^{(p)} = \prod_r (p_r^{(p)})^{m_r(\lambda)}, \qquad z_\lambda = \prod_r r^{m_r(\lambda)} m_r(\lambda)!.$$

Definition 14.9.1 *(Macdonald pairing).* The symmetric bilinear form on $\Lambda_{(p)}$ is specified by

$$\langle p_\lambda^{(p)}, p_\mu^{(p)} \rangle_p = \delta_{\lambda\mu} z_\lambda \prod_{j=1}^{\ell(\lambda)} \frac{1-q_p^{\lambda_j}}{1-t_p^{\lambda_j}}.$$

This is the normalization of Macdonald, *Symmetric Functions and Hall Polynomials*, VI, equation (1.5).

Definition 14.9.2. Define

$$\Lambda^{\mathrm{prim}} = \bigotimes_{p}{}' \Lambda_{(p)} = K[p_r^{(p)} : p \text{ prime},\ r \geq 1].$$

The prime denotes the algebraic tensor product with unit 1 in all but finitely many factors. Give it the tensor product pairing and total degree $\deg p_r^{(p)} = r$.

The form is nondegenerate. Every polynomial lies in a finite tensor product, where its power-sum monomials have nonzero diagonal norms. For real parameters $0 < q_p, t_p < 1$, the same diagonal formula defines a positive Hermitian form on the complex polynomial space, with conjugation in the first argument. Positivity holds for every finite linear combination. It requires no infinite tensor product completion.

Proposition 14.9.3. Let $\Lambda = K[p_1, p_2, \ldots]$, graded by $\deg p_r = r$. A tensor product of two or more $\Lambda_{(p)}$ admits no injective degree-preserving K-linear map to Λ. After forgetting degree, Λ^{prim} and Λ are isomorphic as K-algebras.

Proof. The degree-one space of Λ has dimension one. Each retained prime contributes an independent degree-one generator to the source, proving the obstruction. For the second assertion, choose a bijection b from the pairs (p, r) to the positive integers. The assignments $p_r^{(p)} \mapsto p_{b(p,r)}$ and their inverse extend uniquely to mutually inverse polynomial algebra maps. They need not preserve degree, the pairing or any marked operator. □

Thus $q_p = p^{-s}$ and $t_p = p^{-s-1}$, for real $s > 0$, give a well-defined family of positive pairings. They do not specify one constant pair (q, t) independent of p. An arithmetic comparison must say whether it preserves these pairings and the prime labels. Parameter variation alone is not a nonexistence theorem.

Adjoints, weights and Macdonald bases

Write $c_{p,r} = (1 - q_p^r)/(1 - t_p^r)$. Let $M_{p,r}$ denote multiplication by $p_r^{(p)}$. Its adjoint is

$$D_{p,r} = r c_{p,r} \partial_{p_r^{(p)}}, \qquad [D_{p,r}, M_{\ell,s}] = \delta_{p\ell}\delta_{rs} r c_{p,r} I.$$

Indeed, the squared norm of $(p_r^{(p)})^m$ is $m!(r c_{p,r})^m$. Comparing consecutive norms proves adjunction. This also identifies exactly which coefficient changes when the pairing changes.

Proposition 14.9.4. At $t_p = q_p$, one has $c_{p,r} = 1$. Along $t_p = q_p^2$,

$$c_{p,r} = \frac{1}{1 + q_p^r} \longrightarrow 1 \quad \text{as } q_p \longrightarrow 0.$$

Both give the ordinary Heisenberg squared norm r for $p_r^{(p)}$ in the stated specialization or limit. For any positive numbers w_p, replacing $c_{p,r}$ by w_p^r defines another positive form, with

$$\|p_\lambda^{(p)}\|^2 = z_\lambda w_p^{|\lambda|}.$$

Proof. The two formulas for $c_{p,r}$ follow by cancellation. Every power-sum monomial then has the claimed factorial norm. All its factors are positive in the weighted form. □

The choice $w_p = \log p$ yields $\|p_r^{(p)}\|^2 = r(\log p)^r$. It is extra metric data. Over the real numbers, the map $p_r^{(p)} \mapsto w_p^{r/2} p_r^{(p)}$ is an algebra isometry from this weighted space to the ordinary Hall inner-product space. It need not commute with the usual translation $T\,p_r^{(p)} = r\,p_{r+1}^{(p)}$: its two orders of application give factors $w_p^{r/2}$ and $w_p^{(r+1)/2}$. A conformal comparison must also transport translation and the chosen conformal vector.

Example 14.9.5. In the ordinary Heisenberg pairing, $p_r^{(p)}/\sqrt{r}$ has norm one. This is a statement about a Fock vector. For adjacency on the $(p+1)$-regular tree, the root spectral measure instead has moments

$$\int x^2\,d\nu_p = p+1, \qquad \int x^4\,d\nu_p = (p+1)(2p+1).$$

There are $p+1$ two-step returns. A four-step return either returns at step two, giving $(p+1)^2$ paths, or first reaches distance two, giving $(p+1)p$ paths. Odd moments vanish because the tree is bipartite. These state moments differ from the norms of individual power-sum vectors. Their Hecke recurrence is the one in Proposition 13.5.3.

The tensor product basis

Let m_λ be the monomial symmetric function. In dominance order, $\mu \le \lambda$ means $\sum_{i\le j}\mu_i \le \sum_{i\le j}\lambda_i$ for every j, with equal total size. Macdonald's theorem, VI (4.7), gives the unique orthogonal basis $P_\lambda(x;q,t)$ over $\mathbb{Q}(q,t)$ which is monic triangular in m_λ for this order. At specialized parameters the coefficients must remain defined.

Definition 14.9.6. For a family of partitions with finite support, put

$$P^{\mathrm{arith}}_{(\lambda_p)} = \bigotimes_p{}' P_{\lambda_p}(x^{(p)};q_p,t_p), \qquad P_\varnothing = 1.$$

These tensors form an orthogonal K-basis. Both expansion and linear independence reduce to a finite set of prime factors. For two primes, the degree-two basis consists of

$$P_{(2)}\otimes 1,\quad P_{(1,1)}\otimes 1,\quad P_{(1)}\otimes P_{(1)},$$
$$1\otimes P_{(2)},\quad 1\otimes P_{(1,1)}.$$

A single symmetric-function space has degree-two dimension two, with basis p_2, p_1^2. Symmetric polynomials in two variables also have dimension two in that degree. The three ordinary monomials x_1^2, x_1x_2, x_2^2 belong to the full polynomial space, whose symmetric subspace has basis $x_1^2+x_2^2$, x_1x_2.

DAHA and its geometric comparisons

The double affine Hecke algebra, abbreviated DAHA, acts on a fixed number of Laurent variables. This number is independent of the set of primes indexing a tensor product. The distinction can be seen directly in its polynomial representation.

Theorem 14.9.7 *(Polynomial representation).* Over $K_0 = \mathbb{Q}(q^{1/2}, t^{1/2})$, the DAHA of type GL_n has a faithful representation on $K_0[x_1^{\pm 1}, \dots, x_n^{\pm 1}]$. In the convention of Schiffmann–Vasserot, arXiv:0905.2555, section 1.4, its operators are

$$\begin{aligned} X_i &= x_i, \\ T_i &= t^{1/2} s_i + \frac{t^{-1/2} - t^{1/2}}{x_i/x_{i+1} - 1}(s_i - 1), \\ Y_i &= T_i \cdots T_{n-1} \omega T_1^{-1} \cdots T_{i-1}^{-1}. \end{aligned}$$

Here s_i exchanges x_i, x_{i+1}, $\partial_i f(x) = f(x_1, \dots, qx_i, \dots, x_n)$ and $\omega = s_{n-1} \cdots s_1 \partial_1$. The spherical subalgebra is $e\mathbb{H}_n e$, where e is the normalized finite Hecke symmetrizer.

This is the standard faithful polynomial representation theorem. The displayed divided difference preserves Laurent polynomials, since $(s_i - 1)f$ is divisible by $x_i - x_{i+1}$. On symmetric polynomials the first spherical operator becomes

$$\sum_{i=1}^{n} \left(\prod_{j \neq i} \frac{t^{-1/2} x_i - t^{1/2} x_j}{x_i - x_j} \right) \partial_i .$$

Its eigenvectors are $P_\lambda(x; q, t^{-1})$, in this convention, with eigenvalues $t^{-(n-1)/2} \sum_i q^{\lambda_i} t^{i-1}$. The inverse in the second Macdonald parameter is part of the normalization.

Remark 14.9.8. The Weyl group acts inside each alphabet. Adams operations can also be defined factor by factor by $\psi_m(p_r^{(p)}) = p_{mr}^{(p)}$, fixing the coefficient field. Operators on distinct tensor factors commute. These definitions pose no incompatibility between prime labels and DAHA rank. An intertwiner between the two operator families remains additional data, as does a geometric interpretation of the factorwise Adams operations.

Two geometric results specify which Hall algebra enters this comparison. Let $T = (\mathbb{C}^\times)^2$ act on the affine plane, and let $L = \bigoplus_{n \geq 0} K_T(\mathrm{Hilb}^n \mathbb{A}^2)$ with equivariant parameters localized to their fraction field. Let H be the convolution algebra generated by the tautological line-bundle powers on adjacent nested Hilbert schemes and the Adams operations of the tautological bundles.

Theorem 14.9.9 *(Schiffmann–Vasserot).* In arXiv:0905.2555, Theorem 3.1 identifies H with the central specialization $\mathcal{E}_c$ of the elliptic Hall algebra at $c = (1, q^{1/2} t^{1/2})$. Its representation on L is the standard symmetric-function representation.

The stable centrally extended degenerate spherical DAHA SH^c of arXiv:1202.2756 has an integral form at $\kappa = 1$. For its specialization SH_1^c, Theorem F.10 gives

$$\mathrm{SH}_1^c \cong U(W_{1+\infty}) \otimes_{\mathbb{C}} \mathbb{C}[c_1, c_2, \dots].$$

Here $W_{1+\infty}$ is the universal central extension of the Lie algebra of regular differential operators on the circle.

The second construction uses the degeneration $q, t \longrightarrow 1$ with $t = q^{-\kappa}$, together with its integral form and central parameters. Its result is an enveloping algebra. A bare substitution $q = 1$ in a rational shuffle formula does not specify this degeneration. Neither geometric theorem constructs the arithmetic Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$.

A rational shuffle construction

One can construct a prime-indexed shuffle algebra without making the geometric identification. In the field K above, put

$$\omega_p(x, y) = \frac{(1 - q_p x/y)(1 - t_p^{-1} x/y)}{(1 - x/y)(1 - q_p t_p^{-1} x/y)}.$$

For $n \geq 0$, let $\mathscr{S}_{p,n} = K(x_1, \ldots, x_n)^{S_n}$, with $\mathscr{S}_{p,0} = K$. For symmetric rational functions $f \in \mathscr{S}_{p,r}$ and $g \in \mathscr{S}_{p,s}$, define

$$(f * g)(x_1, \ldots, x_{r+s}) = \sum_{\substack{I \sqcup J = \{1,\ldots,r+s\} \\ |I| = r}} f(x_I) g(x_J) \prod_{i \in I,\, j \in J} \omega_p(x_i, x_j).$$

This is the sum over subsets, with no factorial normalization.

Definition 14.9.10. Set $\mathscr{S}_p = \bigoplus_{n \geq 0} \mathscr{S}_{p,n}$ and $\mathscr{S}^{\mathrm{prim}} = \bigotimes'_p \mathscr{S}_p$, with unit 1 in degree zero. Separately, a specified family of spherical elliptic Hall algebras $\mathrm{SH}(q_p, t_p)$ defines

$$\mathbb{H}^{\mathrm{arith}} = \bigotimes_p{}' \mathrm{SH}(q_p, t_p).$$

All factors are extended to the common coefficient field.

PROPOSITION 14.9.11. The displayed shuffle product is associative and unital. In $\mathscr{S}^{\mathrm{prim}}$, factors at distinct primes commute, and their cross-prime shuffle coefficient is one. The same commutation holds in $\mathbb{H}^{\mathrm{arith}}$ by its tensor product definition.

Proof. Both orders of a triple shuffle sum over ordered decompositions $I \sqcup J \sqcup L$. Their summand is $f(x_I) g(x_J) h(x_L)$ times the kernels for $I \times J$, $I \times L$ and $J \times L$. Each pair occurs once in both expressions. The scalar kernels commute, proving associativity. The empty block proves the unit law. Multiplication in distinct tensor factors introduces no kernel. □

This proves a property of the specified tensor product. It does not forbid other arithmetic constructions with cross-prime operations. Identifying a shuffle subalgebra with a positive elliptic Hall half requires its presentation and wheel conditions. Recovering the full algebra also requires the negative and Cartan parts and their relations. Associativity of the rational kernel alone proves none of these identifications.

PROPOSITION 14.9.12. The algebraic prime tensor space carries the nondegenerate Macdonald pairing, the tensor Macdonald basis and the factorwise Adams operations above. Its independent parameters are compatible with a prime-indexed family of shuffle or spherical Hall algebras. For the rational shuffle construction, there are no mixed-prime coefficients beyond tensor multiplication.

Proof. Each tensor and each operation uses finitely many factors. Nondegeneracy and the basis assertion reduce to those factors. The Adams substitutions preserve polynomial multiplication and satisfy $\psi_m \psi_n = \psi_{mn}$. The final assertion is Proposition 14.9.11. □

An arithmetic realization must still construct a map to the Hochschild trace carrier and state which operators, pairing, grading and trace functional it preserves. The polynomial space and its prime labels supply a possible domain for such a map. They do not identify its target.

14.10 A geometric Hall kernel on finite differential jets

The curve construction uses a finite field cardinality q. The following example uses a separate nilpotent parameter ϵ. It compares the equivariant cohomological Hall algebra of the three-loop quiver with *zero potential* to an explicitly constructed field algebra on differential jets. The critical algebra for $\mathrm{Tr}(Z[X,Y])$ has different coefficients and requires a further oriented map.

Let $k = \mathbb{Q}(a,b)$, $h = a + b$, and $R_N = k[\epsilon]/(\epsilon^N)$, $N \geq 1$. Give the three arrows weights $\epsilon a, \epsilon b, -\epsilon h$. This is a base change of the two-dimensional equivariant parameter ring. It inverts neither ϵ nor $h\epsilon$. Put

$$\begin{aligned} \ell &= \epsilon h, & P(s) &= s^2 - \ell^2, \\ K_{\mathrm{o}}(s) &= \frac{(s+\epsilon a)(s+\epsilon b)(s-\ell)}{s}, & E_{\mathrm{o}}(s) &= K_{\mathrm{o}}(s)^{-1}, \\ E_{\mathrm{pl}}(s) &= \frac{s(s+\ell)}{(s+\epsilon a)(s+\epsilon b)}, & r(s) &= \frac{E_{\mathrm{pl}}(s)}{E_{\mathrm{pl}}(-s)}. \end{aligned}$$

Then $E_{\mathrm{o}} = E_{\mathrm{pl}}/P$ and $E_{\mathrm{o}}(s)/E_{\mathrm{o}}(-s) = r(s)$. Expand in ϵ first, with the indicated spectral variable inverted.

The charge-d coefficient algebra is $A_d = R_N[x_1, \dots, x_d]^{\mathfrak{S}_d}$. The representation space before base change is $\mathrm{End}(\mathbb{C}^d)^3$. Its equivariant cohomology has this polynomial description.

The invariant-subspace correspondence gives

$$(F * G)(X) = \sum_{\substack{I \sqcup J = [d+e] \\ |I| = d}} F(X_I)\, G(X_J) \prod_{i \in I,\, j \in J} K_{\mathrm{o}}(x_j - x_i). \tag{14.17}$$

There is no factorial divisor in this proper flag pushforward.

At a coordinate flag, the three moving arrow Euler factors are $y - x + \epsilon a$, $y - x + \epsilon b$, $y - x - \ell$. The flag tangent factor is $y - x$. Their ratio is K_{o}. This is the shuffle calculation of Theorem 12.8.1 with these weights.

Proposition 14.10.1. The product (14.17) is polynomial and associative. Its inverse-Euler spectral coefficient map is

$$\Delta^{\mathrm{o}}_{d,e}(s)F = \prod_{i,j} E_{\mathrm{o}}(s + y_j - x_i)\, F(x - s, y) \in (A_d \otimes_{R_N} A_e)((s^{-1})). \tag{14.18}$$

It is rationally coassociative. In charge split $(1,1)$,

$$1 * 1 = 2\big((y-x)^2 + \epsilon^2(ab - h^2)\big), \qquad \Delta^{\mathrm{o}}_{1,1}(s)1 = E_{\mathrm{o}}(s + y - x).$$

Proof. Proper pushforward is defined before equivariant localization, so the shuffle sum is polynomial. Directly, residues on each possible root diagonal cancel between the two flags exchanged there. Either bracketing of three factors sums over the same ordered three-block partitions with one K_{o} per ordered cross-block pair. This proves associativity with the displayed normalization.

The inverse Euler factors and translation of the first block give (14.18). For a triple split, both composites have one factor for each pair, at parameters $s, t, s+t$, and evaluate the input at $(x - s - t, y - t, z)$. They agree before Laurent expansion. Finally $K_{\mathrm{o}}(v) + K_{\mathrm{o}}(-v)$ gives the displayed product in charge two. □

With roots and ϵ of degree two, a root polynomial of degree m in charge d has shifted Hall degree $2m - 2d^2$. The product is homogeneous and all charges have even parity. This grading is distinct from the cochain grading, which places the differential Hopf states below in degree zero.

There are two reasons to change the polynomial carrier before constructing these fields. Before nilpotent base change, take the three arrow weights to be 1, 1, -2. Then

$$r(s) = \frac{(s+2)(s-1)^2}{(s-2)(s+1)^2}, \qquad \operatorname{Res}_{s=2} r(s)\, ds = \frac{4}{9}.$$

Its expansion has an infinite nonzero tail. A coefficientwise injective marking preserves that tail. Thus the unchanged exchange cannot become a finite Laurent polynomial on the same pair of states. Completing only the charge grading leaves this charge-two obstruction unchanged, and a modification supported only at $s = 0$ cannot cancel the pole at $s = 2$.

Also, if $T^M a = 0$ and $Y(Ta, z)b = \partial_z Y(a, z)b$, then $\partial_z^M Y(a, z)b = 0$. Over a $\mathbb{Q}$-algebra the falling factorial of a negative integer is a unit. A lower-truncated Laurent series with this property is therefore a polynomial of degree less than M. The root derivative $-\sum_i \partial_{x_i}$ is locally nilpotent on A_d. Finite jets reverse this behavior: the transpose derivative raises jet order.

A difference primitive and its Hopf form

We first realize the normalized factor E_{pl}. There is a unique formal series $F(z) \in (\epsilon/z)k[[\epsilon/z]]$ satisfying

$$F(z - \ell) - F(z) = \log E_{\mathrm{pl}}(-z).$$

To prove it, write $t = \epsilon/z$, $F = \sum_{n\geq 1} f_n t^n$, and $g_j = (a^j + b^j - h^j)/j$. The right side is $\sum_{j\geq 2} g_j t^j$. Comparison of coefficients gives the recurrence

$$f_{j-1} = \frac{g_j - \sum_{n=1}^{j-2} f_n \binom{j-1}{j-n} h^{j-n}}{(j-1)h} \qquad (j \geq 2).$$

Its denominator is a unit in k, and no division by ϵ occurs. This construction uses h^{-1} and has not been specialized to $h = 0$. The identity $E_{\mathrm{pl}}(z - \ell) = E_{\mathrm{pl}}(-z)$ shows that $-F(-z)$ solves the same equation. Uniqueness makes F odd.

With $\varpi(z) = \exp F(z)$, this gives

$$\varpi(z)\varpi(-z) = 1, \qquad \frac{\varpi(z-\ell)}{\varpi(z)} = E_{\mathrm{pl}}(-z), \qquad \frac{\varpi(z)^2}{\varpi(z-\ell)\varpi(z+\ell)} = r(z). \tag{14.19}$$

For example, $F(z) = -(ab/h)\epsilon z^{-1} + (a^2b^2/(6h))\epsilon^3 z^{-3} + O(\epsilon^5)$. Reduce all these series modulo ϵ^N.

Take the commutative, cocommutative Hopf algebra

$$H_N = R_N[g, g^{-1}, b_0, b_1, \ldots],$$

where g is group-like, the b_i are primitive, $\varepsilon(g) = 1, \varepsilon(b_i) = 0, Sg = g^{-1}$ and $Sb_i = -b_i$. The derivation $T_H g = g b_0, T_H b_i = b_{i+1}$ is also a coderivation and satisfies $\varepsilon T_H = 0$. Every algebraic coproduct is finite.

For integers m, n and finite lists of formal variables u_i, v_j, define a bilinear form by differentiation at zero in those variables:

$$\rho_z^H\left(g^m e^{\sum_i u_i b_i}, g^n e^{\sum_j v_j b_j}\right) = \exp B_z^H,$$
$$B_z^H = mnF + n\sum_i u_i F^{(i+1)} + m\sum_j (-1)^{j+1} v_j F^{(j+1)} + \sum_{i,j} (-1)^{j+1} u_i v_j F^{(i+j+2)}.$$

Here $F^{(i)} = \partial_z^i F$. Differentiation, rather than an unnormalized coefficient, specifies the factorial convention on monomials. Every coefficient of B_z^H is divisible by ϵ, so the form has values in $R_N[z, z^{-1}]$, including on negative powers of g.

The identities needed below can be stated explicitly. For a Hopf algebra with translation T, write $a(z) = e^{zT} a$, and sum over coproduct subscripts. They are

$$\begin{aligned} \rho_z(1, a) &= \varepsilon(a) = \rho_z(a, 1), \\ \rho_z(ab, c) &= \rho_z(a, c_1)\rho_z(b, c_2), \\ \rho_z(a, bc) &= \rho_z(a_1, c)\rho_z(a_2, b), \\ \rho_z(a_1, b_1)a_2(z)b_2 &= b_1 a_1(z)\rho_z(a_2, b_2), \\ \rho_z(Ta, b) &= \partial_z \rho_z(a, b) = -\rho_z(a, Tb), \\ \rho_z(a_1, b_1)\rho_{-z}(b_2, a_2) &= \varepsilon(a)\varepsilon(b). \end{aligned} \tag{14.20}$$

The form ρ^H satisfies all six. The formal exponential inputs are group-like, and B_z^H is additive in each input list. This proves the two multiplicativities after differentiation. A zero list gives the unit rule.

Commutativity and cocommutativity give the fourth identity. The first-input translation rule on (g, g) is

$$\rho_z^H(T_H g, g) = \varpi F' = \varpi'.$$

The second-input derivative has the opposite sign. On the b_i, it follows by differentiating the displayed entries. Derivation and coderivation extend it to products and inverses.

Finally $F^{(i)}(-z) = (-1)^{i+1} F^{(i)}(z)$ makes the two exponents cancel when inputs are exchanged and z is replaced by $-z$. This proves the last, convolution identity.

Restoring the even Euler factor

The factor P^{-1} in E_0 changes the contraction while canceling from the exchange. To retain it, use a second commutative, cocommutative Hopf algebra

$$B_N = R_N[U, U^{-1}, V, V^{-1}, c_{\alpha,i} : \alpha = 1, 2,\ i \geq 0].$$

Let $g_1 = U$, $g_2 = V$ be group-like and the $c_{\alpha,i}$ primitive. Set $T_B g_\alpha = g_\alpha c_{\alpha,0}$, $T_B c_{\alpha,i} = c_{\alpha,i+1}$, with the corresponding group-like and primitive antipodes and counits. Write $J = \left(\begin{smallmatrix} 0 & -1 \\ 1 & 0 \end{smallmatrix}\right)$ and $L(z) = P'(z)/P(z)$.

The form is specified by

$$\begin{aligned}\rho^B_z(g_\alpha, g_\beta) &= P(z)^{J_{\alpha\beta}},\\ \rho^B_z(c_{\alpha,i}, g_\beta) &= J_{\alpha\beta}L^{(i)}(z),\\ \rho^B_z(g_\alpha, c_{\beta,j}) &= (-1)^{j+1}J_{\alpha\beta}L^{(j)}(z),\\ \rho^B_z(c_{\alpha,i}, c_{\beta,j}) &= (-1)^{j+1}J_{\alpha\beta}L^{(i+j+1)}(z).\end{aligned}$$

Precisely, its value on $g^m e^{\sum p_{\alpha,i}c_{\alpha,i}}$ and $g^n e^{\sum q_{\beta,j}c_{\beta,j}}$ is $P^{m^t Jn}\exp B^B_z$. Here $m, n \in \mathbb{Z}^2$, $g^m = U^{m_1}V^{m_2}$, and the auxiliary variable lists are finite. Set

$$B^B_z = \sum_{\alpha,\beta} J_{\alpha\beta}\Big(n_\beta \sum_i p_{\alpha,i}L^{(i)} + m_\alpha \sum_j (-1)^{j+1}q_{\beta,j}L^{(j)} + \sum_{i,j}(-1)^{j+1}p_{\alpha,i}q_{\beta,j}L^{(i+j+1)}\Big).$$

Again differentiate in the auxiliary variables at zero. For each coefficient only finitely many exponential terms contribute. Integral powers of P and derivatives of L are finite Laurent polynomials modulo ϵ^N.

This form also satisfies (14.20). Additivity of B^B and bilinearity of $m^t Jn$ prove multiplicativity. Units and commutation follow as before. Translation starts from $(P^J)' = JP^J L$.

For the last identity, P is even, J is alternating, and $L^{(i)}(-z) = (-1)^{i+1}L^{(i)}(z)$. The powers of P and all exponential terms cancel under reversal. This proof does not require L to be divisible by ϵ.

The shear

$$\sigma U = UV, \quad \sigma V = V, \quad \sigma c_{1,i} = c_{1,i} + c_{2,i}, \quad \sigma c_{2,i} = c_{2,i}$$

is a Hopf automorphism commuting with T_B and preserving the form. Its matrix $A = \left(\begin{smallmatrix} 1 & 0 \\ 1 & 1 \end{smallmatrix}\right)$ satisfies $A^t JA = J$. Its inverse sends U to UV^{-1} and $c_{1,i}$ to $c_{1,i} - c_{2,i}$, fixing V and the $c_{2,i}$.

On $\widetilde{H}_N = H_N \otimes_{R_N} B_N$ take the product form, total translation T, and

$$\vartheta = e^{\ell T_H} \otimes \sigma.$$

The exponential is finite because $\ell^N = 0$. It is a Hopf automorphism preserving the form: simultaneous translation differentiates a scalar value by $\partial_z - \partial_z = 0$. Such an automorphism is the *level* used in this algebraic construction. It is additional data on the specified Hopf carrier.

Put $G = gU$, $G(v) = e^{vT}G$ and $J_m = T^m G$. The subalgebra $W^+_N = R_N[J_0, J_1, \ldots]$ is freely polynomial. After $U = V = 1$, $c_{\alpha,i} = 0$, the J_m become $T^m_H g$. Their ratios by g are triangular polynomials in $b_0, \ldots, b_{m-1}$ with coefficient one on b_{m-1}. Localization at g proves algebraic independence.

Give each J_m charge one and denote charge d by $W^+_{N,d}$. The ambient charge assigns g degree one and $U, V, b_i, c_{\alpha,i}$ degree zero. It restricts to this grading and is preserved by ϑ.

The field and its charge bounds

For any level θ preserving the form, define

$$\delta_\theta(a) = a_2 \otimes a_3 S^{-1}(\theta a_1) = a_{(0)} \otimes a_{(1)}.$$

The field and exchange on the algebraic Hopf carrier are

$$\begin{aligned}Y_\theta(a, z)b &= a_1(z)b_{(0)}\rho_{-z}(b_{(1)}, a_2),\\ \mathcal{S}_\theta(z)(a \otimes b) &= a_{(0)} \otimes b_{(0)}\rho_z(a_{(1)}, b_{(1)}).\end{aligned}$$

All sums are finite.

The unit rule gives $Y_\vartheta(1, z) = I$ and $Y_\vartheta(a, z)1 = e^{zT}a$. The translation rule and total coderivation rule for δ_ϑ give covariance. For this commutative Hopf algebra, we check the remaining field identities on group-like generating series. Auxiliary differentiation then gives them on all states.

Theorem 14.10.2. The fields at level ϑ preserve W_N^+, add creation charges, and satisfy

$$Y_\vartheta(G, z)G = E_0(-z)G(z)G, \qquad \mathcal{S}_\vartheta(z)(G \otimes G) = r(z)G \otimes G,$$

$$Y_\vartheta\Big(\prod_i G(u_i), z\Big)\prod_j G(v_j) = \prod_i G(z + u_i)\prod_j G(v_j)\prod_{i,j} E_0(-z - u_i + v_j). \tag{14.21}$$

The exchange of the two blocks multiplies by $\prod_{i,j} r(z + u_i - v_j)$. Every finite product has a common rational expansion with the field associativity and exchange identities. For charges d, e and total input jet order M, a pole bound is $2de + N - 1 + M$.

Proof. The coaction of G is $G \otimes C$, where

$$C = G\vartheta(G)^{-1} = \frac{g}{e^{\ell T_H} g}\, V^{-1}.$$

Equations (14.19) and the auxiliary form give $\rho_{-z}(C, G) = E_{\mathrm{pl}}(-z)P(z)^{-1} = E_0(-z)$ and $\rho_z(C, C) = r(z)$. The auxiliary contribution to the latter is $\rho_z^B(V^{-1}, V^{-1}) = 1$. This proves the generator formulas. Multiplicativity and translation give the block formulas. Auxiliary derivatives express every coefficient in the polynomial algebra on the J_m.

For three or more blocks, either nesting includes the same contractions between each pair of elementary generating states, with the same translated regular product. This proves weak associativity as equality of expansions of a common rational germ.

Interchanging adjacent blocks uses $r(s)E_0(-s) = E_0(s)$. Reversal uses $r(s)r(-s) = 1$. Three exchanges multiply the same scalar factors, giving the Yang–Baxter identity, and splitting a block factors the same product, giving compatibility with a field insertion.

Differentiating proves these identities on every polynomial jet input. Clearing the finitely many pairwise denominators gives the corresponding exchange locality, with a bound depending on the two inputs.

Each contraction has baseline inverse degree two. For de pairs the baseline is $2de$. Its further inverse degree equals its ϵ degree and is at most $N - 1$. Input differentiation adds at most M. This proves the stated lower Laurent bound and all required truncations. □

Modulo ϵ^4,

$$E_0(-z) = z^{-2} + (h^2 - ab)\epsilon^2 z^{-4} - abh\epsilon^3 z^{-5}, \qquad r(z) = 1 + 2abh\epsilon^3 z^{-3}.$$

The even factor changes the zeroth-order contraction from 1 to z^{-2}, while leaving the cubic exchange unchanged.

Transposing the Hall coefficient map

Let $A_d[m]$ denote homogeneous root degree m, and put $A_d^\circ = \bigoplus_m \mathrm{Hom}_{R_N}(A_d[m], R_N)$. This is the continuous dual of $\prod_m A_d[m]$ with its degree topology. Pair it with $W_{N,d}^+$ by

$$\langle J_{m_1} \cdots J_{m_d}, F\rangle = \partial_{x_1}^{m_1} \cdots \partial_{x_d}^{m_d} F\big|_{x=0}.$$

Monomial symmetric functions and unordered derivative lists pair diagonally with nonzero factorials. Hence this pairing is perfect in every degree and gives $\iota_d : \mathcal{A}_d^\circ \cong W_{N,d}^+$.

THEOREM 14.10.3. For finite-jet inputs of charges d, e,

$$Y_{\mathcal{S}}(\iota_d\alpha, z)\iota_e\beta = \iota_{d+e}\big((\Delta_{d,e}^\circ(-z))^\circ(\alpha\otimes\beta)\big).$$

The right side is defined coefficientwise on polynomial tests and lies in $W_{N,d+e}^+((z))$. Translation is $T = -D^\circ$ for $D = -\sum_i \partial_{x_i}$. The exchange is the transpose of the inverse Hall multiplier at parameter $-z$.

Proof. Pair (14.21) with F. The result is

$$\prod_{i,j} E_0(-z-u_i+v_j)F(z+u_1,\dots,z+u_d,v_1,\dots,v_e).$$

It is exactly (14.18) at $s=-z$, evaluated at $(x,y)=(u,v)$. Every finite auxiliary derivative proves the asserted equality.

For each Laurent coefficient only a finite derivative order of the polynomial test is needed, so its coefficient belongs to the restricted dual. The preceding pole bound gives a common lower bound on the fixed input. Transposing $-\partial_x$ sends the mth derivative functional to minus the $(m+1)$st one. Finally P is even, and $r(-s)^{-1} = r(s)$ gives the stated exchange variance. □

With the opposite Hall grading, $\deg(J_{m_1}\cdots J_{m_d}) = 2d^2 - 2\sum_i m_i$. Translation has degree -2, and $\deg z = 2$ makes the transpose homogeneous. Ordinary multiplication in the ambient Hopf algebra has a different charge-dependent grading. Its cochain degree remains zero.

Charge completion gives $\prod_d W_{N,d}^+$ with outputs in $\prod_d W_{N,d}^+((z))$. Each fixed total charge has finitely many splittings, but there is no uniform pole bound over all charges. The coefficient map (14.18) has not been extended to every formal root series: translation by s does not preserve the root-adic topology.

The level map on the ambient Hopf carrier is different: $(\theta_2\otimes 1)\Delta$ sends G to $\theta_2(G)\otimes G$. Both output factors have creation charge one. A Hall split has output charges adding to its input charge. Moreover $\mathcal{S}(G) = (e^{\ell T_H}g)UV$ need not lie in W_N^+.

Thus the transpose theorem identifies Hall charge cooperation with a field product on finite jets. It does not identify it with a level-adding coproduct. The corresponding field tensor, if that further comparison is sought, must retain its spectral twist and this change of charge.

14.11 Moving centers and Cartan operations

Assume $N \geq 4$ and extend the coefficients to

$$R = \mathbb{C}(a,b)[a_{\mathrm{fr}}, \beta, \beta^{-1}, y_1, y_2, \kappa, \epsilon]/(\epsilon^N), \qquad \lambda = a_{\mathrm{fr}} + \epsilon b.$$

The affine parameter κ and labels y_1, y_2 are retained independent coefficients. They are not the root coordinates of the Hall correspondence.

On polynomial Hall coefficients define the connection

$$\nabla_d = \beta\left(\partial_{a_{\mathrm{fr}}} + \sum_{i=1}^{d}\partial_{x_i}\right).$$

On a tensor product over R this is the tensor connection over the single coefficient derivation $\beta\partial_{a_{\mathrm{fr}}}$. Every kernel depends only on root differences, so the simultaneous root derivative kills it. Translation of the first block by s also commutes with this derivative. Thus both the Hall product and (14.18) are horizontal.

The coordinates $\xi_i = x_i - \lambda$ are horizontal. Completion along this moving section therefore has a continuous dual with horizontal basis

$$v_{\mathbf{m},\lambda}(F) = \partial_{x_1}^{m_1} \cdots \partial_{x_d}^{m_d} F\big|_{x_i=\lambda}.$$

Indeed the chain rule gives

$$\beta\partial_{a_{\mathrm{fr}}}\langle v_{\mathbf{m},\lambda}, F\rangle = \langle v_{\mathbf{m},\lambda}, \nabla_d F\rangle.$$

Sending this basis to $\prod_i J_{m_i}$ gives the moving-center version of the transpose theorem. Its proof evaluates F at $(\lambda + z + u, \lambda + v)$, with the same scalar kernels. The first insertion has the horizontal character $F \mapsto F(\lambda)$. On $F = x$ both sides of the horizontality identity are β.

Evaluation at a nonnilpotent λ is not a finite linear combination of derivatives at zero. These are jets at a moving section, with no implicit $e^{\lambda T}$ on the fixed algebraic state space. The state derivative T raises jet order. The coefficient connection fixes the displayed basis.

The Cartan extension of the Hall coproduct

Let $\mathsf{H} = R[\mathsf{p}_0, \mathsf{p}_1, \ldots]$ have primitive generators acting on A_d by multiplication by $\sum_i x_i^n$. These act as derivations of the Hall product, because the power sums add on concatenated root lists. Form the smash product $\mathsf{B} = (\bigoplus_d A_d)\#\mathsf{H}$ with relations $[\mathsf{p}_n, F] = (\sum_i x_i^n)F$. For a spectral variable p define

$$\Phi(p) = \exp\left(\sum_{n\ge 0} \frac{(-1)^n}{n!}\mathsf{p}_n \partial_p^n \log r(p)\right). \tag{14.22}$$

Every coefficient in p^{-1} uses finitely many p_n. On a finite root list L, substitution $\mathsf{p}_n = \sum_{l\in L} l^n$ gives $\Phi_L(p) = \prod_{l\in L} r(p-l)$. This is a root-addition current. A framed highest-weight current is further data.

Proposition 14.11.1. In the localized spectral tensor target, the formulas

$$\Delta^{\mathrm{ext}}_{d,e}(s)F = \Delta^{\circ}_{d,e}(s)F \prod_{j=1}^{e} \Phi_L(y_j + s),$$

$$\Delta^{\mathrm{ext}}(s)\mathsf{p}_n = \sum_{i=0}^{n} \binom{n}{i}(-s)^{n-i}\mathsf{p}_i \otimes 1 + 1 \otimes \mathsf{p}_n$$

give a unital algebra coproduct on B. The coefficients of each Φ_L lie in the left output factor, to the right of its Hall coefficient in the displayed product. The coproduct is rationally coassociative and horizontal when $\nabla\mathsf{p}_n = \beta n \mathsf{p}_{n-1}$ and $\nabla\mathsf{p}_0 = 0$.

Proof. For multiplicativity, split the first input into root blocks A, C and the second into B, D, with A, B in the left output. Cancellation of cross Euler factors leaves

$$\prod_{b\in B, c\in C} \frac{E_0(s + c - b)}{E_0(-s + b - c)} = \prod_{b\in B, c\in C} r(s + c - b).$$

When the separate extended coproducts are multiplied, the smash relation moves the first Cartan factor past B and replaces its list L by $L \sqcup B$. The factor changes by precisely this product. All other factors coincide. The even factor P cancels from the ratio.

The binomial formula preserves the Cartan relations with shifted roots.

Evaluation on all finite root lists is jointly faithful. At length at least the largest positive power-sum index, those power sums are algebraically independent. Varying the length tests the polynomial in p_0. This remains valid coefficientwise modulo ϵ^N. The root calculation therefore proves the algebra identity. For a triple split, both sides have Cartan factor $\Phi_L(Y+s)\Phi_L(Z+s+t)\Phi_M(Z+t)$ and the same Euler factors, proving coassociativity.

Finally differentiating (14.22) by $\nabla \mathsf{p}_n = \beta n \mathsf{p}_{n-1}$ gives $-\beta\partial_p\Phi$. It cancels the derivative $\beta\partial_{y_j}\Phi_L(y_j+s)$. The raw Euler part is horizontal, and the binomial formula commutes with the same connection. This proves horizontality on all generators. □

The Cartan operation also has a direct state realization. For $C = G\mathcal{S}(G)^{-1}$ set

$$\mathcal{U}(p)x = x_{(0)}\rho_p(C, x_{(1)}).$$

It is an invertible algebra operator with

$$\mathcal{U}(p)G(v) = r(p-v)G(v), \qquad \mathcal{U}(p)1 = 1.$$

Multiplicativity follows from the group-like C and the multiplicative coaction. C^{-1} gives its inverse. It preserves W_N^+ coefficientwise.

Pairing its products and derivatives with polynomial tests shows that multiplication by $\prod_i r(p-x_i)$ has finite-jet transpose $\mathcal{U}(p-\lambda)$ at the moving center. In particular $(\beta\partial_{a_{\mathrm{fr}}} + \beta\partial_p)\mathcal{U}(p-\lambda) = 0$.

In the Laurent domain with p large compared with z, the creation field satisfies

$$\mathcal{U}(p)Y_{\mathcal{S}}(G,z)\mathcal{U}(p)^{-1} = r(p-z)Y_{\mathcal{S}}(G,z). \tag{14.23}$$

Apply both sides to a product of $G(v_j)$. The field adds the regular factor $G(z)$ and its contractions. The Cartan operator multiplies this new factor by $r(p-z)$ and cancels its factors on the input. Differentiation proves the relation on all finite jets. At $p - z = \beta u$, the cubic coefficient is $2abh\beta^{-3}u^{-3}$.

14.12 Framing markings and the supported current

The next calculation retains a moment complex with both odd relation directions. Before localizing in a, b, use

$$R^{\circ} = \mathbb{C}[a, b, a_{\mathrm{fr}}, \beta, \beta^{-1}, y_1, y_2, \kappa, \epsilon]/(\epsilon^N), \qquad N \geq 4, \quad \lambda = a_{\mathrm{fr}} + \epsilon b, \quad c = ab(a+b).$$

Its generic base change is the ring R above.

The two odd directions occur already in a rank-two framed moment chart. Take

$$X = \begin{pmatrix} x_1 & B_0 \\ 0 & x_2 \end{pmatrix}, \quad Y = \begin{pmatrix} v_1 & D_0 \\ 0 & v_2 \end{pmatrix}, \quad i = \begin{pmatrix} i_1 \\ i_2 \end{pmatrix}, \quad j = (1, 0).$$

The four entries of $[X,Y] + ij$ are i_1, $(x_1-x_2)D_0 - (v_1-v_2)B_0$, i_2, 0. Eliminating the two regular Koszul pairs for i_1, i_2 leaves odd generators η, χ with

$$d\eta = (x_1-x_2)D_0 - (v_1-v_2)B_0, \qquad d\chi = 0.$$

The elimination is explicit: for $d\zeta = i$, the contraction sends i^m to ζi^{m-1} for $m \geq 1$. Tensor the two contractions with their Koszul signs.

On the open $B_0 \neq 0$, the change of basis $\mathrm{diag}(1, \gamma)$ preserves j and the flag. It scales B_0, D_0 by γ^{-1}, so uniquely fixes $B_0 = 1$. Derived restriction to $v_1 = v_2 = 0$ then leaves $d\eta = uD_0$, $u = x_1 - x_2$, and still $d\chi = 0$. The zero-equation generator survives the restriction.

This specifies a moment coefficient chart. Orientations for a Hall pushforward have not been supplied by the matrix calculation.

In position coordinates z, w, t, put $u = z - w$, $v = t - w$, and define

$$\mathcal{T} = \bigoplus_{p,r\geq 1} R^0[w]u^{-p}v^{-r}, \qquad \mathcal{M} = \mathcal{T}[D_0] \otimes \Lambda(\eta, \chi), \quad d\eta = uD_0, \quad d\chi = 0.$$

Here η, χ have degree -1, D_0 degree zero. Principal-part multiplication discards nonnegative powers: $u\,u^{-1} = v\,v^{-1} = 0$ in their respective factors. There is only a direct sum of normal orders.

For $\mathcal{T}_1 = \ker(u : \mathcal{T} \to \mathcal{T})$,

$$\begin{aligned} H^0(\mathcal{M}) &= \mathcal{T}, \\ H^{-1}(\mathcal{M}) &= \eta\mathcal{T}_1[D_0] \oplus \chi\mathcal{T}, \\ H^{-2}(\mathcal{M}) &= \eta\chi\mathcal{T}_1[D_0]. \end{aligned} \tag{14.24}$$

Indeed u is surjective on $\mathcal{T}$, so the image of uD_0 is $D_0\mathcal{T}[D_0]$ and its kernel is $\mathcal{T}_1[D_0]$. Tensor with the closed χ factor. The degree-zero and χ summands use $D_0 = 0$.

The required cubic contact class is

$$\gamma_N = 2c\epsilon^3\beta^{-3}u^{-3}v^{-1} \in H^0(\mathcal{M}). \tag{14.25}$$

It is nonzero: c is a non-zero-divisor in the polynomial coefficient ring and $\epsilon^3 \neq 0$ at $N \geq 4$.

The three normal coefficients of a marking

A scalar marking is an action of $R^0[\ell_{\mathrm{fr}}]$ on $\mathcal{M}$ in which ℓ_{fr} multiplies by $s(u, w) = \sum_{j\geq 0} a_j(w)u^j$, with $a_j \in R^0[w]$. Every principal part has finite u-pole order, so this action is defined without completing $\mathcal{T}$. It commutes with d. It specifies a coefficient action, not the Hopf level constructed in the preceding section.

Proposition 14.12.1. The relation $(s - \lambda)\gamma_N = 0$ holds exactly when

$$a_0 - \lambda, \quad a_1, \quad a_2 \in \epsilon^{N-3}R^0[w].$$

At all compatible precisions, the coefficientwise criterion is

$$s = \lambda + u^3h(u, w).$$

Proof. Multiplication by u^j kills u^{-3} for $j \geq 3$, and

$$(s - \lambda)\gamma_N = 2c\epsilon^3\beta^{-3}\big((a_0 - \lambda)u^{-3} + a_1u^{-2} + a_2u^{-1}\big)v^{-1}.$$

The three principal parts are independent. The annihilator of $c\epsilon^3$ is (ϵ^{N-3}), proving the criterion. At all compatible precisions, each fixed ϵ^m coefficient of these three series vanishes by taking $N > m + 3$. The converse is immediate. □

In particular an unramified normal marking, for which a_1 is a unit, cannot preserve the contact. Even $s = \lambda + \beta u$, with the correct diagonal character, leaves the defect $2c\epsilon^3\beta^{-2}u^{-2}v^{-1}$. Modulo ϵ^4 at $a = b = \beta = 1$ its coefficient is 4. The ramified marking $s = \lambda + \beta u^3$ does preserve the contact and gives the nonzero cochain map $1 \mapsto \gamma_N$ from $R^\circ[0]$ with character λ. It has different translation behavior.

Let $\nabla = \partial_w$ at fixed u, v, fixing the coefficient ring and the moment generators. It commutes with d and differentiates simultaneous translation of z, w, t. Call a marking translation-covariant with slope β when $[\nabla, m_s] = \beta I$.

THEOREM 14.12.2. Such a marking has $s = \beta w + b(u)$ with $b(u) \in R^\circ[[u]]$. For every $\lambda' \in R^\circ$, multiplication by $s - \lambda'$ is injective on every $H^i(\mathcal{M})$. Consequently a cochain map from a complex whose cohomology has character λ induces zero on cohomology if it intertwines the marking, even up to homotopy.

Proof. The commutator condition is $\partial_w s = \beta$. Coefficientwise integration in characteristic zero gives the displayed form.

On $\mathcal{T}$, take the largest u-pole of a nonzero element. Its leading coefficient is multiplied by $\beta w + b(0) - \lambda'$, a non-zero-divisor because its leading coefficient in w is the unit β. It remains nonzero.

On $\mathcal{T}_1[D_0]$, u acts by zero and the same polynomial proves injectivity. Formula (14.24) treats the closed odd factors as well.

For an intertwining map Φ, compatibility on cohomology gives $(s - \lambda)H(\Phi)(x) = H(\Phi)((\ell_{\mathrm{fr}} - \lambda)x) = 0$. Injectivity forces $H(\Phi)(x) = 0$. A compatibility homotopy gives this same equality. □

Conjugating the marking by a cochain isomorphism or adding $dH + Hd$ leaves the injectivity conclusion unchanged on cohomology. The ramified marking above has $[\nabla, m_s] = 0$, so it is outside this theorem's covariance hypothesis.

The moving framing fiber

Set

$$f = \beta(w + u) - \epsilon y_1 - \lambda, \qquad Q = \mathcal{M}/f\mathcal{M}.$$

Multiplication by f is injective on the terms and cohomology of $\mathcal{M}$: its highest w coefficient is multiplied by the unit β. Thus the ordinary quotient represents the derived framing fiber and $H^*(Q) = H^*(\mathcal{M})/fH^*(\mathcal{M})$. It eliminates w by $w = (\lambda + \epsilon y_1)/\beta - u$. In degree zero the remaining basis is $u^{-p}v^{-r}$ over R°, and $\tilde{\gamma}_N \neq 0$.

The operator $\nabla = \partial_w$ does not descend: $\nabla f = \beta$ would force $Q = 0$ if the ideal were stable. Nor can an R°-linear operator on Q have commutator βI with its marking, which is the scalar λ.

The connection

$$\nabla_{\mathrm{fr}} = \partial_w + \beta\partial_{a_{\mathrm{fr}}} \tag{14.26}$$

does descend. It annihilates f, commutes with the moment differential, and satisfies $[\nabla_{\mathrm{fr}}, m_\lambda] = \beta I$. Its coefficient rule is $\nabla_{\mathrm{fr}}(rx) = \beta(\partial_{a_{\mathrm{fr}}} r)x + r\nabla_{\mathrm{fr}}x$. This changes both the recipient and the kind of connection. It does not contradict the obstruction on the unchanged complex.

The Cauchy comparison and both odd directions

Work first over $A = R^\circ[z, w] = R^\circ[u, w]$. For the current coordinate t define

$$P_z = A[t, (t - z)^{-1}]/A[t], \qquad P_w = A[t, (t - w)^{-1}]/A[t],$$

$$P_{zw} = A[t, ((t - z)(t - w))^{-1}]/A[t], \quad \mathcal{K}_{zw} = [P_z \oplus P_w \xrightarrow{(a,b)\mapsto a-b} P_{zw}].$$

The two terms have degrees -1, 0 and use proper rational representatives at $t = \infty$. There is a relative differential-module quasi-isomorphism $\Theta : \mathcal{K}_{zw} \to \mathcal{T}[0]$, zero in degree -1. In degree zero, expand at $v = 0$, take its v-principal part, and then take its u-principal part. Explicitly,

$$\Theta\left(\frac{1}{v^a (v-u)^b}\right) = (-1)^b \sum_{j=0}^{a-1} \binom{b+j-1}{j} u^{-b-j} v^{j-a}. \tag{14.27}$$

Here is a direct proof on the stated quotient. Monic division by $(t-z)(t-w)$ makes P_{zw} free over A. P_z, P_w have their usual inverse-power bases. After inverting u, partial fractions separate the two poles.

The integral summands have zero intersection. Coefficientwise in ϵ, a function belonging to both has poles only at z and only at w. It therefore has no pole and, being proper, is zero.

Expansion gives (14.27) and kills both single-pole summands. At fixed $a + b$, its matrix is triangular with diagonal entries $(-1)^b$, so it surjects onto every negative u, v monomial.

If its value vanishes, the w-principal part has no u-pole and lies in P_w. Subtracting it leaves a member of P_z. This proves the kernel assertion.

Principal parts commute with derivatives, since differentiating a regular power creates no pole. The physical derivatives are $\partial_z = \partial_u$ and $\partial_w^{\mathrm{phys}} = \partial_w - \partial_u - \partial_v$, which proves relative differential linearity.

The derived diagonal restriction of $\mathcal{K}_{zw}$ has P_w in degree -1 and zero in degree zero: its differential becomes $(a, b) \mapsto a - b$ on two copies of P_w. In contrast, the ordinary restriction $\mathcal{T}/u\mathcal{T}$ is zero because u is surjective on $\mathcal{T}$.

Let $K_f = A[D_0] \otimes \Lambda(\eta, \chi)$ with $d\eta = uD_0$, $d\chi = 0$. It is bounded with free A-terms, so $1 \otimes \Theta : K_f \otimes_A \mathcal{K}_{zw} \to \mathcal{M}$ is a quasi-isomorphism, fixing both odd generators. The tensor differential $d(\xi \otimes a) = d\xi \otimes a + (-1)^{|\xi|} \xi \otimes da$ and A-linearity prove its cochain equation. It retains all the cohomology in (14.24). It does not provide separate commuting position connections on K_f: with D_0 fixed, $[\partial_u, d]\eta = D_0$.

Now pass to the generic coefficient ring R and the current G already constructed. Define

$$G_r = \frac{(\beta T)^{r-1} G}{(r-1)!}, \qquad \mathcal{J}_G = \bigoplus_{r \geq 1} R G_r, \qquad \mathcal{Q}_G = \left(\bigoplus_{p \geq 1} R u^{-p}\right) \otimes_R \mathcal{J}_G[D_0] \otimes \Lambda(\eta, \chi).$$

Let $vG_1 = 0$, $vG_r = G_{r-1}$ for $r > 1$, and let w act by $(\lambda + \epsilon y_1)/\beta - u$. Keep $d\eta = uD_0$, $d\chi = 0$. The coefficient connection is $\beta \partial_{a_{\mathrm{ft}}}$, fixing this displayed basis.

Theorem 14.12.3. There is an isomorphism of coefficient complexes with connection

$$\Psi : \mathcal{Q} \otimes_{R^0} R \longrightarrow \mathcal{Q}_G,$$
$$u^{-p} v^{-r} D_0^m \eta^e \chi^{e'} \longmapsto u^{-p} G_r D_0^m \eta^e \chi^{e'}.$$

It retains both odd moment directions and satisfies $\Psi(-\partial_v) = \beta T \Psi$. The composition with $1 \otimes \Theta$, followed by derived base change to $f = 0$, is a quasi-isomorphism for the single common-translation connection (14.26). It sends the cubic contact to

$$\Psi(\tilde{\gamma}_N) = 2abh\epsilon^3 \beta^{-3} u^{-3} G_1.$$

Proof. Elimination of w gives a unique finite expression in the displayed basis. The G_r are independent, so Ψ is an isomorphism of modules. It preserves u, D_0, η, χ and the specified v, w actions, hence

the differential. After eliminating w, ∇_{fr} differentiates only the coefficients of this basis, which proves horizontality. The derivative identity follows from $-\partial_v v^{-r} = r v^{-r-1}$ and $\beta T G_r = r G_{r+1}$.

Simultaneous translation is $\partial_z + \partial_w^{\mathrm{phys}} + \partial_t = \partial_w$ at fixed u, v. It fixes $u D_0$. The Cauchy map commutes with it and with the coefficient derivative. f is horizontal. Derived base change preserves its quasi-isomorphism. Injectivity of f on terms and cohomology identifies its derived target with the ordinary quotient $\boldsymbol{Q}$.

For the contact, expand the actual rational section $(r(\beta(z-t)) - 1)(t-w)^{-1}$. Its cubic coefficient is $2abh\epsilon^3\beta^{-3}/((z-t)^3(t-w))$. Formula (14.27), with $z - t = u - v$, gives the positive class $2abh\epsilon^3\beta^{-3}u^{-3}v^{-1}$. Applying Υ gives the stated value. For v^{-r}, the same expansion retains the first r Taylor coefficients, precisely the corresponding Leibniz derivatives of (14.23). □

Under the formal marking $x_i = \beta z_i - \epsilon y_i$, the exact Cartan argument is $\beta(z_1 - z_2) - \epsilon(y_1 - y_2)$. Its correction first occurs at order ϵ^4, so the cubic normalization above is unchanged. The common connection becomes $\sum_i \partial_{z_i} + \beta\partial_{a_{\mathrm{fr}}}$, and on the supported chart it is (14.26). The separate derivative βT differentiates the relative output current. These formulas do not identify plane eigenvalues in the moment chart with tautological Chern roots of a Hall correspondence.

The surviving classes include $\eta u^{-1} G_1$ and $\eta\chi u^{-1} G_1$ in degrees $-1, -2$. Hence the comparison cannot factor through a degree-zero polynomial projection. It also supplies only the common connection, with the separate-position obstruction still given by $[\partial_u, d]\eta = D_0$.

14.13 The remaining geometric comparison

The scalar charge-zero coaugmentation is 1. A local vacuum is a separate state marking. On the test module $R\nu \otimes_R W_N^+$, take fields $1 \otimes Y_S$ and distinguished state $\nu \otimes 1$. Its first creation state is $\nu \otimes G_1$, on which the first tautological coefficient acts by $F(\lambda)$. Then the identity field preserves $\nu \otimes 1$.

This specifies the field test module and its framing character. It does not identify it with a geometric framed module.

Problem 14.13.1. Construct an oriented critical Hall/Hecke coefficient family whose two-point map lands in $K_f \otimes_A \mathcal{K}_{zw}$ and whose derived framing fiber maps through Theorem 14.12.3. Require the Cartan and creation operations to give (14.23), with cubic contact (14.25). Preserve the framing character $F(\lambda)$, both odd moment directions, the common coefficient connection, the scalar coaugmentation and the local vacuum marking. Construct the comparison over R, and its descent to R° before localization in a, b.

On the same coefficient family, construct the nonconsecutive 13|2 comparison and the required small-diagonal homotopies. A comparison with a level-adding coproduct must additionally specify its different charge map and its twisted field tensor target.

The zero-potential Euler calculation and the finite-jet transpose are positive constructions on their named carriers. The supported moving fiber also has a constructed comparison, including its two odd directions and one common connection. The oriented map from actual critical Hall coefficients is still missing. A physical identification must distinguish the nilpotent coefficient parameter ϵ from a Moyal parameter or a loop parameter. It must also distinguish the exchange contact from a gauge anomaly. Equal scalar Euler factors alone give none of these further maps.

Chapter 15

Marked finite quantum dilogarithms

Consider two simple objects $\mathbf{1}$, ρ with

$$\rho \otimes \rho \simeq \mathbf{1} \oplus \rho.$$

An additive strong tensor functor to ordinary finite-dimensional vector spaces would give a positive integer D satisfying $D^2 = 1 + D$. No such integer exists. Nevertheless, the rule has a realization by finite bimodules, whose tensor product is balanced over an algebra with two idempotents. Its associativity maps retain information that the dimension equation forgets.

A real quadratic unit produces a family of such examples. The input is a finite function obtained from a meromorphic quantum dilogarithm. Its values become coefficients of explicit fusion maps. A normalized network recovers those values from the category. We construct the category over the field of its normalized arithmetic values, then construct its finite bimodule realization. Along the way, a rank-one correction separates a finite operator identity from the categorical pentagon.

15.1 The arithmetic function

Write $\mathrm{e}(z) = \exp(2\pi i z)$. For $|q| \neq 1$, define the q-Pochhammer symbol by

$$(x;q)_\infty = \begin{cases} \displaystyle\prod_{j \geq 0} (1 - xq^j), & |q| < 1, \\ \displaystyle\prod_{j \geq 1} (1 - xq^{-j})^{-1}, & |q| > 1. \end{cases}$$

The first product converges locally uniformly in x. The second defines a meromorphic function of x. For $\gamma = \left(\begin{smallmatrix} a_\gamma & b_\gamma \\ c_\gamma & d_\gamma \end{smallmatrix}\right) \in SL_2(\mathbb{Z})$ and integers m, n, put

$$\Phi_{\gamma,m,n}(z;\tau) = \frac{(q^m \mathrm{e}(z);q)_\infty}{(\widetilde{q}^{\,n} \mathrm{e}(z/(c_\gamma\tau + d_\gamma));\widetilde{q})_\infty}, \qquad q = \mathrm{e}(\tau), \quad \widetilde{q} = \mathrm{e}(\gamma\tau). \tag{15.1}$$

Initially $\tau \notin \mathbb{R}$, and the quotient is interpreted meromorphically in z.

The modular quantum dilogarithm has a meromorphic continuation to

$$(z,\tau) \in \mathbb{C}^2, \qquad c_\gamma\tau + d_\gamma \notin \mathbb{R}_{\leq 0}.$$

We use the continuation of Radchenko–Wheeler, equation (1) and Section 2.2.[1]

[1] D. Radchenko and C. Wheeler, *Real quadratic fields and finite quantum dilogarithms I*. Version 2. arXiv:2609.21892v2. The product conventions are in Appendix A.1. The arithmetic identities are in Theorems 1–2 and Section 4. The fusion reconstruction is Theorem 12 and Appendix B.

For $c_\gamma > 0$, fix the Dedekind eta multiplier

$$\mu_\gamma = \frac{\eta(\gamma w)}{\eta(w)\sqrt{c_\gamma w + d_\gamma}}, \qquad w \in \mathbb{H},$$

using the holomorphic square root with positive value on the positive real axis. Here $\eta(w) = \mathrm{e}(w/24)\prod_{r\geq 1}(1-\mathrm{e}(rw))$. The quotient defining μ_γ is independent of w and is a twenty-fourth root of unity.

A quadratic lattice and its finite group

Fix a real quadratic field $K \subset \mathbb{R}$. Write x' for the other real embedding of $x \in K$. Let $I \subset K$ be a free abelian subgroup of rank two. Choose a totally positive unit $\varepsilon > 1$ satisfying $\varepsilon I = I$. Its norm is one.

Define

$$G_I = (\varepsilon - 1)^{-1} I/I, \qquad N = |G_I| = \mathrm{Tr}_{K/\mathbb{Q}}(\varepsilon) - 2.$$

Indeed, multiplication by $\varepsilon - 1$ identifies this group with $I/(\varepsilon - 1)I$. The absolute determinant is $|\mathrm{Nm}(\varepsilon - 1)| = \mathrm{Tr}(\varepsilon) - 2 > 0$.

An oriented basis (β_1, β_2) of I satisfies $\beta_1\beta_2' - \beta_1'\beta_2 > 0$. Choose one with β_2 totally positive, and write

$$\varepsilon\beta_1 = a_\gamma\beta_1 + b_\gamma\beta_2, \qquad \varepsilon\beta_2 = c_\gamma\beta_1 + d_\gamma\beta_2.$$

The resulting matrix γ lies in $SL_2(\mathbb{Z})$. For $\tau = \beta_1/\beta_2$, one has

$$\gamma\tau = \tau, \qquad c_\gamma\tau + d_\gamma = \varepsilon, \qquad c_\gamma = \frac{\varepsilon - \varepsilon^{-1}}{\tau - \tau'} > 0.$$

Thus τ is the attractive real fixed point, inside the domain of the continued function.

For $x \in G_I$, choose a representative in K. There are unique integers u, v with

$$(\varepsilon^{-1} - 1)x = u\beta_1 + v\beta_2.$$

For a nonzero class define

$$E_I(x) = \mu_\gamma \Phi_{\gamma,u,0}(x/\beta_2; \tau), \qquad E_I(0) = \sqrt{\varepsilon} > 0. \tag{15.2}$$

The continuation in (15.1) precedes this evaluation. At the real fixed point the two separate products need not converge. Their formally matching arguments therefore cannot be cancelled.

The representative and oriented-basis independence of (15.2) follows from the modular cocycle and its index-shift identities. We use the precise lattice formulation and change-of-basis theorem of the reciprocity paper.[2] In particular, the prescribed meromorphic function selects the arithmetic values. The scalar identities below do not alone specify that selection.

[2] *Stark units for real quadratic fields and reciprocity laws*, 4 October 2026, Definition 1, Theorems 1–2, Proposition 1 and Appendix B, `https://www.danrad.net/papers/stark-reciprocity.pdf`.

The Gaussian and Fourier normalization

Let $\omega_I : I \times I \to \mathbb{Z}$ be the alternating form with $\omega_I(\beta_1, \beta_2) = 1$, extended $\mathbb{Q}$-bilinearly to K. For $t \in I$, set

$$\vartheta_I(t) = \begin{cases} 1, & t \in 2I, \\ -1, & t \notin 2I. \end{cases}$$

The Gaussian and its polarization are

$$Q_I(x) = \vartheta_I((\varepsilon - 1)x)\mathrm{e}\big(\tfrac{1}{2}\omega_I(x, \varepsilon x)\big), \tag{15.3}$$

$$\chi_I(x, y) = \frac{Q_I(x + y)}{Q_I(x)Q_I(y)} = \mathrm{e}\big(\omega_I(x - \varepsilon x, y)\big). \tag{15.4}$$

Both are well defined on G_I.

To see the descent of Q_I, use

$$\vartheta_I(t + s)\vartheta_I(t)\vartheta_I(s) = (-1)^{\omega_I(t,s)}, \qquad t, s \in I,$$

and $\omega_I(\varepsilon x, \varepsilon y) = \omega_I(x, y)$. Replacing x by $x + t$ changes the sign and exponential by inverse factors. The same calculation gives (15.4). One has $Q_I(0) = 1$, $Q_I(-x) = Q_I(x)$, and all values of Q_I are roots of unity.

The bicharacter χ_I is nondegenerate. Indeed,

$$\omega_I(x - \varepsilon x, y) = \omega_I(\varepsilon x, (\varepsilon - 1)\, y).$$

If its exponential is one for every $y \in (\varepsilon - 1)^{-1} I$, unimodularity of ω_I gives $\varepsilon x \in I$. Hence $x \in I$.

For a function $f : G_I \to \mathbb{C}$, use the Fourier transform

$$\widehat{f}(y) = \frac{1}{\sqrt{N}} \sum_{x \in G_I} f(x)\chi_I(x, -y),$$

with the positive square root of N. Orthogonality of the characters gives $\widehat{\widehat{f}}(x) = f(-x)$.

Theorem 15.1.1 *(Arithmetic input).* Let $E = E_I$, $Q = Q_I$, and $\chi = \chi_I$. For a twenty-fourth root of unity λ, the arithmetic values satisfy

$$\begin{aligned} E(g)E(-g) &= Q(g)^{-1} \qquad (g \neq 0), \\ \widehat{E}(g) &= \lambda Q(g)E(g), \\ \chi(x, y)E(x)E(y) &= -\widehat{E}(0) + \frac{1}{\sqrt{N}} \sum_t E(y - t)E(t)Q(t)E(x - t). \end{aligned}$$

At zero the separate normalization is

$$E(0)^2 = \sqrt{N}\, E(0) + 1. \tag{15.5}$$

Every $E(g)$ is an algebraic unit.

Let m be the exponent of G_I, and let $\mathcal{O} = (I : I) = \mathbb{Z} + c\mathcal{O}_K$. The normalized values $e_{I,g} = E_I(g)/E_I(0)$ belong to $\mathcal{O}_L^\times$, where $L = H^+_{\mathcal{O},m}$ is the narrow ray class field modulo $m\mathcal{O}$. For an integral invertible $\mathcal{O}$-ideal $\mathfrak{a}$ prime to cm,

$$\mathrm{Art}(\mathfrak{a})(e_{I,g}) = e_{\mathfrak{a}^{-1}I,g}. \tag{15.6}$$

The right-hand label is the class of the same representative. The Artin symbol uses arithmetic Frobenius.

The scalar identities and algebraicity are the Radchenko–Wheeler theorems. The unit and reciprocity assertions are Theorems 1–2 of the reciprocity paper. These are imported arithmetic results. The identity (15.5) also follows directly from $\varepsilon + \varepsilon^{-1} = N + 2$. It remains part of the input when $N \le 4$, where a bare cubic equation can have additional solutions.

15.2 The arithmetic coefficient field

Suppress I in the notation. Put $u = \sqrt{\varepsilon} > 0$ and $s = \sqrt{N} > 0$. Then $s = u - u^{-1}$. Define

$$b_g = \frac{E(g)}{s}, \qquad b_0 = \frac{\varepsilon}{\varepsilon - 1} = \frac{\varepsilon - 1}{N}, \qquad b_g = b_0 e_g. \tag{15.7}$$

Consequently the coefficient field is

$$F_I = K(b_g : g \in G_I) = K(e_g : g \in G_I) \subseteq L.$$

Neither u nor s needs to belong to F_I. Every coefficient used in the algebraic construction below does.

Set

$$d = -b_0^{-1} = \varepsilon^{-1} - 1, \qquad \beta = \sum_g b_g, \qquad a = \frac{\beta}{N b_0}, \qquad c_1 = \frac{b_0}{\beta}. \tag{15.8}$$

Fourier evaluation at zero gives $\beta = \lambda u \neq 0$. Thus $a = \lambda/s$, $c_1 = \lambda^{-1}/s$, and $a c_1 = 1/N$. The notation c_1 distinguishes this coefficient from the conductor c.

Reflection recovers the Gaussian over the same field:

$$Q(0) = 1, \qquad Q(g) = \frac{1}{N b_g b_{-g}} \quad (g \neq 0).$$

Its polarization therefore has values in F_I. The arithmetic identities become

$$\begin{gathered} b_0^2 - b_0 = 1/N, \qquad d^2 = N(d+1), \\ \sum_x b_x \chi(x, -y) = N a Q(y) b_y, \\ \sum_t b_{y-t} b_t Q(t) b_{x-t} - \chi(x, y) b_x b_y = \beta/N. \end{gathered} \tag{15.9}$$

These follow by substituting $E(g) = s b_g$. In particular, the constant in (15.9) retains the Fourier normalization.

Example 15.2.1. Take $I = \mathbb{Z}[\varepsilon]$ with $\varepsilon = (3 + \sqrt{5})/2$. Then $N = 1$, G_I is trivial, and

$$b_0 = \frac{1 + \sqrt{5}}{2}, \qquad d = \frac{1 - \sqrt{5}}{2}, \qquad a = c_1 = 1.$$

The fusion rule will be $\rho^2 \simeq \mathbf{1} \oplus \rho$. The roots b_0, d will give its positive dimension and the specified duality closure, respectively.

15.3 The Leavitt presentation

Let $\mathcal{B}_I$ be the unital F_I-algebra generated by

$$X_g,\ X'_g,\ T_g,\ T'_g, \qquad g \in G_I,$$

with relations

$$X'_g X_h = T'_g T_h = \delta_{g,h} \mathrm{I}, \qquad X'_g T_h = T'_g X_h = 0,$$
$$\sum_g (X_g X'_g + T_g T'_g) = \mathrm{I}.$$

Primes denote algebraic dual generators, without any complex-conjugate or adjoint operation. This is the Leavitt algebra on $2N$ generator pairs.

For $g \in G_I$, define

$$\alpha_g(X_h) = X_{g+h}, \qquad \alpha_g(X'_h) = X'_{g+h},$$
$$\alpha_g(T_h) = \chi(g,h)^{-1} T_h, \qquad \alpha_g(T'_h) = \chi(g,h) T'_h.$$

These formulas preserve the relations and give $\alpha_g \alpha_h = \alpha_{g+h}$. Also define

$$U_g = \sum_h \chi(g,h)^{-1} X_h X'_h + \sum_h T_{h-g} T'_h. \tag{15.10}$$

Direct multiplication gives

$$U_0 = \mathrm{I}, \qquad U_g U_h = U_{g+h}, \qquad \alpha_g(U_h) = \chi(g,h) U_h.$$

Thus each U_g is invertible, with inverse U_{-g}.

The noninvertible generator of the category is an endomorphism ρ of $\mathcal{B}_I$. Its four families of images are

$$\rho(X_g) = U_g \left(d^{-1} \sum_h X_h + \sum_h Q(h) T_h T_{-h} \right) U_{-g}, \tag{15.11}$$

$$\rho(X'_g) = d^{-1} U_g \left(\sum_h X'_h + \sum_h Q(h)^{-1} T'_{-h} T'_h \right) U_{-g}, \tag{15.12}$$

$$\begin{aligned} \rho(T_g) = {} & \frac{a}{d} \sum_{h,k} \chi(h-g,k) X_h T'_k + \frac{c_1}{Q(g)} \sum_{h,k} \chi(g+h,k)^{-1} T_k X_h X'_h \\ & + \sum_{h,k} Q(h) b_{h+g} \chi(g,k)^{-1} T_{h+k} T_{-h} T'_k, \end{aligned} \tag{15.13}$$

$$\begin{aligned} \rho(T'_g) = {} & c_1 \sum_{h,k} \chi(h-g,k)^{-1} T_k X'_h + a Q(g) \sum_{h,k} \chi(g+h,k) X_h X'_h T'_k \\ & + \sum_{h,k} \frac{Q(g+h)}{Q(h)} b_{-h-g} \chi(g,k) T_k T'_{-h} T'_{h+k}. \end{aligned} \tag{15.14}$$

All sums run over G_I. All four formulas are over F_I.

The tensor category and its duality

For unital endomorphisms σ, τ of $\mathcal{B}_I$, put

$$\mathrm{Hom}(\sigma,\tau) = \{x \in \mathcal{B}_I : x\sigma(z) = \tau(z)x \text{ for every } z \in \mathcal{B}_I\}.$$

Composition is multiplication, and tensor product of objects is composition of endomorphisms. For $x : \sigma \to \sigma'$ and $y : \tau \to \tau'$, set

$$x \otimes y = x\sigma(y) = \sigma'(y)x : \sigma\tau \longrightarrow \sigma'\tau'. \tag{15.15}$$

This gives a strict tensor category. Let $\mathcal{C}_I$ be the additive idempotent completion of its subcategory generated by the α_g and ρ.

A fusion category is a rigid semisimple linear tensor category with finitely many simple objects, finite-dimensional Hom spaces and a simple tensor unit. It is split over F_I when the endomorphism field of every simple object is F_I.

THEOREM 15.3.1. Equations (15.11)–(15.14) define a unital endomorphism. The category $\mathcal{C}_I$ is a split rigid fusion category over F_I. Its simple objects are the pairwise distinct α_g, $g \in G_I$, and ρ, with rules

$$\alpha_g\alpha_h = \alpha_{g+h}, \qquad \alpha_g\rho \simeq \rho \simeq \rho\alpha_g, \qquad \rho^2 \simeq \bigoplus_g \alpha_g \oplus \rho^{\oplus N}. \tag{15.16}$$

For $\rho^\vee = \rho$, one may choose coevaluation X_0 and evaluation dX_0'.

Proof. Start with the complex Leavitt reconstruction of Radchenko–Wheeler, Section 5.4, Theorem 12 and Appendix B. In its notation make the change

$$X_g = \sqrt{d}\, S_g, \qquad X_g' = S_g'/\sqrt{d}.$$

The Leavitt relations are unchanged. Substitution gives exactly (15.11)–(15.14). The two mixed coefficients in $\rho(T_g)$ become $a/d, c_1$. Those in $\rho(T_g')$ become c_1, a. The quadratic terms in $\rho(X_g)$ lose their square root, and both terms in $\rho(X_g')$ acquire d^{-1}.

The reconstruction theorem proves the defining relations and

$$\alpha_g\rho = \rho, \qquad \rho\alpha_g = \mathrm{Ad}(U_g)\rho, \qquad \rho^2(z) = \sum_g X_g\alpha_g(z)X_g' + \sum_h T_h\rho(z)T_h'. \tag{15.17}$$

Faithful extension of scalars from F_I to $\mathbb{C}$ descends these equalities.

The same extension descends the Hom calculation. The intertwiner equations need only be imposed on the $4N$ algebra generators. Each Hom space is consequently the kernel of one F_I-linear map

$$\mathcal{B}_I \longrightarrow \mathcal{B}_I^{4N}.$$

A field extension preserves this kernel, even though $\mathcal{B}_I$ is infinite-dimensional. The complex calculation therefore gives $\mathrm{End}(\alpha_g) = \mathrm{End}(\rho) = F_I$ and zero Hom spaces between distinct displayed simples.

The last formula in (15.17) splits ρ^2, with inclusions X_g, T_h and projections X_g', T_h'. The Leavitt relations give their orthogonality and completeness. Every tensor word therefore splits into the listed simples. Finite sums and idempotent summands give a split semisimple category with finite-dimensional Hom spaces.

The dual of α_g is α_{-g}, with both maps 1. For ρ, the two snake equations are

$$dX_0'\rho(X_0) = 1, \qquad \rho(dX_0')X_0 = 1.$$

For the first, the X_0 term contributes $d\, d^{-1} = 1$, and every T-term vanishes. The second follows by the dual contraction in (15.12). This proves rigidity over the stated field. □

For the fusion rules above, the Frobenius–Perron dimension is the positive dimension function assigning dimension one to each invertible simple object.

Proposition 15.3.2. The Frobenius–Perron dimension of ρ is $\delta = \varepsilon - 1 = Nb_0$, while the specified duality closure of 1_ρ is $d = \varepsilon^{-1} - 1 < 0$. Moreover,

$$\varepsilon = 1 + Nb_0 = \frac{b_0}{b_0 - 1}, \qquad K = \mathbb{Q}(b_0).$$

There is no additive strong tensor functor from $\mathcal{C}_I$ to ordinary finite-dimensional vector spaces over any field.

Proof. The positive dimension satisfies $\delta^2 = N(1 + \delta)$. The identity $(\varepsilon - 1)^2 = N\varepsilon$ selects $\delta = \varepsilon - 1$. The other root is d. The chosen cup and cap have composite $dX_0'X_0 = d$. Formula (15.7) recovers the period and its quadratic field.

Under the proposed tensor functor, every invertible α_g would have dimension one. The image of ρ would have a nonzero integer dimension D, since its square contains the tensor unit. Then $D^2 = N(D + 1)$. It follows that $D + 1$ divides D^2, hence divides 1, which is impossible for $D > 0$. No faithfulness assumption is needed. □

An integral coefficient algebra

Put $\mathcal{S} = \mathcal{O}_L[1/N]$. The normalized units e_g and $b_0(b_0 - 1) = 1/N$ show that every b_g is a unit of $\mathcal{S}$. Also $\beta = \lambda u$ is an algebraic unit. Since $\beta \in L$, it belongs to $\mathcal{O}_L^\times$. Thus d, a, c_1, $Q(g)$ and all their required inverses lie in $\mathcal{S}$.

Proposition 15.3.3. The Leavitt presentation and all four formulas for ρ are defined over $\mathcal{S}$. The underlying Leavitt algebra is free as an $\mathcal{S}$-module. Its extension to L agrees with the extension of the F_I-presentation to L.

Proof. For the freeness assertion, combine the X and T generators into $s_1, \dots, s_{2N}$, with dual generators $t_1, \dots, t_{2N}$. Use the reduction rules

$$t_i s_j \longmapsto \delta_{ij}, \qquad s_{2N} t_{2N} \longmapsto 1 - \sum_{i<2N} s_i t_i.$$

Choose a length and lexicographic order with s_{2N} larger than the other positive generators. Every reduction decreases this order. The irreducible words are 1, pure positive or negative words, and positive words followed by negative words without the forbidden middle pair $s_{2N}t_{2N}$.

The only nontrivial overlap types are $t_i s_{2N} t_{2N}$ and $s_{2N} t_{2N} s_j$. Reducing either end of the first gives $\delta_{i,2N} t_{2N}$. Reducing either end of the second gives $\delta_{2N,j} s_{2N}$. Disjoint reductions commute. Hence the irreducible words give a basis over any coefficient ring.

All displayed coefficients lie in $\mathcal{S}$. The free normal form embeds this algebra into its scalar extension over L. The endomorphism identities already hold there, so they hold over $\mathcal{S}$. □

This integral model permits specialization away from N. It makes no semisimplicity assertion about the resulting category over a residue field. Primes dividing N require an additional integral construction.

15.4 FUSION BASES AND THE ARITHMETIC NETWORK

The fusion rule alone does not specify associativity coefficients. Here the Leavitt intertwiners give complete labeled splitting maps. For simple objects i, j, k, let $v_{ij}^{k,\mu} : k \to i \otimes j$ and $\bar{v}_{ij}^{k,\mu} : i \otimes j \to k$ denote dual inclusions and projections. Choose them as follows:

$i \otimes j,\ k$	$v_{ij}^{k,\mu}$	$\bar{v}_{ij}^{k,\mu}$
$\alpha_g\alpha_h,\ \alpha_{g+h}$	1	1
$\alpha_g\rho,\ \rho$	1	1
$\rho\alpha_g,\ \rho$	U_g	U_{-g}
$\rho^2,\ \alpha_g$	X_g	X'_g
$\rho^2,\ \rho$ in channel h	T_h	T'_h

They satisfy

$$\bar{v}_{ij}^{k,\mu} v_{ij}^{l,\nu} = \delta_{kl}\delta_{\mu\nu} 1_k, \qquad \sum_{k,\mu} v_{ij}^{k,\mu} \bar{v}_{ij}^{k,\mu} = 1_{i\otimes j}.$$

For four simple objects i, j, k, l, form bases of $\mathrm{Hom}(l, i \otimes j \otimes k)$:

$$L_{p,\mu,\nu} = (v_{ij}^{p,\mu} \otimes 1_k) v_{pk}^{l,\nu}, \qquad R_{q,\alpha,\beta} = (1_i \otimes v_{jk}^{q,\alpha}) v_{iq}^{l,\beta}.$$

Their dual projections are denoted by $\bar{L}, \bar{R}$. The full recoupling matrix is

$$F_{ijk}^{l}[(q,\alpha,\beta),(p,\mu,\nu)] = \bar{R}_{q,\alpha,\beta} L_{p,\mu,\nu}, \qquad (F^{-1})[(p,\mu,\nu),(q,\alpha,\beta)] = \bar{L}_{p,\mu,\nu} R_{q,\alpha,\beta}. \quad (15.18)$$

Each entry is a scalar in $\mathrm{End}(l) = F_I$. Formula (15.15) and Leavitt reduction compute every entry from the stated generators.

The completeness identities give $F^{-1}F = FF^{-1} = 1$. For four tensor factors, every composite of successive changes of basis equals the direct change between its first and last fusion trees. The two routes around the pentagon therefore agree. The unit choices give the triangle equations in the same way. A strict endomorphism presentation thus produces nontrivial recoupling matrices on its chosen simple-object skeleton.

Recovering the normalized values

Consider the endomorphism of ρ

$$\mathcal{N}_g = T'_{\mathrm{o}}(T'_{\mathrm{o}} \otimes 1_\rho)(1_\rho \otimes T_g)T_{\mathrm{o}} = T'_{\mathrm{o}}T'_{\mathrm{o}}\rho(T_g)T_{\mathrm{o}}. \quad (15.19)$$

The second expression is in the strict presentation. In a general presentation the first expression includes its specified associativity maps.

PROPOSITION 15.4.1. The network satisfies

$$\mathcal{N}_g = b_g 1_\rho, \qquad \mathcal{N}_g\mathcal{N}_{\mathrm{o}}^{-1} = e_g 1_\rho.$$

The scalars are intrinsic to the category with labeled invertible simples. They are preserved by linear tensor equivalences respecting those labels.

Proof. Substitute (15.13). Every mixed X-term vanishes. The right contraction forces $k = 0$, and the next forces $h = 0$. The remaining coefficient is b_g.

To recover the marking, choose isomorphisms $a_g : \alpha_g \otimes \rho \to \rho$. The equations

$$(a_g \otimes 1_\rho)(1_{\alpha_g} \otimes T_0) = T_0 a_g \quad \text{for every } g$$

define a line in $\mathrm{Hom}(\rho, \rho^2)$. In the explicit basis the action is $T_h \mapsto \chi(g,h)^{-1} T_h$. Nondegeneracy of χ makes the common invariant space exactly $F_I T_0$.

Choose $u_g : \rho \to \rho \otimes \alpha_g$. Normalize it so that

$$(1_\rho \otimes a_g)(u_g \otimes 1_\rho)$$

acts identically on $\mathrm{Hom}(\mathbf{1}, \rho^2)$. This fixes the endomorphism U_g.

Set $T_g = U_{-g} T_0$, and choose the dual projections T'_g. Only a common rescaling of the T_g remains. Its two factors cancel the two inverse factors in (15.19). The construction is therefore preserved by the stated equivalences. □

The unit summand normalizes U_g, but T_0 itself belongs to $\mathrm{Hom}(\rho, \rho^2)$. These are different channels. The specified duality closure is

$$dX'_0(1_\rho \otimes \mathcal{N}_g)X_0 = d\, b_g = -e_g. \tag{15.20}$$

Thus the closure recovers a normalized arithmetic unit, with its negative sign.

This closure cannot be replaced by a normalized cyclic functional on the ambient Leavitt algebra. Indeed,

$$\sum_{i=1}^{2N} [t_i, s_i] = (2N - 1)1.$$

In characteristic zero, the unit has zero image in

$$HH_0(\mathcal{B}_I) = \mathcal{B}_I / [\mathcal{B}_I, \mathcal{B}_I].$$

Every linear functional vanishing on commutators therefore sends 1 to zero. The marked categorical closure in (15.20) has a different domain.

Relabelling invertible simples relabels b_g. A semilinear tensor equivalence applies its field embedding to each network coefficient. Recovering the unnormalized $E(g)$ also requires the chosen $\sqrt{N}$. The normalized coefficients and their ratios are already defined over F_I.

15.5 The finite Heisenberg operators

The multiplicity space

$$H_I = \mathrm{Hom}(\rho, \rho^2) = \bigoplus_{h \in G_I} F_I T_h$$

carries two group actions:

$$p^g(T_h) = U_g T_h = T_{h-g}, \qquad q^g(T_h) = \alpha_{-g}(T_h) = \chi(g,h) T_h.$$

Their commutation rule is

$$p^g q^h = \chi(g,h) q^h p^g.$$

Because $Q(g+h) = Q(g)Q(h)\chi(g,h)$, the formula

$$(p+q)^g = Q(g)q^g p^g$$

also gives a group action. Here $p+q$ denotes this action, rather than the sum of two operators.

For any group action r and function $f : G_I \to F_I$, define

$$f(r) = \frac{1}{N} \sum_{x,y \in G_I} f(y)\chi(x,-y)r^x. \tag{15.21}$$

Character orthogonality gives $f(q)T_h = f(h)T_h$. Let δ_0 denote the indicator of zero, and put

$$P_0 = \delta_0(q), \qquad P_{\mathrm{av}} = \delta_0(p), \qquad D = P_0 P_{\mathrm{av}}.$$

The first two are projections, respectively onto $F_I T_0$ and the invariant vectors for translation. Their product acts by

$$D\left(\sum_h v_h T_h\right) = \frac{1}{N}\left(\sum_h v_h\right) T_0, \qquad D^2 = \frac{D}{N}, \qquad \mathrm{Tr}(D) = \frac{1}{N}.$$

For $N > 1$, the rank-one operator D is not an idempotent.

Although E need not be F_I-valued, its Fourier transform is:

$$\eta(g) := \widehat{E}(g) = NaQ(g)b_g \in F_I.$$

THEOREM 15.5.1. On H_I, one has

$$\eta(p)\eta(q) - \eta(q)\eta(p+q)\eta(p) = -N\beta D. \tag{15.22}$$

The tensor-unit projection of ρ^2 acts as zero on H_I, whereas $D \neq 0$.

Proof. Fourier inversion and (15.21) give

$$\eta(p) = \sum_x b_x p^{-x}, \qquad \eta(q) = \sum_y b_y q^{-y}, \qquad \eta(p+q) = \sum_t b_t Q(t) q^{-t} p^{-t}.$$

Order every term as $q^{-y}p^{-x}$. The coefficient of that term in the difference is

$$\chi(x,y)b_x b_y - \sum_t b_{y-t} b_t Q(t) b_{x-t} = -\frac{\beta}{N},$$

by (15.9). On the other hand,

$$D = \frac{1}{N^2} \sum_{x,y} q^{-y} p^{-x}.$$

This proves the factor N in (15.22).

The tensor-unit projection is $X_0 X_0'$. For every $v : \rho \to \rho^2$, the composite $X_0' v$ lies in $\mathrm{Hom}(\rho, \mathbf{1}) = 0$. Its action on H_I vanishes. By contrast, $D(T_0) = T_0/N \neq 0$. □

Example 15.5.2. Let $I = \mathbb{Z}[\sqrt{3}]$, $\varepsilon = 2 + \sqrt{3}$, and orient I by $(\sqrt{3}, 1)$. The nonzero class of $G_I \simeq \mathbb{Z}/2$ is represented by $x = (\sqrt{3} - 1)/2$. Since

$$(\varepsilon - 1)x = 1, \qquad \omega_I(x, \varepsilon x) = \frac{1}{2},$$

formula (15.3) gives $Q(x) = -i$.

Reflection gives $2b_1^2 = i$. Among its two signs, the Fourier condition $|\beta| = \sqrt{\varepsilon}$ selects

$$b_0 = \frac{1 + \sqrt{3}}{2}, \qquad b_1 = \frac{1 + i}{2}, \qquad \beta = 1 + \frac{\sqrt{3} + i}{2}.$$

In the basis T_0, T_1,

$$\eta(p) = \begin{pmatrix} b_0 & b_1 \\ b_1 & b_0 \end{pmatrix}, \qquad \eta(q) = \begin{pmatrix} \beta & 0 \\ 0 & b_0 - b_1 \end{pmatrix}.$$

Put $Q_q = \operatorname{diag}(1, -i)$. Then $\eta(p + q) = Q_q^{-1}\eta(p)Q_q$, and multiplication yields

$$\eta(p)\eta(q) - \eta(q)\eta(p + q)\eta(p) = -\beta \begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix} = -2\beta D.$$

In particular, both the chosen multiplicity space and the normalization of the correction are visible in two dimensions.

The identity (15.22) is not an associativity failure of C_I. Its recoupling matrices satisfy the categorical pentagon. Moreover, the nonzero correction cannot be the image of a boundary under a chain map to $\operatorname{End}(H_I[0])$. That target has no term in degree -1. A comparison with supported chiral operations must retain a larger complex and specify its reduction to this multiplicity space.

15.6 Finite bimodule realization

We now construct the finite realization promised at the beginning. Let k be a field of characteristic zero, and let $\mathcal{C}$ be a split fusion category over k. Choose simple representatives $(S_i)_{i \in \mathcal{I}}$, with $S_0 = \mathbf{1}$, and set

$$A = \bigoplus_{i \in \mathcal{I}} k e_i, \qquad \omega(X)_{ij} = \operatorname{Hom}_{\mathcal{C}}(S_i, X \otimes S_j).$$

Declare $e_i \omega(X) e_j = \omega(X)_{ij}$. For $f : X \to X'$, the map $\omega(f)$ is postcomposition with $f \otimes 1$. Each $\omega(X)$ is a finite-dimensional A-bimodule.

Write

$$a_{X,Y,Z} : (X \otimes Y) \otimes Z \longrightarrow X \otimes (Y \otimes Z)$$

for the associator of $\mathcal{C}$. For $u : S_i \to X \otimes S_j$ and $v : S_j \to Y \otimes S_k$, define

$$\Phi_{X,Y}(u \otimes_A v) = a^{-1}_{X,Y,S_k}(1_X \otimes v)u. \tag{15.23}$$

The output belongs to $\operatorname{Hom}(S_i, (X \otimes Y) \otimes S_k)$. The balanced tensor retains precisely the matching middle labels.

Theorem 15.6.1. The maps $\Phi_{X,Y}$ are isomorphisms. Together with $\omega(\mathbf{1}) \simeq A$, they make

$$\omega : \mathcal{C} \longrightarrow \operatorname{Bimod}_A^{\mathrm{fd}}$$

a faithful exact strong monoidal functor. It need not be full.

Proof. For each $Y \otimes S_k$, choose splitting maps

$$v_{j\alpha} : S_j \longrightarrow Y \otimes S_k, \qquad w_{j\alpha} : Y \otimes S_k \longrightarrow S_j$$

with

$$w_{j\alpha} v_{l\beta} = \delta_{jl}\delta_{\alpha\beta} 1_{S_j}, \qquad \sum_{j,\alpha} v_{j\alpha} w_{j\alpha} = 1.$$

The inverse to (15.23) is

$$h \longmapsto \sum_{j,\alpha} (1_X \otimes w_{j\alpha}) a_{X,Y,S_k} h \otimes_A v_{j\alpha}.$$

Composing in one order uses the sum of the splitting idempotents. Composing in the other uses their pairwise orthogonality. A change of splitting basis acts by inverse matrices on the two factors, so the displayed sum is independent of that choice.

For three objects, both iterated tensorators compose the same three maps from simple objects. The associator pentagon equates the two parenthesizations. The same argument handles every finite tensor string, and the unitors give $\omega(\mathbf{1}) \simeq A$. The column $j = 0$ is $\bigoplus_i \mathrm{Hom}(S_i, X)$. It detects every morphism out of X, proving faithfulness. Split semisimplicity gives exactness.

Finally, $\mathrm{End}_{A-A}(A) = A$, whereas $\mathrm{End}_C(\mathbf{1}) = k$. For more than one simple label, the induced map on these endomorphism spaces is not surjective. □

An associator detected by its endpoint

Take the pointed category with labels $\mathbb{Z}/2$ and scalar associator

$$c(g,h,l) = (-1)^{ghl}.$$

Its pentagon is the mod-two three-cocycle equation.

The bimodule $\omega(g)$ has one-dimensional entries at $i = g + j$. On the component with right endpoint r, the tensorator is multiplication by $c(g,h,r)^{-1}$. Its coherence equation is

$$c(g,h,l)c(g,h,l+r)^{-1}c(g+h,l,r)^{-1} = c(h,l,r)^{-1}c(g,h+l,r)^{-1}.$$

At $g = h = l = 1$, forgetting the endpoint factors would leave the false equality $-1 = 1$. The strict ambient category of bimodules thus retains the nontrivial source associator through its tensorator.

The finite arithmetic detector

Apply the construction to C_I over $k = F_I$, with labels $\mathcal{I} = G_I \sqcup \{\rho\}$. Let W_X be the matrix with entries $(W_X)_{ij} = \dim_k \omega(X)_{ij}$. The fusion rule gives

$$W_{\alpha_g} = P_g \oplus [1], \qquad W_\rho = \begin{pmatrix} 0_{N\times N} & \mathbf{1} \\ \mathbf{1}^t & N \end{pmatrix},$$

where P_g is the translation permutation on G_I. Matrix multiplication records the balanced tensor product:

$$W_\rho^2 = \sum_g W_{\alpha_g} + NW_\rho, \qquad \dim_k \omega(\rho) = 3N.$$

For $N = 2$, this is

$$W_\rho = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 0 & 1 \\ 1 & 1 & 2 \end{pmatrix}.$$

Its entries sum to 6, while the entries of W_ρ^2 sum to 18. The ordinary vector-space tensor square would have dimension 36.

Transport every map in (15.19) through ω, using Φ for each tensor product. The resulting endomorphism M_g of $\omega(\rho)$ satisfies

$$M_g = b_g \mathrm{I}_{\omega(\rho)}, \qquad b_g = \frac{\mathrm{Tr}_k(M_g)}{3N}, \qquad E(g) = \frac{\sqrt{N}}{3N}\,\mathrm{Tr}_k(M_g).$$

The first recovery takes place over F_1. The second uses the chosen radical. Ratios recover e_g without it.

This matrix trace works because the specified composite ends in the simple object ρ and is scalar there. It does not identify ordinary matrix trace with the duality closure (15.20) on arbitrary diagrams. The finite realization also keeps its chosen categorical intertwiners, rather than every bimodule map.

Finally, it is not a finite-dimensional unital representation of $\mathcal{B}_I$. Such a representation on V would give $V \simeq V^{\oplus 2N}$ from the Leavitt generators. Equivalently, matrix trace applied to $\sum_i [t_i, s_i] = (2N-1)1$ gives $0 = (2N-1)\dim_k V$, impossible in characteristic zero.

The arithmetic values have therefore been retained by actual fusion maps, a normalized network and a finite balanced tensor. A further field realization must transport these maps and their duality, rather than only the scalar detector. Its supported operation complex must also explain how the correction $-N\beta D$ arises after reduction.

Chapter 16

Arithmetic fusion as singular interfaces

The marked network of Chapter 15 has value b_g, and its specified duality closes it to $-e_g$. Insert the same junctions into two Heisenberg currents. Their contraction produces the double pole

$$-\frac{e_g}{(z_1 - z_3)^2}.$$

The intervening insertions remain part of the ordered coefficient product. Thus the singular amplitude retains a marked fusion composition that its scalar residue alone would not determine.

We construct this realization on all oscillator states and every collision stratum. It has infinite-dimensional coefficient spaces. A second realization uses the finite bimodules of the preceding chapter, together with the categorical symmetry that singles out their allowed maps. Tensoring them with the E_8 lattice theory gives finite conformal grades and convergent relative sewing.

For the order-two arithmetic category, two further realizations have a single conformal vacuum in their ambient vertex algebra. Changing the quadratic embedding gives the E_6 module category at affine $\mathfrak{sl}_2$ level ten. The original embedding is realized by the Virasoro theory of central charge $-39/10$. We compare their actual junctions, full descendant fields and collision coefficients. The coefficient algebra, the finite bimodule, the conformal state space and the conformal-block bundle will remain separate objects throughout.

16.1 The junction and its coefficient field

Use the arithmetic data of Section 15.1 and write $F = F_I$, $B = \mathcal{B}_I$, $C = C_I$ and $G = G_I$. Thus F has characteristic zero and

$$G = (\varepsilon - 1)^{-1} I/I, \qquad N = |G| = \varepsilon + \varepsilon^{-1} - 2.$$

The generators X_g, X'_g, T_g, T'_g, their endomorphisms α_g, ρ, and the elements U_g are those of Section 15.3. Primes denote algebraic generators, not adjoints. In the notation used below,

$$e_g = E_g/E_0, \quad b_g = E_g/\sqrt{N}, \quad b_0 = \frac{\varepsilon - 1}{N}, \quad d = -b_0^{-1} = \varepsilon^{-1} - 1. \tag{16.1}$$

The positive roots obey $\sqrt{N} = \sqrt{\varepsilon} - \varepsilon^{-1/2}$. Put $\beta = \sum_g b_g$, $a = \beta/(N b_0)$ and $c = b_0/\beta$. Here c is the coefficient denoted c_1 in (15.8). The Gaussian Q and bicharacter χ retain the conventions of (15.4).

Tensor categories and their functors are linear over their stated fields, except where semilinearity is specified. Complexes are cohomologically $\mathbb{Z}$-graded, with the Koszul sign for tensor products of homogeneous maps.

The endomorphism presentation gives

$$\alpha_g \rho = \rho, \qquad \rho \alpha_g = \mathrm{Ad}(U_g)\rho, \qquad \alpha_g(U_h) = \chi(g,h) U_h. \tag{16.2}$$

Here $\mathrm{Ad}(u)(z) = uzu^{-1}$. The first two identities are proved in Theorem 15.3.1. The last follows by applying α_g to (15.10). The specified cup and cap are X_0 and dX_0'.

The fusion ring records the quadratic period. For $r = [\rho]$ and $S = \sum_g [\alpha_g]$, the relations $r^2 = Nr + S$ and $rS = Nr$ give

$$(1 + r)(1 - r + S) = 1.$$

The positive dimension character takes $1 + r$ to ε, while the specified duality dimension takes it to ε^{-1}. The inverse is a virtual class, not an inverse object for $1 \oplus \rho$.

The marked network of Proposition 15.4.1 is

$$\mathcal{N}_g = T_0' T_0' \rho(T_g) T_0. \tag{16.3}$$

Its value and its duality closure are

$$\mathcal{N}_g = b_g 1, \qquad dX_0' \rho(\mathcal{N}_g) X_0 = db_g = -e_g. \tag{16.4}$$

The calculation following (15.20) shows why this closure must retain the marked object: in the ambient algebra,

$$\sum_g \big([X_g', X_g] + [T_g', T_g] \big) = (2N - 1)1,$$

so the unit has zero Hochschild class.

For $\varepsilon = 2 + \sqrt{3}$, the simples are 1, g, ρ, with $g^2 = 1$, $g\rho = \rho g = \rho$ and $\rho^2 = 1 \oplus g \oplus \rho^{\oplus 2}$. Their coefficients are

$$b_0 = \frac{1 + \sqrt{3}}{2}, \qquad b_1 = \frac{1 + i}{2}, \qquad d = 1 - \sqrt{3}.$$

The second marked network closes to the negative of

$$e_1 = \frac{(\sqrt{3} - 1)(1 + i)}{2}, \qquad e_1^4 + 2e_1^3 + 2e_1^2 - 2e_1 + 1 = 0. \tag{16.5}$$

The singular construction will recover this value as the coefficient of a double pole.

16.2 Operator coefficients at a nonconsecutive collision

A coefficient multiplying a field may be noncommutative. This changes the operation at a collision that passes an intervening insertion. For example, take $A = C = E_{12}$ and $D = E_{21}$ in $\mathrm{Mat}_2(F)$. Then $AC = 0$ while $ADC = E_{12}$. The algebra B contains such matrix units: choose two of its positive generators L_1, L_2, and put $E_{ij} = L_i L_j'$. This gives a matrix corner with identity $E_{11} + E_{22}$.

The exchange of Section 5.4 retains this context. It is the linear map

$$c_B : B \otimes B \longrightarrow B \otimes B, \qquad c_B(x, y) = xy \otimes 1 + 1 \otimes xy - x \otimes y.$$

Let m denote multiplication in B. Direct expansion gives

$$\begin{aligned} c_B^2 = 1, \quad & mc_B = m, \quad c_B(1, x) = (x, 1), \quad c_B(x, 1) = (1, x), \\ & (c_B)_{12}(c_B)_{23}(c_B)_{12} = (c_B)_{23}(c_B)_{12}(c_B)_{23}, \\ & c_B(1 \otimes m) = (m \otimes 1)(1 \otimes c_B)(c_B \otimes 1), \\ & c_B(m \otimes 1) = (1 \otimes m)(c_B \otimes 1)(1 \otimes c_B). \end{aligned} \tag{16.6}$$

For example, the two braid words on $x \otimes y \otimes z$ both give

$$\begin{aligned} xyz \otimes 1 \otimes 1 - xy \otimes z \otimes 1 + 1 \otimes 1 \otimes xyz + 1 \otimes xy \otimes z \\ + x \otimes yz \otimes 1 - 1 \otimes x \otimes yz - x \otimes y \otimes z. \end{aligned}$$

No dimension hypothesis occurs in these identities.

Let f be a map between finite ordered sets. Define q_f by three steps. Sort the inputs into the fibers of f with adjacent c_B's. Multiply inside each fiber, and insert 1_B in an empty fiber. The relations (16.6) imply

$$q_g q_f = q_{gf}, \qquad q_{\mathrm{id}} = 1. \tag{16.7}$$

To prove this, use the braid and involution relations to change a sequence of adjacent crossings. Crossings inside one fiber disappear by $mc_B = m$. The last two relations move a merger through a crossing. Every composite therefore reduces to the sorting diagram for the composite map, followed by the multiplications in its fibers. Associativity and the unit equations remove the remaining choices. These moves also prove naturality in every unital algebra homomorphism $B \to B'$.

At three inputs, with the remaining blocks ordered as $2|13$, this gives

$$q_{2|13}(x, y, z) = xy \otimes z + 1 \otimes xyz - x \otimes yz, \qquad mq_{2|13}(x, y, z) = xyz.$$

At four inputs,

$$q_{13|24}(x, y, z, w) = xyz \otimes w + x \otimes yzw - xy \otimes zw.$$

The intermediate factors have not been replaced by the product of the colliding entries. This is the coefficient information needed for the geometric residue identities.

16.3 A singular construction in every arity

Use the level-one Heisenberg vertex algebra V of Section 6.1, now over F. Its state space is $F[x_1, x_2, \ldots]$, its vacuum is 1, and its current modes are

$$J_{-m} = x_m, \qquad J_m = m\partial_{x_m} \quad (m > 0), \qquad J_0 = 0.$$

Write $J = x_1$ for the current state. The translation operator is $T_V = \sum_{m>0} m x_{m+1} \partial_{x_m}$. The field of x_m is $\partial_z^{m-1} J(z)/(m-1)!$. The field of a monomial is the normal ordered product of these fields. The commutator $[J_m, J_n] = m\delta_{m+n,0}$ gives

$$J(z)J(w) \sim \frac{1}{(z-w)^2}.$$

The double pole is the contraction $\sum_{m>0} m z^{-m-1} w^{m-1} = (z-w)^{-2}$ in the region $|z| > |w|$. Thus the pole and its normalization are fixed by the oscillator commutator. The arithmetic coefficients will multiply this contraction. All states are polynomials, and all products have an input-dependent finite pole order. No completion of the coefficient algebra is imposed.

Take $X = \mathbb{A}^1_F$ and $H = \omega_X \otimes_F V$. We use right differential modules, with

$$(f(z)\,dz \otimes v)\partial_z = -f'(z)\,dz \otimes v - f(z)\,dz \otimes T_V v.$$

For $t = z_1 - z_2$, the local-current face is the full principal-part map

$$r_V(f; v, w) = \mathrm{pp}_{t=0}\big(f Y_V(v, t) w\big).$$

Normal derivatives are retained: t^{-q-1} corresponds to $\partial\,\partial_t^{q}/q!$, where $\partial t = 0$. Thus multiplication by t lowers the principal-part order and right multiplication by ∂_t raises it with coefficient $q+1$.

We use the local-current Chevalley–Cousin construction of Beilinson–Drinfeld, §3.4.11. Its input is the chiral differential module of V, with the above full faces. The two-step face sum vanishes: disjoint collisions cancel with their determinant signs, and a three-block collision is the chiral Jacobi identity. For the Heisenberg algebra these identities also follow from Wick expansion and the central commutator of the modes. This local-current input is distinct from the ordered coefficient multiplication in B.

For n labeled positions, the ordered collision scheme R_n has one chart X^n for each ordering. Identify two charts away from the diagonals on which their orderings disagree.

A partition π has one coordinate for each block. Write $i_\pi : X^\pi \to X^n$ for its diagonal and j_π for the distinct-block open subset of X^π. Define

$$Q_\pi(V) = (i_\pi)_*(j_\pi)_* j_\pi^*(\boxtimes_{A\in\pi} H).$$

Order the blocks by their last entries and retain the later root at a merger. Orient its normal coordinate by $z_i - z_j$ for $i < j$. With the ordered density line the face that removes block i has sign $(-1)^{i-1}$. These conventions fix the signed current face $d^V_{\pi,\eta}$ for every elementary coarsening $\pi \lessdot \eta$.

The associative construction uses consecutive cuts in a fixed word, meaning a finite ordered list of insertion positions. To specify its carrier, let $\mathrm{OrdSurj}_+$ have the nonempty finite ordered sets as objects and monotone surjections as arrows. Put

$$\mathcal{W}_X = D(F) \times \varprojlim_{\mathrm{OrdSurj}_+} D\,\mathrm{Mod}(X^n),$$

The limit is taken in stable ∞-categories. We use unbounded right differential modules with quasi-coherent underlying modules. For $\alpha : [n] \twoheadrightarrow [m]$, the transition is extraordinary inverse image along the diagonal $d_\alpha(x)_i = x_{\alpha(i)}$. An object includes the transition identifications and their coherences. The factor $D(F)$ records the empty configuration independently.

For $0 < p < n$, let $U_p \subset X^n$ be the open set where the first p positions are distinct from the remaining positions. Write $j_p : U_p \hookrightarrow X^n$. The cut product is

$$(M \star N)_n = \bigoplus_{p=0}^{n} (j_p)_*\,(M_p \boxtimes N_{n-p})\big|_{U_p}.$$

An empty block means scalar tensoring on all of X^n. The unit is F at the empty configuration and zero elsewhere. A strong cut coalgebra has a counit and coassociative cut maps whose restrictions to each U_p are isomorphisms. For a connected coaugmented such coalgebra C, its cut cobar is the tensor algebra $T_\star(C_+[-1])$ on its positive part. Writing tc for desuspension, its differential is the derivation with

$$d(tc) = -t(d_C c) + \sum_{\overline{\Delta} c = c'\otimes c''} (-1)^{|c'|+1}(tc')(tc'').$$

Here $\overline{\Delta}$ is the sum of the nonempty cut maps.

THEOREM 16.3.1. Let B be a nonzero unital associative F-algebra concentrated in degree zero. The chartwise formula

$$C_n(V,B) = \bigoplus_{\pi\vdash[n]} Q_\pi(V)[|\pi|] \otimes_F B^{\otimes|\pi|}, \qquad d = \sum_{\pi\lessdot\eta} d^V_{\pi,\eta}\otimes q_{\pi,\eta} \tag{16.8}$$

defines a complex on every ordered chart and glues on R_n. The complexes on the standard word charts form a connected strong cut coalgebra in $\mathcal{W}_X$, with $C_0(V, B) = F$. This coalgebra is natural in unital algebra maps. Its cut cobar

$$\mathcal{A}_B = \Omega_{\mathrm{cut}} C(V, B)$$

is an associative algebra in the ordered cut-convolution category. Its binary field system is

$$Y(v \otimes b, z)(w \otimes c) = Y_V(v, z)w \otimes bc, \qquad T = T_V \otimes 1. \tag{16.9}$$

Proof. For fixed π and ν separated by two mergers, (16.7) makes every coefficient composite equal to $q_{\pi,\nu}$. The corresponding component of d^2 is therefore

$$\left(\sum_{\pi \lessdot \eta \lessdot \nu} d^V_{\eta,\nu} d^V_{\pi,\eta} \right) \otimes q_{\pi,\nu} = 0.$$

On a chart overlap use the usual current permutation and determinant identification, and use c_B to reorder coefficient blocks. The braid relation gives the overlap cocycle, and (16.7) gives compatibility with the differential. A partition containing an internal pair whose orders disagree has empty support on that overlap.

Under an ordered collision $\alpha : [n] \twoheadrightarrow [m]$, a partition term survives exceptional pullback only when it is saturated for α. Otherwise its distinct-block open factor is pulled to a collision, and $i^! j_* = 0$ makes that term vanish. The surviving terms are exactly $\pi = \alpha^{-1}(\eta)$, with the same coefficient factors and faces as $C_m(V, B)$. Closed-diagonal base change identifies their differential modules. For composite collisions the same saturated partitions survive, so the comparisons compose.

On the open subset where the first p positions are distinct from the last $n - p$, every partition crossing that cut disappears. A remaining partition is uniquely a partition of each block. Its coefficient complex is the external product of the two block complexes. These are the strong cut comparisons, and their associativity follows from splitting into three blocks.

The cobar is the tensor algebra on the shifted positive coefficient, with differential given by d and these cut maps. At a fixed configuration its positive tensor length is bounded by the arity. No infinite sum in that length is needed.

All arguments take place in the category of differential modules allowing arbitrary coefficient vector spaces. Tensoring a differential module by a vector space means the corresponding direct sum. Localization and closed-diagonal direct image commute with these sums. Thus neither an algebraic dual of B nor a finite-rank Riemann–Hilbert assertion is used.

For a finitely generated algebra, filter by word length and put the total word-length filtration on $B^{\otimes s}$. The maps c_B and q_f preserve it. Each finite-arity coefficient diagram is the filtered colimit of its finite-dimensional coefficient diagrams. This applies to the Leavitt algebra, even though its finite word-length spaces are not subalgebras. Naturality and the binary assertion follow directly from the formulas. □

The positive-cut contraction of Section 3.1 retains every nonconsecutive stratum. Here its normal derivatives and coefficient maps can be written explicitly. The cobar retracts onto a complex supported on

$$Z_n = \bigcap_{p=1}^{n-1} \bigcup_{i \le p < j} \Delta_{ij}; \qquad Z_3 = \Delta_{13}, \quad Z_4 = \Delta_{14} \cup (\Delta_{13} \cap \Delta_{24}).$$

The differential modules on these strata retain all normal derivatives. For a partition π, let $J(\pi)$ be the cuts crossed by none of its blocks. A cobar term is indexed by a subset $Q \subseteq J(\pi)$, with coefficient

$$\big(Q_\pi(V) \otimes B^{\otimes|\pi|}\big)[|\pi| - |Q| - 1].$$

If $r_{\le c}$ is the number of blocks to the left of a cut c, adding $c \notin Q$ has sign $(-1)^{\#\{q\in Q: q<c\}+1-r_{\le c}}$. Merging root-indexed blocks $i < j$ in the ℓth consecutive segment has sign $(-1)^{\ell-1+i}$ and coefficient map $r^V_{ij} \otimes q_{ij}$, where r^V_{ij} is the unsigned current face. Write v and δ for these two parts of the differential.

For $J(\pi) \neq \varnothing$, put $c_0 = \min J(\pi)$. Define h_0 to remove c_0 with sign $(-1)^{1-r_{\le c_0}}$ when $c_0 \in Q$, and to be zero otherwise. It is also zero when $J(\pi) = \varnothing$.

Let i include the terms with no admissible cut, and let p_0 project onto them. Adding and removing c_0 gives $vh_0 + h_0 v = 1 - ip_0$. All other cut terms cancel in pairs. Merging blocks cannot create an admissible cut, so these terms form a subcomplex for δ. The perturbed projection and homotopy are

$$p = p_0 \sum_{q=0}^{n-1} (-\delta h_0)^q, \qquad H = h_0 \sum_{q=0}^{n-1} (-\delta h_0)^q.$$

Each residue lowers the number of blocks, which proves finiteness. With these maps one has $dH + Hd = 1 - ip$. After suspension, put $\bar H = -sHs^{-1}$, $\bar i = sis^{-1}$ and $\bar p = sps^{-1}$. If b_2 is the suspended cobar product, its transferred operations are specified in every arity by

$$F_1 = \bar i, \quad \Lambda_n = \sum_{a+b=n} b_2(F_a \otimes F_b), \quad F_n = -\bar H \Lambda_n, \quad B_n = \bar p \Lambda_n \quad (n \ge 2).$$

These are finite homological perturbation formulas. The coefficient maps commute with the contraction, so algebra homomorphisms preserve the full transferred system.

For the arithmetic algebra, (16.9) realizes (16.3) with a genuine pole. Let ϵ_V extract the constant Fock coefficient. It is a linear functional, not a character of the vertex algebra. In the expansion region $|z_1| > |z_3|$,

$$\begin{aligned}(\epsilon_V \otimes 1) Y(J \otimes T'_0, z_1) Y(1 \otimes T'_0, z_2) Y(J \otimes \rho(T_g), z_3) Y(1 \otimes T_0, z_4)(1 \otimes 1) \\ = \frac{b_g}{(z_1 - z_3)^2}\, 1_B.\end{aligned}$$

Closing the coefficient line multiplies this by d, giving $-e_g/(z_1 - z_3)^2$. The rational function determines the other expansion regions. Arithmetic enters through the marked endomorphisms and junctions. The Heisenberg level remains one.

16.4 Relative interfaces and the connected comparison

The field realization retains compositions of coefficients. For its tensor structure, recall the bimodules of Section 8.4 with the following conventions. Put $R = B^{\mathrm{op}}$. For an endomorphism σ of B, let P_σ have underlying vector space B and actions

$$a^{\mathrm{op}} \cdot b \cdot c^{\mathrm{op}} = \sigma(c) b a.$$

An intertwiner $x : \sigma \to \tau$ acts by $b \mapsto xb$. Every left R-linear map has this form, and right R-linearity is exactly the intertwining equation. Hence this construction is fully faithful. The tensor comparison is

$$P_\sigma \otimes_R P_\tau \longrightarrow P_{\sigma\tau}, \qquad b \otimes c \longmapsto \sigma(c) b. \tag{16.10}$$

It is balanced, has inverse $z \mapsto z \otimes 1$, and is associative because $\sigma(\tau(e)c)b = \sigma\tau(e)\sigma(c)b$. It takes tensor products of intertwiners to $x\sigma(y)$. The unit is $P_{\mathrm{id}} = R$. Every P_τ is free as a left R-module, so the same formula computes the derived balanced product.

Let $A = \mathcal{A}_F$ be the Heisenberg cut cobar, let $\star$ denote ordered cut convolution, and put

$$\mathfrak{R} = A \otimes_F R, \qquad \mathfrak{P}_\sigma = A \otimes_F P_\sigma.$$

Coefficient vector spaces act centrally on differential modules. The A-factors are always multiplied in their original order.

Theorem 16.4.1. There is a faithful strong tensor functor

$$C \longrightarrow \mathrm{Bimod}_{\mathfrak{R}}(\mathcal{W}_X), \qquad \sigma \longmapsto \mathfrak{P}_\sigma,$$

where $\mathcal{W}_X$ is the derived ordered cut-convolution category and the target tensor product is $\star^{\mathbb{L}}_{\mathfrak{R}}$. It preserves the specified duality and all fusion-network evaluations.

Proof. For coefficient bimodules of this form, the two-sided bar gives

$$(A \otimes P) \star^{\mathbb{L}}_{A \otimes R} (A \otimes Q) \simeq A \otimes (P \otimes^{\mathbb{L}}_R Q). \tag{16.11}$$

The comparison multiplies the A-factors in simplicial degree n in their original order and leaves the coefficient bar $P \otimes R^{\otimes n} \otimes Q$. One can compute using the free left coefficient resolution of Q. After extension by A its terms are free left $A \otimes R$-modules. The augmented resolution contracts by its extra unit degeneracy. This proves (16.11).

Equivalently, for P_σ and P_τ it is the internal version of the explicit free-module isomorphism (16.10).

All parenthesizations for three or more factors realize the same multisimplicial bar. Multiplying the geometric factors in order gives the same map in each case, proving the associativity and unit coherences.

Combine this comparison with (16.10) and extend to finite sums and retracts. Evaluation at the empty configuration recovers P_σ and its coefficient maps, proving faithfulness. The images of the cup and cap obey the same snake equations. Applying the functor to (16.4) proves the assertion about network values. □

Here $\mathfrak{R}_\emptyset = R$. This empty algebra is part of the tensor comparison. There is also a connected construction with empty coefficient F, and the relation between them is an actual algebra map. Apply Theorem 16.3.1 to R, and set $G_R = \mathcal{A}_R$. If $m_\pi : R^{\otimes|\pi|} \to R$ multiplies in block order, then

$$m_\eta q_{\pi,\eta} = m_\pi.$$

Let $\tau : C(V, F)_+ \to A$ be the universal cobar twisting map. On the π-term define $t_R = \tau \otimes m_\pi$. The last identity makes it compatible with residues, and on a cut the total product is the product of the two block products. Thus t_R obeys the twisting equation and induces

$$\theta_R : G_R \longrightarrow \mathfrak{R}. \tag{16.12}$$

On a cobar monomial it retains the geometric monomial and multiplies all coefficient factors in their original order. This construction takes place in the word category $\mathcal{W}_X$ and is natural in R. Its empty component is the unit map $F \to R$.

Intertwiners have a linear connected realization as well. For an R-bimodule P, form the square-zero algebra $R \ltimes P$. Give R weight zero and P weight one. Multiplication and the exchange preserve total weight, so $\mathcal{A}_{R\ltimes P}$ is weight graded. Its weight zero part is G_R. Its weight one part, denoted $L_R(P)$, is a G_R-bimodule.

Each coefficient in weight one contains exactly one P-factor. Consequently $P \mapsto L_R(P)$ is additive and linear on bimodule maps. Its one-point component is $H \otimes P$, so it is faithful on degree-zero coefficient maps.

Taking weight one in (16.12) for $R \ltimes P$ gives the comparison

$$L_R(P) \longrightarrow \mathrm{Res}_{\theta_R}(A \otimes P). \tag{16.13}$$

It is the identity at one point. At the empty configuration it is $0 \to P$.

This extraction of weight one is necessary. For example, with $M_\sigma = {}_\sigma B_B$, an intertwiner x gives an algebra map

$$B \ltimes M_\sigma \longrightarrow B \ltimes M_\tau, \qquad (b, m) \longmapsto (b, xm).$$

The algebra map has the identity on its weight zero part, so it is not linear as a function of x. Its weight one map is linear. Such maps realize the intertwiners, but do not identify their transported tensor product with $\bigstar^{\mathbb{L}}_{G_R}$.

16.5 Analytic states and relative sewing

Fix an embedding $F \hookrightarrow \mathbb{C}$ and extend scalars along it. The oscillator construction has an analytic realization on all states. This also gives an analytic meaning to the relative interfaces.

For an R-bimodule P put

$$\mathsf{H}(P) = V \otimes P, \qquad \mathsf{H}(P)_n = V_n \otimes P, \qquad \widehat{\mathsf{H}(P)} = \prod_{n\geq 0} \mathsf{H}(P)_n.$$

Here $\deg x_m = m$. States belong to the direct sum. Outputs of fields belong to the product. The restricted dual is $\bigoplus_{n\geq 0} \mathsf{H}(P)_n^*$, with the full algebraic dual in each degree.

The conformal vector is $\frac{1}{2}x_1^2 \otimes 1$ in $\mathsf{A} = \mathsf{H}(R)$. Its central charge is one.

An *oscillator interface* is $\mathsf{H}(P)$ with its Heisenberg action and commuting left and right R-actions. Morphisms commute with these three actions. If $f : P \otimes_R Q \to S$ is a bimodule map, define

$$\mathcal{I}_f(v \otimes p, z)(w \otimes q) = Y_V(v, z)w \otimes f(p \otimes_R q). \tag{16.14}$$

A balanced intertwining operator means an intertwining operator for the Heisenberg vertex algebra, with these left, right, and balancing identities on its coefficient factors. This definition includes every oscillator descendant.

THEOREM 16.5.1. The oscillator interfaces have the following properties.

(i) Their morphisms are exactly $1_V \otimes f$, for bimodule maps f. Every balanced intertwining operator is uniquely of the form (16.14). Consequently their relative fusion is represented by

$$\mathsf{H}(P) \boxtimes_{\mathsf{A}} \mathsf{H}(Q) = \mathsf{H}(P \otimes_R Q).$$

(ii) Products and iterates of their fields converge absolutely after pairing with any restricted-dual state, in the usual nested-disc regions. They are expansions of rational functions. Every genus-zero sewing of these interfaces respects their tensor associativity and units.

(iii) The functor $\sigma \mapsto \mathsf{H}(P_\sigma)$ is fully faithful and strong tensor. It preserves the specified cups, caps, and marked arithmetic junctions on all states. Its tensor-product field is

$$\mathcal{I}_{\sigma,\tau}(v \otimes b, z)(w \otimes c) = Y_V(v, z)w \otimes \sigma(c)b.$$

(iv) Taking full normal principal parts gives the relative chiral interfaces of Theorem 16.4.1. The comparison commutes with every collision, consecutive cut, and cobar differential.

Proof. The vectors killed by all positive Heisenberg modes in $\mathsf{H}(P)$ are exactly $1 \otimes P$. A map commuting with the modes is determined there, because the negative modes generate every polynomial state. The coefficient actions give the bimodule condition. This proves the morphism assertion.

For an intertwining operator $\mathcal{I}$, translation gives $\partial_z \mathcal{I}(1 \otimes p, z) = 0$. Its value on $1 \otimes q$ has weight zero, hence is $1 \otimes f(p, q)$. The Heisenberg commutator and iterate identities determine its values on all states by induction on the number of negative modes. They give exactly (16.14). Balancing says $f(pr, q) = f(p, rq)$, and the outer actions say that the induced map on $P \otimes_R Q$ is a bimodule map. This proves the universal property in (i).

Wick expansion of finitely many polynomial states has finitely many contraction patterns. Each contraction is a derivative of $(z_i - z_j)^{-2}$. Pairing with a restricted-dual state leaves a finite sum of rational functions. Their Taylor expansions converge absolutely when each inner disc is contained in its outer disc and avoids the remaining insertions. The finitely many coefficient products lie in a finite-dimensional subspace of the algebraic coefficient space, so no norm or completion of R is needed. Changing a tree changes only the expansion region of the same function and the bracketing of the same balanced coefficient product.

This proves (ii).

Apply (i) to (16.10). Its associativity, unit, and intertwiner equations prove (iii), first on endomorphisms and then on finite sums and retracts. The cups and caps are the corresponding coefficient maps tensored with 1_V. Their snake identities therefore hold on every descendant.

Finally, the state identification sends $x_{m_1} \cdots x_{m_l} \otimes p$ to $J_{-m_1} \cdots J_{-m_l} 1 \otimes p$. It intertwines translation and all fields. It therefore identifies the right differential-module actions and every full principal part. The coarsenings multiply the same ordered coefficients on both sides. The cut maps select the same partitions. These identities identify the whole Cousin diagram and hence its cobar, proving (iv). □

The sum over oscillator descendants in a sewing is explicit. For a partition $\lambda = (1^{m_1} 2^{m_2} \cdots)$ put $x_\lambda = \prod_j x_j^{m_j}$ and $z_\lambda = \prod_j j^{m_j} m_j!$. Normalize the Heisenberg pairing by $\langle 1, 1\rangle = 1$ and $\langle J_{-m} v, w\rangle = \langle v, J_m w\rangle$. Identify the opposite-coordinate dual Fock space through this pairing.

Its sewing tensor is

$$\mathcal{P}(t) = \sum_\lambda \frac{t^{|\lambda|}}{z_\lambda} x_\lambda \otimes x_\lambda, \qquad |\lambda| = \sum_j j m_j.$$

Coefficient factors are contracted over R, by the relative evaluation. They are not summed over a vector-space basis of R. The Wick argument in the proof establishes the convergence of the resulting matrix coefficients on a sewing annulus. Omitting the positive oscillator degrees would change, for example, the expansion

$$\frac{1}{(z - w)^2} = \sum_{n \geq 1} n\, z^{-n-1} w^{n-1}.$$

Thus every arithmetic category in the construction has a full analytic ordered realization, with nonconstant fields and all descendants. It is a relative theory with infinite-dimensional weight-zero coefficients.

This qualification cannot be removed by truncating the same coefficient action. A finite-dimensional unital B-module W would satisfy $W \simeq W^{\oplus 2N}$ by the Leavitt generators, hence $\dim W = 2N \dim W$ and $W = 0$. A realization with finite-dimensional homogeneous state spaces must use a different coefficient carrier.

16.6 Finite coefficients and categorical symmetry

Semisimplicity provides a finite carrier. Its extra structure is essential: the allowed maps must respect the right action of the fusion category. Without this condition a finite matrix realization introduces new junctions.

Continue over $\mathbb{C}$. Choose representatives $(S_i)_{i\in I}$ of the simple objects of C, with $S_0 = 1$, and put

$$R_0 = \bigoplus_{i\in I} \mathbb{C}e_i, \qquad e_i \mathsf{P}_X e_j = \mathrm{Hom}_C(S_i, X \otimes S_j).$$

The e_i are orthogonal idempotents with sum one. A map $x : X \to Y$ acts on P_X by $f \mapsto (x \otimes 1)f$. With $a_{X,Y,Z} : (X \otimes Y) \otimes Z \to X \otimes (Y \otimes Z)$, the tensor comparison is

$$\mu_{X,Y} : \mathsf{P}_X \otimes_{R_0} \mathsf{P}_Y \longrightarrow \mathsf{P}_{X\otimes Y}, \qquad f \otimes g \longmapsto a^{-1}_{X,Y,S_k}(1_X \otimes g)f, \tag{16.15}$$

where $f : S_i \to X \otimes S_j$ and $g : S_j \to Y \otimes S_k$.

To describe the retained symmetry, associate to a finite R_0-bimodule P the linear functor

$$T_P(S_j) = \bigoplus_i S_i \otimes_{\mathbb{C}} e_i P e_j.$$

Here tensoring an object with a vector space means the corresponding finite direct sum. Extend T_P to sums and maps by linearity.

A right C-module structure on T_P consists of natural isomorphisms

$$\lambda_{M,Z} : T_P(M \otimes Z) \longrightarrow T_P(M) \otimes Z$$

compatible with the unit and associator. Explicitly, the two maps from $T_P((M \otimes Z) \otimes W)$ to $(T_P(M) \otimes Z) \otimes W$ agree:

$$(\lambda_{M,Z} \otimes 1_W)\lambda_{M\otimes Z,W} = a^{-1}_{T_P(M),Z,W}\lambda_{M,Z\otimes W}T_P(a_{M,Z,W}).$$

A morphism must commute with every $\lambda_{M,Z}$. These are finite conditions: simple M, Z, W and bases of their junction spaces determine all the displayed maps and equations by additivity.

Let $\mathcal{S}_C$ be this category. Its tensor product is composition of module functors, expressed on coefficients by $P \otimes_{R_0} Q$. For P_X, the functor is $L_X(M) = X \otimes M$, and its module structure is $\lambda^X_{M,Z} = a^{-1}_{X,M,Z}$.

THEOREM 16.6.1. The maps (16.15) give a tensor equivalence

$$C \xrightarrow{\sim} \mathcal{S}_C, \qquad X \longmapsto (\mathsf{P}_X, \lambda^X).$$

In particular the symmetry-compatible junctions between these finite bimodules are exactly the original junctions of C. The equivalence preserves the specified duality and spherical evaluations.

Proof. Choose inclusions $g_{j,\alpha} : S_j \to Y \otimes S_k$ and projections $\bar{g}_{j,\alpha}$ with $\sum_{j,\alpha} g_{j,\alpha}\bar{g}_{j,\alpha} = 1$. The inverse of (16.15) sends $h : S_i \to (X \otimes Y) \otimes S_k$ to

$$\sum_{j,\alpha} (1_X \otimes \bar{g}_{j,\alpha}) a_{X,Y,S_k} h \otimes g_{j,\alpha}.$$

The two composite identities follow from this resolution of the identity. They also prove independence of its choice. The associativity coherence is the pentagon for a, and the unit coefficient is $\mathsf{P}_1 = R_0$.

Every linear functor of the finite semisimple category is recovered from its matrix of spaces $\mathrm{Hom}(S_i, T(S_j))$. The same resolution proves that composition of functors is the balanced product of their matrices. Thus the definition of $\mathcal{S}_C$ retains exactly the module functors and their module-natural maps.

For a module functor T, its structure map at $(1, M)$ identifies $T(M)$ naturally with $T(1) \otimes M$. The module-functor equation makes this identification compatible with the right action. For a module-natural map $\eta : L_X \to L_Y$, the same equation gives $\eta_M = \eta_1 \otimes 1_M$, with the unit constraints understood. Evaluation at 1 is therefore an inverse equivalence, on both objects and maps. Composition identifies $L_X L_Y$ with $L_{X\otimes Y}$ through a^{-1}. This proves the tensor assertion.

Transport the given evaluations, coevaluations, and pivotal maps through this equivalence. Their defining equations are preserved, as is every closed composition. This gives the asserted duality. □

For the near-group rules the size of the construction is explicit. Order the simples by G followed by ρ. The matrix of dimensions of P_ρ is

$$D_\rho = \begin{pmatrix} 0_{N\times N} & \mathbf{1} \\ \mathbf{1}^{\mathrm{t}} & N \end{pmatrix}.$$

For $g \in G$, D_g is the permutation $h \mapsto g + h$ on the G-block and is the identity on the ρ-entry. Hence $\dim R_0 = N + 1$ and $\dim \mathsf{P}_\rho = 3N$.

If $\mathbf{d} = (1, \dots, 1, d)^{\mathrm{t}}$, then

$$D_g\mathbf{d} = \mathbf{d}, \qquad D_\rho\mathbf{d} = d\mathbf{d}, \qquad d^2 = N + Nd.$$

The last identity also explains the relative dimension. Closing a coefficient line over the j-th boundary weights its i-th summand by d_i/d_j. The total is d_X. These weights are the regular-module trace $\mathrm{tr}_{S_i}(1) = d_i$ of the given spherical category. They need not be positive.

The symmetry condition cannot be suppressed. Ordinary bimodule maps $R_0 \to R_0$ form $\mathbb{C}^{\mathcal{I}}$. A module-natural endomorphism of the identity has scalars c_i satisfying $c_i = c_0$ by evaluating its compatibility at $(1, S_i)$. Its space is consequently $\mathbb{C}$, as required by the tensor unit of C.

The reconstructed weak Hopf action

The categorical symmetry has an equivalent description by a finite weak Hopf algebra. It uses the left-insertion tensorator (16.15). The choice matters for its associator coefficients.

Let P denote the vector-space-valued functor underlying the preceding construction and put

$$H_C = \mathrm{Nat}(\mathsf{P}, \mathsf{P}) = \bigoplus_{s\in\mathcal{I}} \mathrm{End}_{\mathbb{C}}(\mathsf{P}_{S_s}).$$

Multiplication is composition. These matrices need not be R_0-bilinear. An element h acts on every P_X, with its action on sums and retracts determined by naturality.

Let $\pi_{X,Y}$ be the balanced quotient and let

$$j_{X,Y}(p \otimes_{R_0} q) = \sum_i pe_i \otimes e_i q$$

be its section. The coproduct is uniquely specified by its action on all pairs of simple representations:

$$(\Delta h)_{X,Y} = j_{X,Y}\mu_{X,Y}^{-1} h_{X\otimes Y}\mu_{X,Y}\pi_{X,Y}. \tag{16.16}$$

In particular $\Delta(1) = E$, where $E(p \otimes q) = \sum_i pe_i \otimes e_i q$. With $\epsilon_0(e_i) = 1$, its counit is

$$\epsilon(h) = \epsilon_0(h_1(1_{R_0})), \qquad \epsilon(1) = |\mathcal{I}|,$$

where $\mathcal{I}$ denotes the chosen set of simple labels.

These formulas define a weak Hopf algebra. Here "weak" means that the coproduct preserves multiplication but its unit is the idempotent E, and the counit obeys the corresponding weak counit identities. Its representation tensor product is $E(U \otimes V)$, with the action given by Δ. Its unit representation is R_0. This is the dual form of Hayashi's finite semisimple reconstruction, Theorems 3.1 and 4.1.

The identities are visible in the formulas. Multiplicativity uses $\pi j = 1$. Coassociativity uses the associativity of μ and the equality of the two projections onto matching triples of boundary idempotents. The weak unit and counit equations reduce to $e_i e_j = \delta_{ij} e_i$ and $\epsilon_0(e_i) = 1$.

The antipode is the transpose action on the dual coefficients. More explicitly, let

$$b_X(q, p) = \epsilon_0 \mathsf{P}(\mathrm{ev}_X)\mu_{X^*,X}\pi_{X^*,X}(q \otimes p).$$

This pairing between P_{X^*} and P_X is nondegenerate. Define $S(h)$ by $b_X(q, S(h)_X p) = b_X(h_{X^*}q, p)$. The duality snake equations give the antipode equations, with the source and target counital projections in place of the scalar unit.

Every finite H_C-module is a sum of the displayed simple modules P_{S_s}. Its intertwiners are precisely the maps coming from C, and (16.16) identifies its tensor product with (16.15). Thus $C \simeq \mathrm{Rep}(H_C)$ as a tensor category. Equivalently, one can impose this weak Hopf action instead of the module-functor symmetry maps.

For the near-group rules,

$$\dim H_C = N(N+1)^2 + 9N^2.$$

At $N = 2$ this is 54. On $\mathsf{P}_\rho \otimes \mathsf{P}_\rho$, the idempotent E has rank 18 in dimension 36. Its role cannot be replaced by the identity.

The associator in a pointed example

Let G_0 be a finite abelian group and let $\Omega : G_0^3 \to \mathbb{C}^\times$ be a normalized three-cocycle. In $\mathrm{Vec}_{G_0}^{\Omega}$, the simple label g has coefficient basis $v_{g,j}$, with left endpoint $g + j$ and right endpoint j. The tensorator is

$$\mu(v_{g,h+j} \otimes_{R_0} v_{h,j}) = \Omega(g, h, j)^{-1} v_{g+h,j}.$$

Thus a nontrivial associator survives even though every simple fusion multiplicity is one.

Write E^{g}_{ab} for the matrix sending $v_{g,b}$ to $v_{g,a}$ and killing the other vectors and simple blocks. The reconstruction gives

$$\begin{aligned} E^{g}_{ab}E^{h}_{cd} &= \delta_{g,h}\delta_{b,c}E^{g}_{ad}, \\ \Delta(E^{s}_{ab}) &= \sum_{g+h=s} \frac{\Omega(g,h,a)}{\Omega(g,h,b)} E^{g}_{h+a,h+b} \otimes E^{h}_{ab}, \\ \epsilon(E^{g}_{ab}) &= \delta_{g,0}, \\ S(E^{s}_{ab}) &= \frac{\Omega(s,-s,b+s)}{\Omega(s,-s,a+s)} E^{-s}_{b+s,a+s}. \end{aligned} \tag{16.17}$$

The counit is nonzero on every matrix unit in the unit block, including the off-diagonal ones.

Indeed, composing μ, the matrix unit and μ^{-1} contributes first $\Omega(g,h,b)^{-1}$, then $\Omega(g,h,a)$. Matching the endpoints gives the displayed matrix indices. Every matrix unit in the unit block sends 1_{R_0} to a vector of coordinate sum one. The dual pairing pairs $v_{-g,j+g}$ with $v_{g,j}$, with factor proportional to $\Omega(-g,g,j)^{-1}$. Its transpose gives the antipode. The evaluation normalization cancels in the ratio.

The identity

$$\Omega(h,k,j)\Omega(g,h+k,j)\Omega(g,h,k) = \Omega(g+h,k,j)\Omega(g,h,k+j)$$

is the equality of the iterated tensorators. It proves coassociativity directly. The matching-endpoint projections and duality snakes give the remaining weak Hopf identities.

For $G_0 = \mathbb{Z}/n$, choose representatives $0,\dots,n-1$ and a primitive root ζ_n. The carry cocycle is

$$\Omega(g,h,j) = \zeta_n^{g\lfloor (h+j)/n \rfloor}.$$

The cocycle equation expresses equality of the total carry under two parenthesizations. At $n=3$, the $(g,h)=(1,2)$ summand of $\Delta(E^{0}_{01})$ and one antipode value are

$$\zeta_3^{-1}E^{1}_{20}\otimes E^{2}_{01}, \qquad S(E^{1}_{02}) = \zeta_3^{-1}E^{2}_{01}.$$

These values distinguish the ratio in (16.17) from its inverse. Even when $\Omega = 1, \Delta(1)$ remains the matching-endpoint projection.

16.7 Finite-dimensional conformal grades for the general family

We now combine this finite coefficient carrier with an explicit conformal theory. Let $\Lambda = E_8$ be the positive definite lattice

$$\Lambda = \{x \in \mathbb{Z}^8 \cup (\mathbb{Z}+\tfrac{1}{2})^8 : \textstyle\sum_i x_i \in 2\mathbb{Z}\}.$$

Its even unimodular form gives the holomorphic lattice vertex algebra $W = V_\Lambda$ of central charge eight, as in Dong–Mason.

Its full space of states is

$$W = \bigoplus_{\alpha\in\Lambda} \operatorname{Sym}\left(\bigoplus_{n>0} \mathbb{C}^8 t^{-n}\right) e^{\alpha}.$$

A monomial $h^{1}_{-n_1}\cdots h^{r}_{-n_r}e^{\alpha}$ has weight $\sum n_i + (\alpha,\alpha)/2$. Positive definiteness makes each weight space finite dimensional.

For completeness, choose a normalized lattice cocycle ϵ with $\epsilon(\alpha,\beta)/\epsilon(\beta,\alpha) = (-1)^{(\alpha,\beta)}$. The currents obey $[h_m, k_n] = m(h,k)\delta_{m+n,0}$, and the lattice fields are

$$Y(e^{\alpha},z) = \exp\Big(\sum_{n>0}\frac{\alpha_{-n}}{n}z^{n}\Big)\exp\Big(-\sum_{n>0}\frac{\alpha_{n}}{n}z^{-n}\Big)e_{\alpha}z^{\alpha_0},$$
$$e_{\alpha}e^{\beta} = \epsilon(\alpha,\beta)e^{\alpha+\beta}.$$

Normal products with differentiated currents define the fields of all other states. The translation is L_{-1} and the conformal vector is $\frac{1}{2}\sum_{a=1}^{8}(h^a_{-1})^2 1$ for an orthonormal basis (h^a).

For $(P,\lambda)\in\mathcal{S}_C$ define $\mathsf{V}(P) = W\otimes P$. Retain the R_0 actions and the finite module-functor maps λ. A field is required to respect them. For a compatible junction $f : P\otimes_{R_0} Q\to S$ it is

$$\mathcal{J}_f(u\otimes p,z)(v\otimes q) = Y_W(u,z)v\otimes f(p\otimes_{R_0} q). \tag{16.18}$$

The algebra of boundary vacua is $W\otimes R_0$. Its weight-zero space is R_0. Completions are products over conformal weights, and states themselves remain finite sums.

Equivalently, H_C acts on the coefficient factors and the fields obey the concrete covariance equation

$$h\,\mathcal{J}_f(u\otimes p,z)(v\otimes q) = \sum_{(h)}\mathcal{J}_f(u\otimes h_{(1)}p,z)(v\otimes h_{(2)}q),\qquad \Delta h = \sum_{(h)} h_{(1)}\otimes h_{(2)}.$$

The weak coproduct projects to the matching boundary sectors before the field is applied.

The sewing domain

A sewing datum starts with finitely many compact pointed Riemann surfaces, possibly disconnected. At each paired point choose coordinate discs of radii r_j, r'_j, with all discs pairwise disjoint. Glue their coordinates by $u_j v_j = t_j$, where

$$0 < |t_j| < r_j r'_j.$$

Each initial connected component must have a marked point that remains unsewn. Fix the local coordinates, contragredient pairings and the initial conformal block. Fractional powers of t_j use a chosen branch of $\log t_j$.

For a C_2-cofinite vertex algebra and finitely generated modules, Gui's theorem gives absolute, locally uniform convergence of the full propagator sums on this domain. Here C_2-cofiniteness means that the quotient by the span of $u_{(-2)}v$ is finite dimensional. The theorem allows simultaneous sewings that create handles. It concerns the specified conformal block. It does not choose a globally normalized scalar partition function.

If an initial component has no remaining insertion, first insert a vacuum. Apply propagation of vacua, then remove the auxiliary mark through the propagation isomorphism. The hypothesis is not removed by simply omitting the point. All finite simultaneous-sewing assertions below use this domain.

THEOREM 16.7.1. Every arithmetic fusion category considered here has a fully faithful analytic ordered realization $X\mapsto \mathsf{V}(\mathsf{P}_X,\lambda^X)$ with finite-dimensional homogeneous state spaces. Its symmetry-compatible relative fusion is

$$\mathsf{V}(\mathsf{P}_X)\boxtimes_{W\otimes R_0}\mathsf{V}(\mathsf{P}_Y) = \mathsf{V}(\mathsf{P}_{X\otimes Y}),$$

with tensorator (16.15) on coefficients. Its junctions, duality, and all fusion-tree sewings recover C. All descendant sewings on the domain of Section 16.7 converge absolutely and locally uniformly, including the permitted sewings that create handles. Taking full collision principal parts gives relative interfaces in the ordered word category, with compatible cut-cobar comparisons in every arity.

Proof. The lattice algebra is simple and its vacuum module has scalar endomorphisms. A W-module map between finite sums of this module is therefore $1_W \otimes f$. The space of vacuum-to-vacuum intertwining operators is one dimensional, generated by Y_W. Consequently every balanced field between these finite sums has the form (16.18). Its balancing and symmetry identities say precisely that f is a morphism in $\mathcal{S}_C$ out of $P \otimes_{R_0} Q$. Theorem 16.6.1 now proves full faithfulness, the tensor assertion, and preservation of the specified duality.

An iterated product is a finite sum of W conformal blocks multiplied by compositions of coefficient maps. The vertex-algebra associativity identifies their analytic continuations. In fusion-tree bases the coefficient comparison is the original associator of C. The module-functor pentagon makes this identity compatible with every retained symmetry map and every further cut.

Positive definiteness makes the lattice algebra regular by Dong–Li–Mason, Theorem 3.16. Abe–Buhl–Dong, Theorem 4.5, then gives rationality and C_2-cofiniteness. All the state spaces in the construction are finite sums of its vacuum module. Its propagator is the sum of the identity tensors of W_n, multiplied by t^n. The coefficient contractions use the transported relative evaluations. They are finite dimensional, so each sewn expression is a finite linear combination of ordinary W sewings.

Gui's Theorem 13.1 applies to each summand with all the hypotheses of Section 16.7. In particular, each initial connected component retains an unsewn marked point. It permits simultaneous sewings and disconnected initial surfaces, including sewings that create handles. Finite linear combinations preserve absolute and locally uniform convergence. The sewing identities on coefficients and states consequently remain valid after these sums.

Finally apply the local-current Cousin construction to the ordinary lattice chiral algebra and denote its cut cobar by A_W. The proof of Theorem 16.3.1 with scalar coefficients uses only translation, finite pole orders, and chiral Jacobi, all of which hold for W. Set

$$\mathfrak{R}_W = A_W \otimes R_0, \qquad \mathfrak{P}_X = A_W \otimes \mathsf{P}_X.$$

The relative bar comparison (16.11) gives

$$\mathfrak{P}_X \star^{\mathbb{L}}_{\mathfrak{R}_W} \mathfrak{P}_Y \simeq A_W \otimes (\mathsf{P}_X \otimes_{R_0} \mathsf{P}_Y) \xrightarrow{1 \otimes \mu_{X,Y}} \mathfrak{P}_{X \otimes Y}.$$

There are no higher coefficient Tor groups because R_0 is semisimple.

The normal principal part of (16.18) is the lattice-current face tensored with its coefficient junction. At a nonconsecutive collision the full ordered coefficient tensor is retained as a spectator. Thus no interchange of the two interface labels is needed. Every geometric face commutes with the finite symmetry maps, and the relative bar comparison commutes with every cut. These identities prove the geometric assertion on the word carrier. □

For example, take a unit-norm current in W and close the arithmetic junction of (16.5) on its coefficient line. The resulting two-current amplitude is $-e_1(z-w)^{-2}$. All its higher oscillator and lattice descendants are present. At $N = 2$, the three sector multiplicities are 3, 3, 6. Since $\dim W_1 = 248$, their first positive grades have dimensions 744, 744, 1488.

This is a theory with specified categorical symmetry and several boundary vacua. The underlying ordinary lattice-module category does not encode C by itself. The finite symmetry maps are part of the field theory, and their compatible junctions encode precisely C. In particular this construction makes no assertion that C is the category of local modules of a vertex algebra.

16.8 THE OBSTRUCTION AT THE EMPTY CONFIGURATION

The defect of restriction along (16.12) is already visible at the empty configuration. Set

$$\mathcal{T}_R = \mathfrak{R} \star^{\mathbb{L}}_{G_R} \mathfrak{R}, \qquad \epsilon_R : \mathcal{T}_R \to \mathfrak{R}.$$

Associativity of relative tensor products gives, for two $\mathfrak{R}$-bimodules P, Q,

$$\operatorname{Res} P \star^{\mathbb{L}}_{G_R} \operatorname{Res} Q \simeq \operatorname{Res}\Big(P \star^{\mathbb{L}}_{\mathfrak{R}} \mathcal{T}_R \star^{\mathbb{L}}_{\mathfrak{R}} Q \Big).$$

The comparison with $\operatorname{Res}(P \star^{\mathbb{L}}_{\mathfrak{R}} Q)$ uses ϵ_R. At the empty configuration it is multiplication $R \otimes_F R \to R$. For $r \notin F$ 1 its kernel contains the nonzero element $1 \otimes r - r \otimes 1$. A linear functional taking 1 to zero and r to one proves nonvanishing. The restricted relative unit also has empty coefficient R, whereas the G_R-bimodule unit has coefficient F.

Changing the particular connected bimodules cannot remove this problem.

THEOREM 16.8.1. Let D be an algebra in $\mathcal{W}_X$ with $D_\emptyset \simeq F$ as a unital algebra. Let $\mathcal{D}$ be a rigid category with the fusion rules

$$\alpha_g \alpha_h = \alpha_{g+h}, \qquad \alpha_g \rho = \rho \alpha_g = \rho, \qquad \rho^2 = \bigoplus_{g \in G} \alpha_g \oplus \rho^{\oplus N}, \quad |G| = N.$$

For $N > 0$, there is no additive strong unital tensor functor $\mathcal{D} \to \mathrm{Bimod}_D(\mathcal{W}_X)$ for the derived balanced cut tensor product.

Proof. Empty evaluation is strong monoidal for that product. Indeed the empty component of its two-sided bar is

$$P_\emptyset \otimes_F D_\emptyset^{\otimes n} \otimes_F Q_\emptyset,$$

whose realization is $P_\emptyset \otimes^{\mathbb{L}}_F Q_\emptyset$. It takes the unit to F. A proposed functor would therefore give a strong tensor functor to the ordinary $\mathbb{Z}$-graded derived category $D(F)$.

Images of rigid objects are dualizable. A coevaluation over a field is a finite sum of homogeneous tensors. The snake identity expresses every cohomology class in the span of their components. Thus these images are perfect complexes.

An invertible object of $D(F)$ is a shift of a one-dimensional vector space. Since each α_g has finite tensor order, its shift is zero and its Euler characteristic is one.

If a is the integer Euler characteristic of the image of ρ, additivity and multiplicativity give $a^2 = N + Na$. This is impossible because

$$(N+1)^2 < N^2 + 4N < (N+2)^2 \qquad (N \geq 1).$$

Thus the dimension polynomial has no integer root. No faithfulness hypothesis was needed. □

The theorem concerns the stated balanced tensor product. Fusion of rooted probes defined by collision or nearby-cycle operations is a different tensor product and is not excluded. Likewise, the coefficient exchange c_B is not a braiding of C. It need not even be linear for the left regular B-action: the difference between $c_B(ab, c)$ and $a\, c_B(b, c)$ is $1 \otimes abc - a \otimes bc$. These operations occur on different carriers.

16.9 Finite recoupling and the E_6 connection

The multiplicity space $M = \mathrm{Hom}(\rho, \rho^2) = \bigoplus_h FT_h$ carries

$$p^g T_h = T_{h-g}, \qquad q^g T_h = \chi(g,h) T_h.$$

Let P_0 project to FT_0, and let P_{av} project to the constant vector by averaging. The rank-one operator $D = P_0 P_{\mathrm{av}}$ obeys

$$D\left(\sum_h v_h T_h\right) = N^{-1} \sum_h v_h T_0, \qquad D^2 = N^{-1} D.$$

For $N > 1$ it is not idempotent. Nor is it the tensor-unit projection in ρ^2: that projection is $X_0 X_0'$, which kills every T_h.

The corrected identity of Radchenko–Wheeler, Section 4.2, acts on M. Its right-hand side is $-N\beta D$, as in (15.22).

The geometric associativity homotopy has a different type. If $dh = L - R$ in a differential graded operation complex, every chain map from that complex to $\mathrm{End}_F(M[0])$ sends $L - R$ to zero. It therefore cannot send this boundary to the nonzero corrected finite-pentagon difference. A comparison through a larger channel system would have to specify the intermediate operations and the compression. The two corrections cannot be identified by a chain map to this degree-zero space.

Allowing negative degrees does not remove this obstruction if the comparison must preserve the full finite operator algebra.

Proposition 16.9.1. Let E be a unital differential graded algebra and $\iota : \mathrm{End}_F(M) \to Z^0(E)$ a unital algebra map. If $\iota(D)$ is exact, then E is acyclic.

Proof. Write E_{ij} for the matrix units in the basis $(T_g)_{g \in G}$. The displayed formula for D gives

$$E_{i0} D E_{0i} = N^{-1} E_{ii}, \qquad N \sum_i E_{i0} D E_{0i} = 1.$$

If $dh = \iota(D)$, the degree -1 element $H = N \sum_i \iota(E_{i0}) h \iota(E_{0i})$ satisfies $dH = 1$, since the matrix units have closed images. Left multiplication by H contracts E: $d(Hx) + H\,dx = x$. Hence every cohomology group vanishes. □

The matrix units are already generated by the finite Heisenberg pair. Indeed, Fourier averaging of the q^g gives P_0, and translates $p^{-i} P_0 p^j$ give E_{ij}. Thus a comparison retaining the Heisenberg operators and their products cannot make the nonzero correction exact in a recipient with nonzero cohomology. A geometric comparison must retain the larger channel system and specify how its compression fails to preserve either differentials or compositions.

Compression and the supported operation complex

Compression can produce a nonzero difference from an identity on a larger space. Suppose $\mathsf{AB} = \mathsf{CDE}$ there. Let $P^2 = P$ and $Q = 1 - P$. Inserting $P + Q$ at every intermediate position gives

$$\begin{aligned}(P\mathsf{A}P)(P\mathsf{B}P) - (P\mathsf{C}P)(P\mathsf{D}P)(P\mathsf{E}P) \\ = P\mathsf{C}Q\mathsf{D}P\mathsf{E}P + P\mathsf{C}P\mathsf{D}Q\mathsf{E}P \\ + P\mathsf{C}Q\mathsf{D}Q\mathsf{E}P - P\mathsf{A}Q\mathsf{B}P.\end{aligned}$$

All four terms record discarded intermediate channels. To obtain $-N\beta D$, one must construct the larger supported maps and the specified projection P, then identify their displayed sum with that operator.

The supported construction retains more than the total diagonal. At three positions it includes

$$[\,\mathcal{V}_{2|13} \xrightarrow{-r_{2,(13)}} \mathcal{V}_{123}\,]$$

in degrees -1, 0, with outer-collision homotopy r_{13}. At four positions it also retains $13|24$. Normal derivatives, the positions of spectator states, the empty cut unit and the local vacuum are part of the comparison.

There is an obstruction calculation for constructing these operations themselves. Let $\mathcal{E}$ be a differential graded nonsymmetric operad of admissible supported operations. Require closure under insertions and impose the translation, differential-module, cut and vacuum conditions in its definition. Use suspended operations, let b_1 be the differential, and write $\partial = [b_1, -]$.

Suppose degree-one operations $b_2, \dots, b_{n-1}$ satisfy all identities below arity n. Define

$$\mathfrak{o}_n = \left(\sum_{i=2}^{n-1} b_i\right)^2_{\text{arity } n} \in \mathcal{E}(n)^2.$$

Then $\partial\mathfrak{o}_n = 0$, and b_n exists exactly when

$$[\mathfrak{o}_n] = 0 \quad \text{in } H^2(\mathcal{E}(n)).$$

It must satisfy $\partial b_n = -\mathfrak{o}_n$. With the lower operations fixed, solutions modulo normalized degree-zero homotopy form an $H^1(\mathcal{E}(n))$-torsor.

Indeed, for $B = b_1 + \cdots + b_{n-1}$, associativity of composition gives $[B, B^2] = 0$. All lower-arity components of B^2 vanish, leaving $[b_1, \mathfrak{o}_n] = 0$ in arity n. Adding b_n changes this component by ∂b_n. The difference of two solutions is a degree-one cocycle, and a normalized homotopy changes it by a boundary.

This is the obstruction to a new operation. The higher-map problem of Theorem 4.3.1 instead has obstruction in degree one and choices in degree zero. Neither cohomology is determined by the rigidity of the finite fusion category or by a calculation on position-free states.

The full recoupling space is larger and is explicitly available. For the quadratic example of (16.5), $\mathrm{Hom}(\rho, \rho^3)$ has dimension six. Its left and right tree bases are

$$L_g = X_g, \quad L_{h,k} = T_h T_k, \qquad R_g = \rho(X_g)U_g, \quad R_{h,k} = \rho(T_h)T_k.$$

Their projections are $L'_g = X'_g$, $L'_{h,k} = T'_k T'_h$, $R'_g = U_{-g}\rho(X'_g)$ and $R'_{h,k} = T'_k\rho(T'_h)$. The change-of-basis matrix is $\mathsf{F}_{ij} = R'_i L_j$. Its inverse has entries $L'_i R_j$. In the order 0, 1, (0, 0), (0, 1), (1, 0), (1, 1), put $r = (1+\sqrt{3})/2$, $t = (1+i)/2$, $\bar{t} = (1-i)/2$ and $c = (1-i)(\sqrt{3}+i)/4$. Direct substitution gives

$$\mathsf{F} = \begin{pmatrix} -r & -r & -r & 0 & 0 & -ir \\ -r & r & 0 & -ir & -r & 0 \\ c & c & r & 0 & 0 & t \\ c & -c & 0 & t & r & 0 \\ c & c & \bar{t} & 0 & 0 & ir \\ -c & c & 0 & -ir & -\bar{t} & 0 \end{pmatrix}. \tag{16.19}$$

Put $a_F = (2+\sqrt{3}+i)/4$. In the same order, the inverse is

$$\mathsf{F}^{-1} = \begin{pmatrix} -r & -r & -a_F & -a_F & -a_F & a_F \\ -r & r & -a_F & a_F & -a_F & -a_F \\ 1 & 0 & r & 0 & t & 0 \\ 0 & -i & 0 & \bar{t} & 0 & ir \\ 0 & 1 & 0 & r & 0 & -t \\ -i & 0 & \bar{t} & 0 & -ir & 0 \end{pmatrix}.$$

Multiplying the two displayed matrices gives the identity. Equivalently, this follows by inserting the resolutions $\sum_i L_i L_i' = \sum_i R_i R_i' = 1$ between their entries.

For every number of inputs the analogous tree bases lie in one intertwiner space. Their change-of-basis matrices obey the pentagon because both products compare the same two bases. The relative chiral functor of Theorem 16.4.1 transports these actual maps and their coherence.

There is an independent singular realization at affine $\mathfrak{sl}_2$ level ten. Write V_j for its fusion label of highest weight j. The E_6 algebra object $V_0 \oplus V_6$ has a module tensor subcategory of type $(\mathbb{Z}/2, 2)$, as in Thornton, Example 1.2.

Its free-module images are

$$V_0 \mapsto 1, \quad V_2 \mapsto \rho, \quad V_4 \mapsto g \oplus \rho, \quad V_6 \mapsto 1 \oplus \rho, \quad V_8 \mapsto \rho, \quad V_{10} \mapsto g.$$

These follow from free-module adjunction and the even $SU(2)_{10}$ fusion rules. Its positive dimension is $1+\sqrt{3}$. It is the other embedding of the dimension parameter in (16.1).

The primary three-input blocks leading to ρ have ranks 3, 2, 1, for total highest weights 2, 4, 6. They come from $V_2^{\otimes 3} = V_0 \oplus 3V_2 \oplus 2V_4 \oplus V_6$ before the free-module functor.

Fix the spin-one basis v_0, v_1, v_2 with $Hv_j = (2-2j)v_j$, $Ev_1 = 2v_0$, $Ev_2 = v_1$, $Fv_0 = v_1$ and $Fv_1 = 2v_2$. The remaining raising and lowering actions vanish. Put $w_{abc} = v_a \otimes v_b \otimes v_c$. Use the ordered bases

$$\begin{aligned} 2: \quad & w_{002} - \tfrac{1}{2} w_{011} + w_{020}, \\ & 4w_{002} - w_{011} - w_{101} + w_{110}, \\ & w_{002} - \tfrac{1}{2} w_{101} + w_{200}; \\ 4: \quad & -w_{001} + w_{010}, \ -w_{001} + w_{100}; \\ 6: \quad & w_{000}. \end{aligned}$$

On these covariant highest-weight spaces the Knizhnik–Zamolodchikov (KZ) connection is

$$\nabla = d - \frac{1}{12}\left(\frac{\Omega_{12}}{z} + \frac{\Omega_{23}}{z-1}\right) dz, \qquad \Omega = \tfrac{1}{2} H \otimes H + E \otimes F + F \otimes E.$$

For highest weight two one obtains the matrices

$$\Omega_{12} = \begin{pmatrix} -2 & 4 & 0 \\ 1 & 0 & 1 \\ 0 & 4 & -2 \end{pmatrix}, \qquad \Omega_{23} = \begin{pmatrix} -4 & -4 & 0 \\ 0 & -2 & -1 \\ 0 & 0 & 2 \end{pmatrix}.$$

For highest weight four they are $\left(\begin{smallmatrix} 0 & 2 \\ 2 & 0 \end{smallmatrix}\right)$ and $\left(\begin{smallmatrix} -2 & -2 \\ 0 & 2 \end{smallmatrix}\right)$. For highest weight six both equal (2).

These matrices are obtained by restricting the ordinary spin-one Casimirs to the kernel of the total raising operator. The exponents at zero are $-1/3, -1/6, 1/6$, then $-1/6, 1/6$, then $1/6$. The system of conformal-block functionals uses the dual connection.

This differential system has nontrivial local monodromy. Its comparison with arithmetic fusion requires the module junctions as well as the ambient affine channels. We construct those junctions first.

16.10 The normalized E_6 tensor comparison

Put $s = \sqrt{3} > 0$, $q = e^{\pi i/12}$, and $[n] = \sin(n\pi/12)/\sin(\pi/12)$. Write $[n]! = \prod_{j=1}^{n}[j]$ and $[0]! = 1$. Let $\mathcal{D}_q$ be the semisimplified category of tilting $U_q(\mathfrak{sl}_2)$-modules, with simple objects $V_0, \dots, V_{10}$. The admissible channels of $V_a \otimes V_b$ are

$$|a-b|,\ |a-b|+2, \dots, \min(a+b, 20-a-b). \tag{16.20}$$

All recouplings below have even external labels.

We specify the trivalent normalization explicitly. For an admissible triple put

$$D(a,b,c) = \frac{[(-a+b+c)/2]![(a-b+c)/2]![(a+b-c)/2]!}{[(a+b+c)/2+1]!}.$$

For a, b, c, d and intermediate labels e, f, put

$$(A_1, A_2, A_3, A_4) = \tfrac{1}{2}(a+b+e,\ a+d+f,\ c+b+f,\ c+d+e),$$
$$(B_1, B_2, B_3) = \tfrac{1}{2}(a+b+c+d,\ a+c+e+f,\ b+d+e+f).$$

The rational Racah normalization is

$$(F_d^{abc})_{fe} = (-1)^{(a+b+c+d)/2}[f+1]D(b,c,f)D(a,f,d) \times \sum_{z=\max A_i}^{\min(B_1,B_2,B_3,10)} \frac{(-1)^z[z+1]!}{\prod_i [z-A_i]! \prod_j [B_j - z]!}. \tag{16.21}$$

An inadmissible entry is zero. Columns are left-tree inclusions and rows are right-tree projections. Equivalently, the column of right-tree projections is F_d^{abc} times the column of left-tree projections. The counterclockwise exchange in channel c is

$$R_c^{ab} = (-1)^{(a+b-c)/2} q^{(c(c+2)-a(a+2)-b(b+2))/4}.$$

Let $A_E = V_0 \oplus V_6$. Its unit is the inclusion of V_0. In the normalization (16.21), define its multiplication by the unit constraints and

$$m_{66}^{0} = -\frac{1}{3} + \frac{s}{6}, \qquad m_{66}^{6} = 1. \tag{16.22}$$

Every other component is zero. This is the connected commutative separable E_6 algebra of Kirillov–Ostrik, §6.

To see the normalization, write $m_{66}^{0} = \alpha$. The channel $e = 2$ of the associativity equation on $V_6^{\otimes 3} \to V_6$ gives

$$\alpha = -\frac{(F_6^{666})_{6,2}}{(F_6^{666})_{0,2}} = -\frac{1}{3} + \frac{s}{6}.$$

Substitution in the remaining channels gives associativity. The two nonzero channels of m_{66} have $R_0^{66} = R_6^{66} = 1$. The uniqueness of the E_6 algebra then identifies this multiplication with the conformal-extension algebra.

Write $\mathcal{D}_q^+$ for the full even-label subcategory and $\mathcal{M}_E = (\mathcal{D}_q^+)_{A_E}$ for its right A_E-modules. Their tensor product is over A_E. The left action on a right module is obtained using the displayed braiding. The free-module functor is $F_E(V) = V \otimes A_E$. Its three simple images are

$$M_1 = F_E(V_0), \qquad M_g = F_E(V_{10}), \qquad M_\rho = F_E(V_2).$$

Adjunction gives their endomorphism spaces and the free-module decompositions displayed above. Every module is a summand of a free module because A_E is separable. These decompositions therefore exhaust the simple objects. They give $M_\rho \otimes_{A_E} M_\rho = M_1 \oplus M_g \oplus 2M_\rho$.

The free-module junctions have a concrete basis. For $a, b, c \in \{0, 10, 2\}$, use adjunction to write

$$\mathrm{Hom}_{A_E}(F_E(V_a) \otimes_{A_E} F_E(V_b), F_E(V_c)) = \mathrm{Hom}_{\mathcal{D}_q}(V_a \otimes V_b, V_c \otimes A_E).$$

Its basis element $p_{ab}^{c;e,t}$ projects to V_e and includes it in $V_c \otimes V_t$, where $t \in \{0, 6\}$ and e occurs in both tensor products. Order these elements by t and then e. In particular the two $\rho\rho \to \rho$ junctions have $(e, t) = (2, 0), (4, 6)$.

To compose such maps, move the first A_E factor past the next input by R and multiply the two A_E factors by (16.22). This prescription and (16.21) determine every module recoupling.

Let $\sigma : F \to \mathbb{C}$ send $\sqrt{3}$ to $-\sqrt{3}$ and fix i. For the order-two example $F = \mathbb{Q}(\sqrt{3}, i)$. Write $C^\sigma = C \otimes_{F,\sigma} \mathbb{C}$. The arithmetic projection bases are those supplied by $1, U_g, X'_g, T'_h$ in the Leavitt presentation. Unit junctions have their unit normalization on both sides.

We give the comparison on the six remaining binary spaces. Put

$$a_* = \frac{(1-i)(-s+i)}{2}, \qquad S = \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

and

$$P = \begin{pmatrix} 1 & \dfrac{(1-i)(3+s(2-i))}{2} \\ -\dfrac{(1+i)(s+1)}{2} & \dfrac{(1-i)^2(3+si)}{2} \end{pmatrix}.$$

Define changes of projection basis N^{a}, N^{q} by

$(a, b; c)$	$N^{\mathrm{a}}_{ab;c}$	$N^{\mathrm{q}}_{ab;c}$
$(g, g; 1)$	1	$-\frac{1}{2} + \frac{s}{3}$
$(g, \rho; \rho)$	1	$-i$
$(\rho, g; \rho)$	1	1
$(\rho, \rho; 1)$	a_*	$1 - \frac{s}{2} + \frac{i}{2}$
$(\rho, \rho; g)$	a_*	$-3 - 3i(2+s)$
$(\rho, \rho; \rho)$	S	P

and set

$$K_{ab;c} = (N^{\mathrm{a}}_{ab;c})^{-1} N^{\mathrm{q}}_{ab;c}, \qquad p^{\mathrm{a}}_{ab;c} \longmapsto K_{ab;c}\, p^{\mathrm{q}}_{ab;c}. \tag{16.23}$$

The projection bases in this equation are columns. The inclusions transform by the inverse matrices, preserving their pairing.

THEOREM 16.10.1. The junction maps (16.23) extend to a tensor equivalence

$$\mathcal{E} : C^{\sigma} \xrightarrow{\sim} \mathcal{M}_{E}, \qquad (1, g, \rho) \longmapsto (M_{1}, M_{g}, M_{\rho}).$$

They preserve the spherical duality and every marked network value.

Proof. Fix a triple (a, b, c) and output d. Applying K at both vertices changes the projection bases by matrices L_K and R_K for the two trees. The required equation is

$$F^{\mathrm{a}} L_K = R_K F^{\mathrm{q}}. \tag{16.24}$$

The quantum computation takes place in

$$\mathrm{Hom}_{\mathcal{D}_q}((V_a \otimes V_b) \otimes V_c, V_d \otimes A_E).$$

Choose its ambient basis by the output label $v \in \{0, 6\}$, the total channel j, and the first-pair channel x. For a left module tree, write its two junction labels as (x, t) and (y, u), with intermediate simple V_e. The coefficient vanishes unless the ambient first-pair channel is the first junction channel x. Its remaining coefficient is

$$\left(\sum_{f} (F_j^{ect})^{-1}_{yf} \, R_f^{tc} \, (F_j^{etc})_{fx} \right) (F_j^{dut})_{vy} \, m^{v}_{ut}.$$

For a right module tree with junction labels (f, t), (y, u), the coefficient is

$$(F_j^{abc})_{fx} \, (F_j^{aet})^{-1}_{yf} \, (F_j^{dut})_{vy} \, m^{v}_{ut}.$$

Inadmissible channels contribute zero. These are respectively the crossing of the first algebra factor and the two associativity changes before multiplying the algebra factors. Writing their columns as L and R gives $F^{\mathrm{q}} = (L^{-1}R)^{\mathrm{t}}$.

Apply the two normalizations N^{a} and N^{q} to the Leavitt composites and to the preceding free-module prescription. Both give the following matrices. Every unit block and every block not listed is the identity. Zero-dimensional blocks are omitted:

$$F_{\rho}^{g\rho g} = F_{g}^{\rho g \rho} = -1, \qquad F_{\rho}^{g\rho\rho} = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},$$

$$F_{\rho}^{\rho g \rho} = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \qquad F_{\rho}^{\rho\rho g} = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix},$$

$$F_{1}^{\rho\rho\rho} = u \begin{pmatrix} 1 & b \\ 1 & -b \end{pmatrix}, \qquad F_{g}^{\rho\rho\rho} = u \begin{pmatrix} b & 1 \\ -b & 1 \end{pmatrix},$$

$$b = -i, \qquad u = \frac{(1 - i)(1 - si)}{4}.$$

For the remaining block put

$$\varphi = \frac{s - 1}{2}, \quad w = \frac{(s - 1)(1 + is)}{8}, \quad y = \frac{1 + i(s - 2)}{4}, \quad z = \frac{-s - i}{4}.$$

In the channel order used in (16.19), that block is

$$F_{\rho}^{\rho\rho\rho}=\begin{pmatrix} \varphi & \varphi & -wb & w & w & -wb \\ \varphi & -\varphi & -wb & w & -w & wb \\ 1 & 1 & -yb & z & y & -zb \\ 1 & 1 & -zb & y & z & -yb \\ 1 & -1 & -yb & z & -y & zb \\ -1 & 1 & zb & -y & z & -yb \end{pmatrix}.$$

For example the arithmetic block is obtained from (16.19) by $\sqrt{3}\mapsto -s$, followed by the two-vertex changes induced by a_* and S. The quantum block is obtained by the free-module composition with $m^{\circ}_{66}=-1/3+s/6$. The displayed scalar, two-dimensional, and six-dimensional blocks exhaust the possible triples. They prove (16.24).

All the matrices K are invertible. Equation (16.24), together with the identity on unit junctions, is the associativity and unit equation for a tensor functor between the two semisimple categories. It therefore defines $\mathcal{E}$ on sums and matrices of simple objects. The three simple images are distinct and exhaustive, so the functor is an equivalence.

There is no nontrivial tensor automorphism of the identity in either category. Indeed its scalar on ρ satisfies both $\lambda_{\rho}^{2}=1$ and $\lambda_{\rho}^{2}=\lambda_{\rho}$, and $\lambda_{g}\lambda_{\rho}=\lambda_{\rho}$. Thus all scalars are one.

The spherical structure is consequently unique. Its dimension on ρ is $\sigma(d)=1+s$, equal to $\dim_{\mathcal{D}_q}(\mathcal{M}_{\rho})/\dim_{\mathcal{D}_q}(\mathcal{A}_E)$. Transporting duality along the tensor equivalence preserves this structure. In particular it preserves cups, caps, and their closed composites. □

The embedding σ is essential. Before changing the embedding, the global dimension is $2+(1-s)^2=6-2s$. That of $\mathcal{M}_E$ is $6+2s$. These are invariants of the fusion categories, so there is no complex-linear tensor equivalence at the original embedding. Replacing i by $-i$ as well also changes the category: the trace of $F_{1}^{\rho\rho\rho}$ changes from $(1-is)/2$ to $(1+is)/2$. It cannot be removed by a binary-junction change of basis.

16.11 Affine descendants and analytic sewing

Let $H_j=L_{\widehat{\mathfrak{sl}}_2}(10,j)$, $0\le j\le 10$. Its lowest-weight space is the ordinary $\mathfrak{sl}_2$-module of highest weight j, and its conformal weights are

$$h_j+n,\qquad h_j=\frac{j(j+2)}{48},\quad n\ge 0.$$

The states are finite sums of negative current modes applied to that space, modulo the integrable null relation

$$E_{-1}^{11-j}v_j=0 \tag{16.25}$$

and the submodule it generates. All homogeneous spaces are finite dimensional. Outputs lie in their product completion. The translation is L_{-1}, and the Sugawara central charge is $5/2$.

Huang–Lepowsky, Theorems 3.7–3.13, give these modules their vertex tensor category $\mathcal{D}_{10}$.

Fix the ribbon equivalence

$$\Phi:\mathcal{D}_q\xrightarrow{\sim}\mathcal{D}_{10},\qquad \Phi(V_j)=H_j,$$

with counterclockwise braiding and vacuum unit normalization. We use Finkelberg's equivalence with the correction in his erratum. The corrected equivalence uses rigidity and the prescribed opposite tensor-category convention before fixing the counterclockwise ribbon structure. Its numerical range includes $\kappa = k + h^\vee \geq h^\vee + 3$. For $\mathfrak{sl}_2$ at $k = 10$, one has $h^\vee = 2$ and $\kappa = 12$, so the bound holds.

The rational trivalent basis (16.21) is transported through this equivalence. This specifies the normalization of every affine intertwining operator used below. A basis obtained by separately setting all three-point highest-weight coefficients to one need not have that normalization.

Write $\Phi_2 : \Phi(X) \boxtimes \Phi(Y) \to \Phi(X \otimes Y)$ for its tensor comparison. The algebra $\widehat{A}_E = \Phi(A_E)$ is the conformal extension $L_{\widehat{\mathfrak{sp}}_4}(1, 0)$. Its underlying H_0-module is $H_0 \oplus H_6$ (Kirillov–Ostrik, Example 5.3 and Section 6).

For an A_E-module M, let $U(M)$ denote its underlying object of $\mathcal{D}_q$ and set $\widehat{M} = \Phi(U(M))$. In particular,

$$\begin{aligned} \widehat{M_1} &= H_0 \oplus H_6, \\ \widehat{M_g} &= H_4 \oplus H_{10}, \\ \widehat{M_\rho} &= H_2 \oplus H_4 \oplus H_6 \oplus H_8. \end{aligned} \tag{16.26}$$

These are full affine state spaces. The last is an ordered, nonlocal $\widehat{A}_E$-sector. It is not an ordinary local module of the extension.

We next define its fields and its relative sewing, including the balancing map. Choose the special Frobenius coproduct of A_E with $m\Delta = 1_{A_E}$, and put $e = \Delta\eta$. It is uniquely determined by m and by the counit $(3 + s)$ times projection to V_0. Explicitly, put $D_E = 3 + s$ and $\alpha = -1/3 + s/6$. In the inclusion bases dual to the projection bases its nonzero components are

$$\Delta_0^{00} = \Delta_6^{06} = \Delta_6^{60} = D_E^{-1}, \qquad \Delta_0^{66} = \frac{D_E - 1}{D_E \alpha}, \qquad \Delta_6^{66} = \frac{D_E - 2}{D_E}.$$

For right modules M, N let r_M, r_N be their actions and $\ell_N = r_N c_{A_E,N}$. The balancing idempotent is

$$P_{M,N} = (r_M \otimes \ell_N)(1_M \otimes e \otimes 1_N). \tag{16.27}$$

Its image is $M \otimes_{A_E} N$. Denote the quotient onto this image by $q_{M,N}$.

For a junction $p : M \otimes_{A_E} N \to P$, define

$$\mathcal{Y}_p = \mathcal{Y}_{\Phi(U(p) q_{M,N})\,\Phi_2}. \tag{16.28}$$

Here $\mathcal{Y}_f$ is the intertwining operator corresponding to the H_0-module map $f : \widehat{M} \boxtimes \widehat{N} \to \widehat{P}$. Thus (16.28) is a definition on all descendants, through the universal property of the vertex tensor product. For an arithmetic projection $p^{\mathrm{a}}_{ab;c,\gamma}$ its operator is

$$\mathcal{Y}^{\mathrm{a}}_{ab;c,\gamma} = \sum_\beta (K_{ab;c})_{\gamma\beta} \mathcal{Y}^{\mathrm{q}}_{ab;c,\beta}. \tag{16.29}$$

The arithmetic sector corresponding to a has the state space $\widehat{M_a}$ of (16.26).

THEOREM 16.11.1. Equations (16.26)–(16.29) give an analytic ordered realization of $\mathcal{C}^\sigma$. The comparison is the identity on the full state spaces and is K on binary junctions. It preserves translation, conformal

grading, relative duality, collision expansions, and sewing in every arity. All products and iterates, paired with restricted-dual states, converge absolutely on their nested-disc domains. Their continuations have the level-ten conformal-block monodromy. Sewing on the domain of Section 16.7 converges absolutely and locally uniformly, including the allowed sewings that create handles.

Proof. The Frobenius and separability equations make (16.27) idempotent and identify its image with the balanced tensor product. They also identify the two iterated balancing quotients of $M \otimes N \otimes P$. Applying the strong tensor functor Φ gives the corresponding identity of affine module maps. The vertex-tensor associativity isomorphism identifies those maps with the products and iterates of (16.28). Its defining identity holds for every state, by Huang–Lepowsky, Theorems 3.7–3.8.

Apply (16.24) to that identity. The changes on its two binary vertices are exactly L_K and R_K, so (16.29) identifies the two complete operator products. Any two binary trees are joined by associativity moves. The pentagon identifies the resulting maps between trees, and the unit constraints handle vacuum insertions. This proves the comparison in every arity. All maps are affine module maps and preserve L_{-1}, L_0, and the null submodules.

For clarity, the sewing along a module H_j uses the tensor

$$\mathcal{P}_j(t) = \sum_{n \geq 0} t^{h_j+n} \sum_{\alpha} u_{j,n,\alpha} \otimes u^{\vee}_{j,n,\alpha}. \tag{16.30}$$

The second basis is dual to the first in the contragredient module, with the specified opposite local coordinate. A branch of $\log t$ fixes the fractional powers. Direct sums, the balancing idempotents, and the relative evaluations specify the analogous sewing for the three sectors.

No descendant degree is omitted. The identity tensor in each finite-dimensional grade is independent of its basis. Thus the junction change K and its dual inverse cancel at an internal edge. The spherical comparison of Theorem 16.10.1 handles cups and caps.

The integrable affine vertex algebra H_0 is rational and C_2-cofinite. Its finite sums $\widehat{M}_a$ are finitely generated modules. Genus-zero absolute convergence is part of the cited vertex tensor theorem.

Sew local coordinates $uv = t$ on disjoint coordinate discs of radii r and r'. The full sums (16.30) converge absolutely and locally uniformly by Gui's Theorem 13.1. Use $0 < |t| < rr'$ and all the hypotheses of Section 16.7. It allows simultaneous sewings and disconnected initial surfaces. The balancing and junction maps form finite sums of such conformal blocks, so the same convergence holds here. Equality before sewing consequently remains equality after each further sewing. □

This construction also has ordinary boundary fields. For boundary conditions $M, N \in \{M_1, M_g, M_\rho\}$ their state space is

$$\mathsf{H}_{MN} = \bigoplus_{j=0}^{10} \operatorname{Hom}_{A_E}(V_j \otimes M, N) \otimes H_j.$$

Composition of the module maps gives their operator-product coefficients, and the corresponding affine intertwining operators give their position dependence.

If $P = M_1 \oplus M_g \oplus M_\rho$, these spaces are the matrix entries of the internal endomorphism algebra of P in $\mathcal{D}_{10}$. Its associativity gives a grading-restricted conformal open-string vertex algebra by Huang–Kong, Theorem 4.3. The three boundary identity states account for its three-dimensional weight-zero space. Its conformal transformations and disc sewings are those of Huang–Kong, Theorem 5.4.

16.12 Collision coefficients of the affine realization

The fractional powers of the affine fields belong to their coefficient connection. They must be canceled before taking a normal principal part. For labels i, j, k, put $a_{ij}^{k} = h_k - h_i - h_j$. On this binary channel write

$$\mathcal{Y}_{ij}^{k}(u) = u^{a_{ij}^{k}} \Theta_{ij}^{k}(u).$$

On homogeneous input states, Θ_{ij}^{k} has integral powers and a finite lower bound.

The coefficient symbol $\xi_{ij}^{k} = u^{-a_{ij}^{k}}$ satisfies $\partial_u \xi_{ij}^{k} = -a_{ij}^{k} u^{-1} \xi_{ij}^{k}$. The collision map is

$$r_{ij}(f \xi_{ij}^{k}; v, w) = \mathrm{pp}_{u=0}\big(f \Theta_{ij}^{k}(v,u) w\big). \tag{16.31}$$

The derivative of ξ_{ij}^{k} and the translation identity of the field make this a map of right differential modules. In particular the term $a_{ij}^{k} u^{-1} \Theta_{ij}^{k}$ in the field derivative is retained.

For more points, the symbols form the inverse conformal-block coefficient system. It is the finite-rank integrable subbundle of the Knizhnik–Zamolodchikov connection. One algebraic description is useful. Let $U_j \subset H_j$ be the lowest-weight space and fix output l. The coefficient at positions $z_1, \dots, z_r$ is the subspace of $\mathrm{Hom}_{\mathfrak{sl}_2}(U_{j_1} \otimes \cdots \otimes U_{j_r}, U_l)$ whose invariant functional τ obeys

$$\tau\left(\left(\sum_{i} z_i E^{(i)}\right)^{n-l} b \otimes v_l^{\vee}\right) = 0 \quad \text{for every lowest-space tensor } b. \tag{16.32}$$

The vector $v_l^{\vee}$ is highest in the module at infinity.

This is the null relation (16.25) moved from infinity by the current Ward identity. The integrable null relations at the other points give the same kernel. It is therefore an algebraic bundle with its induced flat connection, by Beauville, Sections 3–4.

Let $\mathcal{K}_{\mathbf{j}}^{l}$ denote this coefficient bundle, with the inverse-field convention just specified. On a stratum with blocks π, the coefficient with states is

$$(i_\pi)_*(j_\pi)_*\Big(\bigoplus_{\mathbf{j}} \mathcal{K}_{\mathbf{j}}^{l} \otimes \boxtimes_{B \in \pi}(\omega_X \otimes H_{j_B})\Big)[|\pi|]. \tag{16.33}$$

Sewing frames decompose this bundle near a collision over the allowed intermediate labels. The faces in these frames are (16.31), with the determinant signs used in (16.8).

Algebraic coefficients and radial sewing frames

The bundle in (16.32) is algebraic. Its defining matrix is polynomial in the positions, and its kernel has the constant rank given by the integrable fusion multiplicity. A matrix of constant rank on the reduced configuration variety has locally free kernel, image and cokernel. Thus the kernel is locally a direct summand of the constant lowest-state tensor bundle.

It is invariant under common translation and nonzero dilation of the positions. Under translation by c, the operator $\sum_i z_i E^{(i)}$ becomes $\sum_i z_i E^{(i)} + c \sum_i E^{(i)}$. The summands commute. Invariance moves each occurrence of the total raising operator to the highest vector at infinity, where it vanishes. Dilation multiplies the null equation by a nonzero scalar.

The Casimir connection preserves this algebraic kernel. Locally, analytic horizontal conformal blocks span every fiber. Writing an algebraic section in such a frame shows that its covariant derivative lies in

the same kernel at every point. It is therefore an algebraic one-form with values in the subbundle. The inherited connection has regular singularities along diagonals.

Consider a cut with left and right roots y', y'', and put $d = y' - y'' \neq 0$. Contract the two groups by

$$y_B = y' + \lambda v_B \quad (B \text{ on the left}), \qquad y_B = y'' + \lambda v_B \quad (B \text{ on the right}).$$

The root coordinates have $v_B = 0$. The v_B record the internal shapes and λ their common scale. Let A_c be the ring of rational functions of these shapes and roots, with poles allowed only on internal diagonals and $d = 0$.

For total output l, the fused coefficient is

$$\mathcal{K}_c^l = \bigoplus_{a,b=0}^{10} \mathcal{K}_{ab}^l \otimes \mathcal{K}_{\mathbf{j}'}^a \otimes \mathcal{K}_{\mathbf{j}''}^b.$$

Only the integrable channels occur. Compose the integrable germs of the two groups with the two-root germ. The result gives a radial sewing map

$$J_c : \mathcal{K}_c^l \otimes A_c[[\lambda]] \longrightarrow \widehat{\mathcal{K}}_{\mathbf{j}'\mathbf{j}''}^l. \tag{16.34}$$

Its constant term is the composition of the three lowest-state maps. Ward recursion on the integrable modules defines every higher coefficient, including at resonant levels.

Proposition 16.12.1. The map (16.34) is an isomorphism over $A_c[[\lambda]]$, intertwining the fused and full connections. Frames for nested collisions and cuts compose. For fixed shape and roots it converges when

$$|\lambda| \max_B |v_B| < |d|/4.$$

It continues to a holomorphic isomorphism over the region where every left position has larger real part than every right position.

Proof. Insertion of the three germs gives rational Taylor coefficients, with precisely the allowed poles. Ward identities hold at every original point. Uniqueness of the integrable germ determines the series coefficient by coefficient.

The constant term is injective by semisimple composition of lowest-state maps. Locally choose a retraction L_0 of this constant term. Then $L_0 J_c = 1 + O(\lambda)$ is invertible, and $(L_0 J_c)^{-1} L_0$ is a left inverse. The image lies in the kernel of the polynomial null-equation matrix.

Its rank equals the rank of that kernel, since

$$\sum_{a,b} N_{ab}^l N_{\mathbf{j}'}^a N_{\mathbf{j}''}^b = N_{\mathbf{j}'\mathbf{j}''}^l$$

by associativity of integrable fusion. The quotient of the ambient free module by the split image is projective. The null kernel modulo the image is a rank-zero submodule of this torsion-free quotient, so it vanishes. This proves the formal isomorphism.

Two nested frames give the same inserted Ward germ. Their coefficients are finite sums in each state degree, so associativity of insertion identifies the series. Translation of the germ identifies the connections.

Contracting horizontality with $\lambda\partial_\lambda$ gives a regular-singular linear equation

$$\lambda \frac{dJ_c}{d\lambda} = J_c\big(C + R(\lambda)\big) - C^{\circ} J_c.$$

Here C is the sum of internal Casimirs and C° its fused action. Each cross term of R has the form

$$t_{ij}\frac{\lambda(v_i - v_j)}{d + \lambda(v_i - v_j)}, \qquad t_{ij} = \frac{\Omega_{ij}}{12}.$$

It is holomorphic for $|\lambda| \max |v_B| < |d|/2$. Above the finitely many differences of eigenvalues of C and C°, the recursion has an inverse bounded by a constant times the inverse degree. The usual power-series majorant therefore converges on every smaller disc.

The finitely many resonant degrees do not affect convergence: their coefficients have already been fixed by the germs.

Scale contraction keeps the two groups separated in real part. Horizontal continuation from the convergent neighborhood extends J_c through that region. Flatness and uniqueness identify the continuations on intersecting neighborhoods. □

Resonance is a reason to use the germs. For example, at level four the three spin-one inputs with spin-one output have pair exponents $-2/3, -1/3, 1/3$. The degree-one recursion between the first and third channels is singular. Its right side vanishes, since one Lie-algebra generator changes the intermediate spin by at most one. The differential equation alone leaves a free coefficient. The specified integrable germ selects it.

The coupled product on full cut opens

For this construction a state system records a color in $\{0, \dots, 10\}$ and a state factor on every block of every partition. Its coefficient diagram attaches $\mathcal{K}^{l}_{\mathbf{j}}$ to the entire ordered color word. It retains the state factors, densities and block-number shift of (16.33). The maps are generated by maps on states and by collision residues with arbitrary spectator blocks.

Concatenate the two color words and their state factors. Attaching the coefficient bundle of this whole word defines the coupled cut product:

$$\mathcal{K}\mathscr{S}' \star_{\mathcal{K}} \mathcal{K}\mathscr{S}'' = \mathcal{K}(\mathscr{S}' \boxtimes \mathscr{S}''). \tag{16.35}$$

The state tensor is external, but the coefficient bundle includes all cross-Casimir terms. The unit is $\mathbb{C}$ in color zero at the empty word.

A residue of one factor extends by the residue in the enlarged configuration, with the other states as spectators. The radial comparison determines this extension. Rational expansion is injective, state modules are free, and coefficient bundles lie inside constant bundles. The nested-frame identity proves compatibility with compositions of the generating maps.

Thus $\star_{\mathcal{K}}$ is a graded monoidal product. The Koszul rule makes its product differential square to zero. Both parenthesizations carry the same whole-word bundle, so the associator on these diagrams is the identity.

For a consecutive cut c, project onto the partitions having no block that crosses c. A discarded block remains crossing under every coarsening. Hence this is a chain map. The discarded summands have diagonal support outside the cut open U_c. On U_c, every retained term on both sides has the same bundle $\mathcal{K}^{l}_{\mathbf{j}'\mathbf{j}''}$. Consequently the cut map is an isomorphism on the full algebraic open, before radial completion.

Repeated cut projections commute, and the empty word supplies the counit. The resulting strong cut coalgebra has an associative cobar for $\star_{\mathcal{K}}$. Its positive-cut contraction uses the signs and finite sums already given after Theorem 16.3.1. On suspended singleton inputs the transferred operation is

$$B_n(sx_1, \dots, sx_n) = s\, r_{1n}(x_1, \dots, x_n), \qquad n \geq 2;$$

in particular the ternary operation retains the nonconsecutive residue r_{13}.

The radial frame identifies this cut map with the fusion-channel cut after completion. Horizontal frames of two iterated cuts differ by the integrable channel associator. Thus an identity associator on whole-word coefficient diagrams and a nontrivial channel associator describe the same maps in different presentations.

Algebraic reorderings and their monodromy

Let σ, τ be two orders of the insertion labels. For a partition with r blocks, let w carry its root order for σ to its root order for τ. Write c_w for the ordinary permutation of the lowest-state tensor factors. The transition is

$$f \otimes e \otimes x_1 \otimes \cdots \otimes x_r \longmapsto \operatorname{sgn}(w)\, f \otimes e\, c_w^{-1} \otimes x_{w^{-1}(1)} \otimes \cdots \otimes x_{w^{-1}(r)}. \tag{16.36}$$

The sign is the determinant sign of the shifted block factors.

The Casimir connection and infinity null equation are equivariant for these algebraic reorderings. On the chart overlap, a partition containing two labels ordered differently has empty support. For every surviving collision the two colliding roots keep their relative order. Its coordinate, integrable Ward germ and full principal part therefore agree under (16.36). If the deleted root moves from place i to place p, omitting it changes the permutation sign by $(-1)^{i+p}$. This converts the face sign $(-1)^{i-1}$ to $(-1)^{p-1}$.

Hence the order maps commute with the differential. They satisfy the cocycle identity by permutation coherence. For an ordered collision, only saturated partitions survive extraordinary pullback, and their root orders agree. Thus the transition also commutes with every collision comparison.

On a cut-admissible partition, reordering either side is $w_A \times w_B$, with sign $\operatorname{sgn}(w_A)\operatorname{sgn}(w_B)$. The order maps therefore glue the coupled products and their cut isomorphisms. Interchanging the two groups gives a symmetry whose sign on r_A, r_B blocks is $(-1)^{r_A r_B}$. The cut coalgebra is cocommutative for this reordering symmetry. This symmetry does not remove the monodromy of its coefficient bundle.

A half turn describes the order map in continued horizontal frames. At a pair of roots, continuation of u^a through a counterclockwise semicircle contributes $e^{\pi i a}$. The normalized integral-power germ changes by translation and ordinary reordering. The exponent is retained by the coefficient connection. Clockwise continuation gives $e^{-\pi i a}$. Their ratio is the full turn $e^{2\pi i a}$.

These matrices do not generally define transitions on coefficients at the same point for the fixed product (16.35). The distinction already appears for three defining $\mathfrak{sl}_2$ colors.

Proposition 16.12.2. At an integral level $k \geq 2$, the block bundle with three defining inputs and defining output is irreducible of rank two. Consider a flat coefficient transition tensored with state reordering. Compatibility with the fixed coupled product forces one scalar on both binary channels relative to ordinary reordering. The half turn has different scalars and cannot be that transition.

Proof. Put $h = (k+2)^{-1}$. Both singlet and triplet channels are integrable, so the rank is two. On the slice $(0, x, 1)$, the residues at $0, 1, \infty$ have eigenvalues

$$\{-3h/2, h/2\}, \qquad \{-3h/2, h/2\}, \qquad \{0, 2h\}.$$

All exponent differences are nonintegral.

An invariant line would extend to a line bundle whose degree is minus a sum of residue eigenvalues. This sum is one of $-3h, -h, h, 3h$, none an integer when $k + 2 \geq 4$. Thus no invariant line exists.

A flat endomorphism of this irreducible complex local system is scalar. Compatibility with the cut 12|3 extends the binary transition over the third defining input. The two channels therefore have the same scalar relative to reordering. The half turn instead has eigenvalues

$$-e^{-3\pi ih/2}, \qquad e^{\pi ih/2}.$$

After division by the reordering signs, their ratio is $e^{-2\pi ih} \neq 1$. This contradicts the necessary equality. □

At level one only the singlet channel remains. The same rank-two argument applies at irrational h to the full defining-color KZ system: the four possible residue sums are again nonintegral. The proposition fixes the coefficient transition and the coupled product. It makes no assertion about a different tensor product with separately constructed comparison maps.

The rank-two example also distinguishes local meridians from full monodromy. At level two put $\zeta = e^{\pi i/4}$. The two local full turns can be represented as

$$A = \zeta Z, \qquad B = \zeta X, \qquad Z^2 = X^2 = 1, \quad ZX = -XZ.$$

Each has order eight and $ABA^{-1}B^{-1} = -1$. The group they generate on the slice has order sixteen:

$$\{\zeta^a Z^b X^c : a \in \mathbb{Z}/8,\ b, c \in \mathbb{Z}/2,\ a \equiv b + c \pmod 2\}.$$

The full twist of the three moving points contributes ζ^{-31}, so the full pure-braid image has order thirty-two. Projectively it is the Klein four-group.

Indeed, the exponent differences on the three-punctured sphere are $1/2$. Its projective local monodromies are distinct involutions with involutive product. Irreducibility forces their matrix lifts to anticommute.

Adjoining eighth roots of all differences kills the individual local meridians. That abelian cover still contains their commutator loop, whose action is -1. The cover corresponding to the kernel of the full monodromy trivializes the bundle. On it the continued horizontal frames are single valued and the reorderings are constant half-turn matrices. Killing local eigenvalues alone would miss this remaining sign.

PROPOSITION 16.12.3. The full ambient affine coefficient system gives a strong cut coalgebra with the terms (16.33) and the coupled cut product. It glues on the ordered collision schemes. Mark it with the A_E-module junctions on its sewing charts. The arithmetic junction comparison (16.29) identifies these marked residue diagrams, their cut maps, and their cobars. It retains every normal derivative and the vacuum.

Proof. An affine Ward identity moves a negative current mode at one insertion to regular expansions at the others. Induction on total degree therefore determines every germ from its lowest-space value. The singular-vector equation (16.32) is exactly the condition that this germ descend to the integrable quotients. At a collision, inserting a binary integrable germ into an external germ gives its factorization over the allowed intermediate labels. The factorization is an isomorphism by the integrable conformal-block sewing and factorization theorems of Tsuchiya–Ueno–Yamada, Theorems 6.2.1 and 6.2.5. It uses the full tensor (16.30).

For two disjoint collisions the two principal-part maps commute before their determinant signs are inserted, so their signed composites cancel. For three blocks the three routes are the three expansions

of one Ward germ. The two-variable Cousin boundary identity therefore gives their signed sum zero. These statements prove that the sum of the elementary faces squares to zero. They include a collision of the first and third blocks with the second retained as a spectator.

For a consecutive cut, discard exactly the partitions having a block on both sides. Such a block remains crossing under every coarsening, so the projection is a chain map. Its discarded terms have diagonal support outside the cut open. On every retained term the coupled product has the coefficient bundle of the same whole word. The cut map is consequently an isomorphism there. Repeated projections commute and the empty word is the counit.

On two ordered charts, reorder the lowest-space tensor factors and precompose their coefficient functionals by the inverse permutation. The Casimir connection is equivariant for these algebraic reorderings. If a colliding pair has the same relative order in both charts, its Ward germ and principal part are carried to each other. If its order is reversed, its diagonal is absent from the overlap. Thus the reorderings give a cocycle of complexes.

In the continued horizontal frames of Section 16.12, these algebraic maps are represented by half-turn matrices. They are not pointwise coefficient transitions for the fixed coupled product.

Finally (16.29) is an equality of full intertwining operators. Its coefficient symbols transform by the dual inverse of K, preserving their contraction with fields. It therefore commutes with (16.31) and with every spectator extension. The cut maps are the same projections on both sides. The resulting identification of coalgebras identifies their cobars. □

The ambient coefficient bundle is essential here. A projection onto a chosen fusion channel in a sewing frame need not extend to a single-valued flat projection on the whole configuration space. The construction retains that bundle and marks the module junctions on the sewing charts. It does not replace the bundle by constant channel spaces or assert a global splitting into them.

The Heisenberg, lattice, and affine constructions are distinct conformal theories, with central charges 1, 8, and 5/2. Their full state spaces are not identified. They realize the same specified junctions on different conformal carriers. The affine construction also supplies nontrivial conformal-block monodromy at the embedding σ.

16.13 The original embedding in a Virasoro theory

The original arithmetic embedding has $d = 1 - \sqrt{3}$. It therefore requires a different conformal carrier from the positive affine theory. Such a carrier is provided by the Virasoro minimal model

$$W_- = \mathrm{Vir}(12, 5), \qquad c_- = 1 - \frac{6(12-5)^2}{12 \cdot 5} = -\frac{39}{10}.$$

Let U_j be its simple module with Kac label $(j+1, 1)$, $0 \le j \le 10$. Its lowest conformal weight is

$$h_j^- = \frac{(5(j+1) - 12)^2 - 49}{240} = \frac{5j(j+2)}{48} - \frac{j}{2}.$$

Its states are the negative Virasoro modes on a lowest vector, modulo the two singular-vector submodules at levels $j+1$ and $4(11-j)$. This specifies all descendants, including their null relations. The category is rational and C_2-cofinite.

Huang's Theorems 2.1 and 3.8–3.10 give its intertwining operators the convergent vertex tensor structure. Creutzig–Huang–Yang, Section 7, give the related admissible tensor-category formulation.

Put $q_- = e^{5\pi i/12}$. The cyclotomic automorphism $\gamma : q \mapsto q_-$ satisfies $\gamma(\sqrt{3}) = -\sqrt{3}$ and $\gamma(i) = i$. Write $\mathcal{D}^+_{q_-}$ for the even quantum-group category. There is a ribbon equivalence

$$\Psi : \mathcal{D}^+_{q_-} \xrightarrow{\sim} \langle U_0, U_2, U_4, U_6, U_8, U_{10}\rangle, \qquad V_j \longmapsto U_j. \tag{16.37}$$

Here and below the rational Racah bases are transported through Ψ to normalize the Virasoro intertwining operators.

We explain why the parameter and the ribbon structure in this comparison are fixed. The fusion rules of $U_0, \dots, U_{10}$ are (16.20). The object U_1 generates them and $U_1^2 = U_0 \oplus U_2$. Its counterclockwise exchanges on these two channels, computed from their leading primary powers, are

$$e^{\pi i(h^-_0 - 2h^-_1)} = e^{3\pi i/8} = -q_-^{-3/2}, \qquad e^{\pi i(h^-_2 - 2h^-_1)} = e^{5\pi i/24} = q_-^{1/2}.$$

Categories with SL_2 Verlinde rules are reconstructed from the quantum-group categories, up to a cocycle on the parity grading. This is the classification in Etingof–Gelaki–Nikshych–Ostrik, Section 8.27.5.

In the Temperley–Lieb reconstruction, these two eigenvalues fix the braid generator. The successive Jones–Wenzl projections use

$$[n]_- = \frac{\sin(5n\pi/12)}{\sin(5\pi/12)}, \qquad [n]_- \neq 0 \ (1 \le n \le 11), \quad [12]_- = 0.$$

Their path matrix units give the A_{11} fusion paths. The next projection vanishes. Thus the comparison is full on the generated category. A possible parity cocycle restricts to the constant one on the even subcategory. There the twists agree exactly, since $e^{2\pi i h^-_j} = q_-^{j(j+2)/2}$ for even j. This proves (16.37), including its braiding and twists.

In particular it fixes the orientation of analytic continuation, which the fusion rules alone would not determine.

Apply γ to the algebra and junction matrices of Section 16.10. In $\mathcal{D}^+_{q_-}$ the algebra is again $V_0 \oplus V_6$, now with

$$m^0_{66} = -\frac{1}{3} - \frac{\sqrt{3}}{6}, \qquad m^6_{66} = 1, \qquad \dim A_- = 3 - \sqrt{3}.$$

Its associativity, commutativity, separability, and all junction comparison equations are polynomial identities over the cyclotomic field, so they are preserved by γ. The comparison from the original arithmetic category has binary matrices

$$K^-_{ab;c} = \gamma(K_{ab;c}). \tag{16.38}$$

Indeed γ restricts to σ on F, and applying it to C^σ restores the original embedding.

Transport A_- and its three modules through Ψ. Their full Virasoro state spaces are

$$\begin{aligned} \mathsf{H}^-_1 &= U_0 \oplus U_6, \\ \mathsf{H}^-_g &= U_4 \oplus U_{10}, \\ \mathsf{H}^-_\rho &= U_2 \oplus U_4 \oplus U_6 \oplus U_8. \end{aligned} \tag{16.39}$$

Let q be the balancing quotient defined by the conjugate of (16.27). For a module junction p, its full field is the intertwining operator of the module map $\Psi(pq)\Psi_2$. The arithmetic field is K^- times this column of fields.

Theorem 16.13.1. Equations (16.38) and (16.39) give an analytic ordered realization of the order-two arithmetic category at its original complex embedding. It has central charge $-39/10$ and relative dimensions $1, 1, 1-\sqrt{3}$. The comparison preserves every junction, all descendants, translation, relative duality, and collision and sewing operations in every arity. Its sewings on the domain of Section 16.7 converge absolutely and locally uniformly, including finite simultaneous sewings that create handles.

Proof. The ribbon equivalence (16.37) identifies the commutative separable algebra and its balanced module tensor product. The conjugate of (16.24) gives all its binary and ternary comparison maps. The proof of Theorem 16.11.1 now applies with the Virasoro vertex tensor structure in place of the affine one. It is an equality of intertwining operators on entire modules, so it includes their singular-vector quotients and every descendant.

The module dimensions can be checked without a choice of junction basis. The categorical dimension of U_j is

$$(-1)^j \frac{\sin(5(j+1)\pi/12)}{\sin(5\pi/12)}.$$

Divide the sums for the three modules in (16.39) by $3-\sqrt{3}$. They give $1, 1, 1-\sqrt{3}$. The unique spherical structure on the near-group category is therefore the original arithmetic one. In particular the closed marked junction has value $-e_1$.

The sewing tensor on U_j is

$$\sum_{n\geq 0} t^{h_j^- + n} \sum_{\alpha} v_{j,n,\alpha} \otimes v^{\vee}_{j,n,\alpha}.$$

Every grade is finite dimensional. The possible negative lowest weights contribute only fixed powers of t on a chosen logarithmic branch. Rationality and C_2-cofiniteness allow Gui, Theorem 13.1 to be applied with the hypotheses of Section 16.7. This gives the asserted convergence on that domain.

On a binary collision divide the field by $u^{h_k^- - h_i^- - h_j^-}$ and pair it with the inverse coefficient symbol before taking its full principal part. The derivative of that symbol retains the conformal exponent, as in (16.31). The full intertwiner identity commutes with this operation and with every spectator insertion. The Virasoro null-vector equations supply its conformal-block connection. Their sewing identities give the same Cousin boundary and cut identities. Thus the comparison also preserves the collision diagrams. □

For even $j = 0, 2, 4, 6, 8, 10$, the lowest weights are respectively $0, -1/6, 1/2, 2, 13/3, 15/2$. These weights and the central charge belong to the new Virasoro construction. The Galois automorphism acts on the finite junction data. The independently defined Virasoro vertex tensor theory supplies the full analytic lift. These sewings use algebraic contragredients. No positive Hilbert metric is assumed.

16.14 The connected realization beyond order two

The relative E_8 construction works for every arithmetic category considered here. Its vacuum algebra has $N+1$ idempotents. The affine and Virasoro constructions give complete order-two realizations on independently defined conformal state spaces. These results leave a different first example.

Question 16.14.1. For $K = \mathbb{Q}(\sqrt{21})$ and $\varepsilon = (5+\sqrt{21})/2$, one has $N = 3$. Construct a connected rational nonlocal conformal realization of C_I, with its specified module fusion, marked junctions, duality and convergent sewing on full descendant spaces. Which rooted, collision or nearby-cycle tensor realizes its fusion?

Theorem 16.8.1 excludes the stated strong unital realization by the scalar-empty balanced cut tensor. It does not exclude the alternative tensor asked for here. Likewise, the supported recoupling comparison must retain its larger channel system and specify the compression that produces $-N\beta D$. Its first missing map is an operation-preserving supported comparison with that declared compression.

Arithmetic field automorphisms act on the finite junction coefficients. Transport of a conformal theory requires, in addition, its actual tensorator, state spaces and analytic sewing. This distinction is already visible in the different affine and Virasoro conformal weights.

Chapter 17

Artin transport, norms and specialization

The arithmetic fusion category has two kinds of transport. An Artin automorphism moves its marked junctions from one lattice to another. A finite lattice covering instead multiplies arithmetic values over periodic orbits. We construct both maps and compare their tensor properties.

The distinction already appears for $\varepsilon = 2 + \sqrt{3}$ and $I = \mathbb{Z}[\sqrt{3}]$. The category at this period has simples 1, g, ρ, with

$$g^2 = 1, \qquad g\rho = \rho g = \rho, \qquad \rho^2 = 1 + g + 2\rho.$$

Changing to period ε^2 gives a positive map of fusion rings that sends the new noninvertible simple to $1 + g + 4\rho$. The unit occurs once in this image. Tensorator coherence would force a commutation relation on that one-dimensional space which two nonzero scalars cannot satisfy. The ring map survives. Its linear tensor lift does not.

We first transport the full marked category under reciprocity. Periodic points then organize multiplicative norms and their parameter algebras. The unit multiplicity gives obstructions to tensor lifts of every even period ratio. A further cocycle calculation excludes period three for the lattice above. Finally, norms of lines and indexed tensors provide positive multiplicative constructions, with their own coefficient domains.

17.1 Reciprocity on the marked family

Use the arithmetic data of Chapter 15. Thus K is a real quadratic field, $I \subset K$ is an oriented rank-two lattice, and $\varepsilon > 1$ is a totally positive norm-one unit preserving I. Write

$$G_I = (\varepsilon - 1)^{-1} I/I, \qquad N = |G_I| = \varepsilon + \varepsilon^{-1} - 2.$$

Let m be the exponent of G_I, and write $\mathcal{O} = (I : I) = \mathbb{Z} + c_0 \mathcal{O}_K$ for its multiplier order, with conductor c_0.

The normalized arithmetic values are $e_{I,g} = E_{I,\varepsilon}(g)/E_{I,\varepsilon}(0)$. They lie in the narrow ray field $L = H^+_{\mathcal{O},m}$. We use arithmetic Artin symbols: at an unramified prime their reduction acts by the residue-field norm power.

The reciprocity input is Theorem 2 of *Stark units for real quadratic fields and reciprocity laws*. It is stated in (15.6). The coefficients $b_{I,g} = b_0 e_{I,g}$, with $b_0 = (\varepsilon - 1)/N$, define the Leavitt algebra B_I and the marked category C_I. The algebra isomorphism below transports all four generator types X_g, X'_g, T_g, T'_g, including their algebraic duals.

Now let $\mathfrak{a}$ be an integral invertible $\mathcal{O}$-ideal prime to $c_0 m$, and put $J = \mathfrak{a}^{-1} I$. The natural label map is

$$\phi_{\mathfrak{a}} : G_I \longrightarrow G_J, \qquad x + I \longmapsto x + J.$$

Lemma 17.1.1. The map $\phi_{\mathfrak{a}}$ is an isomorphism, and J has multiplier order $\mathcal{O}$.

Proof. Coprimality gives $z \in \mathfrak{a}$ with $z \equiv 1 \pmod{mO}$. The integer $h = \mathrm{Nm}(z) = z\bar{z}$ belongs to $\mathfrak{a}$ and is prime to m. Therefore $h(J/I) = 0$. The kernel of $\phi_{\mathfrak{a}}$ is killed by both h and m, so is zero. Both groups have order N, proving surjectivity. If $tJ \subseteq J$, multiplication by the invertible ideal $\mathfrak{a}$ gives $tI \subseteq I$, and the converse follows by multiplication by $\mathfrak{a}^{-1}$. □

Extend coefficients to L, and write $\sigma_{\mathfrak{a}} = \mathrm{Art}(\mathfrak{a})|_L$. Since $b_0 \in K$, the arithmetic law gives

$$\sigma_{\mathfrak{a}}(b_{I,g}) = b_{J,\phi_{\mathfrak{a}}g}.$$

All reconstruction coefficients are rational expressions in the b_g and N. Thus Q, χ, a, c_1, β transform by the same label map, while d is fixed.

THEOREM 17.1.2. There is a $\sigma_{\mathfrak{a}}$-semilinear strong tensor equivalence

$$\Phi_{\mathfrak{a},I} : C_{I,L} \longrightarrow C_{\mathfrak{a}^{-1}I,L}$$

preserving ρ, sending α_g to $\alpha_{\phi_{\mathfrak{a}}g}$, and preserving the specified duality maps and normalized networks. For two such ideals,

$$\Phi_{\mathfrak{b},\mathfrak{a}^{-1}I}\Phi_{\mathfrak{a},I} = \Phi_{\mathfrak{a}\mathfrak{b},I}$$

on the explicit models.

Proof. Apply $\sigma_{\mathfrak{a}}$ to scalars and $\phi_{\mathfrak{a}}$ to every generator label. This defines a semilinear algebra isomorphism $\Theta_{\mathfrak{a}} : B_{I,L} \to B_{J,L}$. The coefficient formulas show $\Theta_{\mathfrak{a}}\rho_I = \rho_J\Theta_{\mathfrak{a}}$ and the corresponding equality for α_g. Thus intertwiners map to intertwiners, and (15.15) is preserved. Finite direct sums and idempotent splittings are preserved as well.

The zero label and d are fixed, proving duality compatibility. The normalization of Proposition 15.4.1 is preserved. Finally, Artin symbols multiply and both composed label maps send a representative to its class in $(\mathfrak{a}\mathfrak{b})^{-1}I$. The two semilinear maps therefore agree on scalars and generators. □

This is transport on the lattice-indexed family. Identifying its targets with one fixed category would require lattice identifications. This construction lifts the arithmetic law (15.6) to the marked category.

The scalar normalization matters for the unnormalized values. Choose an extension of $\sigma_{\mathfrak{a}}$ to $L(\sqrt{\varepsilon})$. For this extension, reciprocity reads

$$\sigma_{\mathfrak{a}}\big(E_{I,\varepsilon}(x)\big) = \frac{\sigma_{\mathfrak{a}}(\sqrt{\varepsilon})}{\sqrt{\varepsilon}}\, E_{\mathfrak{a}^{-1}I,\varepsilon}(x).$$

The possible sign disappears for $e_{I,x}$. It cannot be dropped from a statement about the raw values.

Transport of singular interfaces and finite symmetry

Let A be the level-one Heisenberg cut cobar over K used in Chapter 16. Put $R_I = B_I^{\mathrm{op}}$. For an endomorphism η of B_I, let P_η have underlying space B_I and actions

$$a^{\mathrm{op}}\, b\, c^{\mathrm{op}} = \eta(c)ba.$$

The relative realization is

$$\mathfrak{R}_I = A_L \otimes_L R_{I,L}, \qquad \mathfrak{P}_\eta = A_L \otimes_L P_{\eta,L}.$$

The map $\Theta_{\mathfrak{a}}$ transports these coefficients. The system A is defined over K, so its coordinates, translation, residues, local vacuum and cut maps are fixed.

Let P, Q be composable coefficient bimodules over $R = R_{I,L}$. In bar degree n, the comparison

$$(A_L \otimes P) \bigstar^{\mathbb{L}}_{A_L \otimes R} (A_L \otimes Q) \simeq A_L \otimes (P \otimes^{\mathbb{L}}_R Q)$$

multiplies the $n+2$ geometric factors in order. It leaves the coefficient bar $P \otimes R^{\otimes n} \otimes Q$. Thus it commutes with $\Theta_{\mathfrak{a}}$ in every degree. The common multibar proves the same assertion for every associativity and unit constraint.

Naturality also transports the connected comparison (16.12) and its weight-one interface (16.13). All normal derivatives and spectator states are retained.

The finite receiver has an equally explicit transport. Take split finite semisimple rigid categories over characteristic-zero fields k, k', with simple units. Let $F : \mathcal{C} \to \mathcal{C}'$ be a specified $\sigma : k \to k'$-semilinear tensor equivalence. Choose its identifications of simple objects, with permutation π of their labels. They give semilinear maps

$$U_i : P_{S_i} \longrightarrow P'_{S'_{\pi(i)}}$$

compatible with the tensorators, units and duality pairings of Section 16.6. The reconstructed algebras are $H_{\mathcal{C}} = \bigoplus_i \operatorname{End}_k(P_{S_i})$ and $H_{\mathcal{C}'}$.

Proposition 17.1.3. The formula

$$\Theta_\sigma(h)_{\pi(i)} = U_i h_i U_i^{-1}$$

defines a semilinear weak Hopf isomorphism. These maps compose with the marked equivalences.

Proof. Conjugation preserves multiplication. The compatibility of U with the balanced tensorator and matching-endpoint projection preserves the coproduct (16.16). Compatibility with the unit and its coordinate-sum functional preserves the counit. Compatibility with the duality pairings preserves their transposes, hence the antipode. Composing the maps U gives the stated composition law. □

In matrices after scalar twisting, this formula is $U_i\, \sigma(h_i)\, U_i^{-1}$, where U_i now denotes the linear matrix of the twisted map. The Artin equivalences supply the required identifications: they preserve X_{o}, dX'_{o} and every marked network. The assertion therefore includes the weak unit, categorical junctions and arithmetic markings.

17.2 Coherence on a fixed presentation

Transport of a marked algebra has two distinct forms. Base change moves the whole presentation to its conjugate. Transport on one fixed presentation first requires identifications with those conjugates, and their associativity has an obstruction. We compute this obstruction before discussing multiplicative norms, whose coherence uses different data.

Let k be a field and let B be an associative unital k-algebra with specified generators, relations and marked intertwiners. Include all roots and normalization constants in k. An automorphism σ of k carries these data to their coefficientwise conjugates. Polynomial relations and compositions are preserved, so this construction gives coherent semilinear transport on the family of conjugate presentations. Identifying its value with a prescribed arithmetic relabelling requires maps of the marked presentations themselves.

The central associativity class

Regard a group Γ acting on k as a discrete group. Suppose we are given σ-semilinear algebra automorphisms ϕ_σ of B and units $u_{\sigma,\tau} \in B^\times$ satisfying

$$\phi_\sigma \phi_\tau = \mathrm{Ad}(u_{\sigma,\tau})\phi_{\sigma\tau}, \qquad \phi_1 = 1, \qquad u_{1,\sigma} = u_{\sigma,1} = 1. \tag{17.1}$$

The last two unit equalities are part of the normalization. Set

$$c_{\sigma,\tau,\nu} = (u_{\sigma,\tau}u_{\sigma\tau,\nu})^{-1}\phi_\sigma(u_{\tau,\nu})u_{\sigma,\tau\nu}. \tag{17.2}$$

The restrictions of the ϕ_σ to $Z(B)$ define an honest Γ action, because inner automorphisms are trivial on the center. Write $\sigma(z) = \phi_\sigma(z)$ for $z \in Z(B)$.

PROPOSITION 17.2.1 *(Associativity of a fixed presentation).* The elements (17.2) form a normalized 3-cocycle with values in this Γ-module $Z(B)^\times$. Replacing $u_{\sigma,\tau}$ by $z_{\sigma,\tau}u_{\sigma,\tau}$ for a normalized central 2-cochain changes c by

$$(\delta z)_{\sigma,\tau,\nu} = \frac{\sigma(z_{\tau,\nu})z_{\sigma,\tau\nu}}{z_{\sigma,\tau}z_{\sigma\tau,\nu}}. \tag{17.3}$$

For the supplied automorphisms and inner comparisons, coherent implementers with $c = 1$ exist exactly when $[c] = 0$ in $H^3(\Gamma, Z(B)^\times)$.

Proof. Both $u_{\sigma,\tau}u_{\sigma\tau,\nu}$ and $\phi_\sigma(u_{\tau,\nu})u_{\sigma,\tau\nu}$ implement the same comparison between $\phi_\sigma\phi_\tau\phi_\nu$ and $\phi_{\sigma\tau\nu}$. Their ratio is therefore central.

Compare the five parenthesizations of four automorphisms using these implementers. The central triple ratios commute with every remaining factor. The two paths around the pentagon give

$$\sigma(c_{\tau,\nu,\kappa})c_{\sigma,\tau\nu,\kappa}c_{\sigma,\tau,\nu} = c_{\sigma\tau,\nu,\kappa}c_{\sigma,\tau,\nu\kappa}.$$

This is the multiplicative cocycle equation.

The unit equalities in (17.1) make c equal to 1 when any argument is the identity. Substitution of zu into (17.2) gives (17.3). Finally, two units implementing the same inner automorphism differ by a central unit. These cochains exhaust the choices for fixed ϕ. Their coboundaries therefore give exactly the stated vanishing criterion. □

When $c = 1$, the direct sum

$$B \rtimes_{\phi,u} \Gamma = \bigoplus_{\sigma\in\Gamma} BU_\sigma,$$
$$(bU_\sigma)(dU_\tau) = b\phi_\sigma(d)u_{\sigma,\tau}U_{\sigma\tau}$$

is a unital associative algebra over k^Γ. Indeed expansion of a triple product uses $\phi_\sigma\phi_\tau = \mathrm{Ad}(u_{\sigma,\tau})\phi_{\sigma\tau}$ to reduce its two parenthesizations to the two products of implementers in (17.2). For general c, the right-associated product is the left-associated one multiplied in its coefficient by $c_{\sigma,\tau,\nu}$. This also makes the defect of associativity explicit.

Normalization of ϕ_1 alone is insufficient. For example, take $B = \mathbb{Q}$, $\Gamma = \mathbb{Z}/3$ written additively, all $\phi = 1$, and choose $u_{0,1} = 2$, $u_{0,2} = 3$, with all other $u = 1$. The inner relation still holds, but $c_{0,1,1} = 3/2$. The units at an identity argument are central and can be normalized first. The displayed c becomes normalized only after this correction.

The strict maps on an arithmetic family in Theorem 17.1.2 and the fixed-presentation datum (17.1) have different domains. A family action does not by itself supply the identifications and inner implementers needed to define this class. Conversely, the class does not obstruct coefficientwise transport on the whole conjugate family.

17.3 Periodic points and normalized norms

The lattice operations have a geometric organization independent of the chiral background. Form the real two-torus

$$\mathbb{T}_I = (K \otimes_{\mathbb{Q}} \mathbb{R})/I.$$

Multiplication by ε induces a hyperbolic automorphism u_I with eigenvalues $\varepsilon, \varepsilon^{-1}$. For every integer $r \geq 1$,

$$\operatorname{Fix}(u_I^r) = (\varepsilon^r - 1)^{-1} I/I, \qquad N_r = |\operatorname{Fix}(u_I^r)| = \operatorname{Tr}(\varepsilon^r) - 2.$$

Indeed, a lift is fixed precisely when $(\varepsilon^r - 1)x \in I$. The real-linear map $\varepsilon^r - 1$ is invertible, and its determinant gives the stated cardinality.

The formal periodic-point zeta function is

$$\exp\left(\sum_{r\geq 1} \frac{N_r}{r} t^r\right) = \frac{(1-t)^2}{1 - \operatorname{Tr}(\varepsilon)t + t^2}.$$

This follows by expanding the logarithms of $(1-\varepsilon t)$, $(1-\varepsilon^{-1}t)$ and $(1-t)^2$.

An inclusion $I \subset J$ of lattices preserved by ε gives an equivariant finite covering $f : \mathbb{T}_I \to \mathbb{T}_J$. A fiber over a point fixed by u_J^r is permuted by u_I^r. Its elements need not all have period r. The orbit lengths determine the norm.

More generally, let u denote compatible automorphisms on spaces with finite equivariant coverings. A multiplicative periodic datum with values in a field M consists of $w(x, r) \in M^\times$, for $r \geq 1$ and $u^r x = x$, satisfying

$$w(ux, r) = w(x, r), \qquad w(x, rs) = w(x, r)^s \quad (s \geq 1). \tag{17.4}$$

For an equivariant finite covering f, define

$$(f_* w)(z, r) = \prod_{O \in u^r \backslash f^{-1}(z)} w(y_O, r|O|), \tag{17.5}$$

where y_O is any representative of the orbit. The first identity in (17.4) makes the choice irrelevant.

Proposition 17.3.1. The datum $f_* w$ satisfies (17.4). For composable equivariant finite coverings, $(g \circ f)_* w = g_*(f_* w)$. If the covers have constant degree and preserve a distinguished fixed point 0, the normalized operations

$$N_f^\circ(w)(z, r) = \frac{(f_* w)(z, r)}{(f_* w)(0, r)}$$

also satisfy $N_g^\circ N_f^\circ = N_{g\circ f}^\circ$.

Proof. Applying u permutes the orbits in a fiber and preserves their weights. To verify the power law, an orbit of length s under u^r splits into $\gcd(s, t)$ orbits under u^{rt}. Each new weight is the old weight raised to $t/\gcd(s, t)$. Their product is its t-th power.

For transitivity, fix a point of period dividing r in the last space. An orbit in the middle fiber has length s. Above one of its representatives, an orbit under u^{rs} has some length t. It gives one orbit of length st in the composite fiber, and every composite orbit is obtained uniquely this way. Both products therefore have the same factors $w(x, rst)$.

Put $v = f_* w$. Before applying g_*, normalization divides the factor on an orbit of length s by $v(0, rs) = v(0, r)^s$. The total denominator is $v(0, r)^{\deg(g)}$, independent of the target point. It cancels when the result is normalized at zero. Ordinary transitivity then proves normalized transitivity. □

For the arithmetic system take $M = \overline{\mathbb{Q}}$ and

$$w_I(x, r) = \frac{E_{I,\varepsilon^r}(x)}{E_{I,\varepsilon^r}(0)}.$$

The period identities give (17.4). Proposition 3 of *Stark units for real quadratic fields and reciprocity laws* gives the product over the orbits in a covering fiber. Dividing that identity by its value at zero removes its root-of-unity multiplier and proves

$$N_f^0(w_I) = w_J.$$

The product of the orbits' zero-value normalization factors is $\varepsilon^{r \deg(f)/2}$, independent of their decomposition. Thus replacing raw values by w_I gives the same normalized law.

If $H \subset G_{I,\varepsilon}$ and $J/I = H$, the law reduces, for $x \in G_{I,\varepsilon}$, to

$$e_{J,\varepsilon}(\pi x) = \prod_{h \in H} \frac{e_{I,\varepsilon}(x + h)}{e_{I,\varepsilon}(h)}.$$

The denominator is the zero-point normalization. The image of G_I/H need not fill G_J. The other points are handled by the longer orbits in (17.5).

One can encode each weight as a one-dimensional M-space with its scalar automorphism. The products then become tensor products of lines, and normalization tensors with the dual reference line. This realizes the norm law on lines with automorphisms. It does not construct tensor functors between the fusion categories.

For example, take $J = (\varepsilon - 1)^{-1} I$. Then $G_I = J/I$, so its image in G_J consists only of zero. But $|G_J| = N$. If $N > 1$, every other fixed point of $\mathbb{T}_J$ has a fiber with no fixed lift. The longer orbits in (17.5) are necessary.

The arithmetic identity uses quotient coverings of lattices. It is not invariant under every equivariant map of tori. For the order-two example of (16.5), translation by the nonzero fixed point exchanges the values $1, e_1$. Its normalized norm sends e_1 to $e_1^{-1} \neq e_1$.

The algebra of normalized periodic parameters

These nonlinear operations become algebra maps on parameter spaces. Define the Laurent algebra

$$\mathcal{P}_I = K[z_{x,r}^{\pm 1} : r \geq 1, x \in \mathrm{Fix}(u^r)] \big/ (z_{ux,r} - z_{x,r}, z_{x,rs} - z_{x,r}^s, z_{0,r} - 1),$$

where the power relation is imposed only when $u^r x = x$. The pullback for f is the finite monomial formula

$$f^*(z_{z,r}) = \frac{\prod_{O \subset f^{-1}(z)} z_{y_O, r|O|}}{\prod_{O \subset f^{-1}(0)} z_{y_O, r|O|}}.$$

The orbit argument proves that it respects the relations and that these pullbacks compose. Applying Theorem 16.3.1 over K gives all-arity chiral algebra maps $\mathcal{A}_{\mathcal{P}_J} \to \mathcal{A}_{\mathcal{P}_I}$. Arithmetic evaluation to $\overline{K}$ commutes with them. For any finite collection of periods, Artin transport is compatible under the common coefficient extension and its stated coprimality conditions. A single finite ray class field is not asserted for all periods at once.

17.4 Changing the period

Write $G_r = (\varepsilon^r - 1)^{-1} I / I$. The quotient map $I/(\varepsilon^r - 1)I \to I/(\varepsilon - 1)I$ gives a canonical surjection

$$\pi_r : G_r \longrightarrow G_1, \qquad x \longmapsto (1 + \varepsilon + \cdots + \varepsilon^{r-1})x.$$

This is distinct from the inclusion $G_1 \subset G_r$ used in the arithmetic power identity.

Let R_{G_1} be the integral fusion ring with basis α_g, ρ and rules (15.16). Put

$$A_G = \sum_{g \in G_1} \alpha_g, \qquad W_r = (1 + \rho)^r - 1.$$

The element W_r is positive in the fusion basis, since it is a sum of positive tensor powers with nonnegative integer coefficients.

Theorem 17.4.1. There is a positive unital ring homomorphism

$$\Psi_r : R_{G_r} \longrightarrow R_{G_1}, \qquad \alpha_h \longmapsto \alpha_{\pi_r(h)}, \qquad \rho_r \longmapsto W_r.$$

These homomorphisms compose under successive changes of period.

Proof. In $R_{G_1} \otimes \mathbb{Q}$, the element $e = A_G/N$ satisfies $e^2 = e$, $e\rho = \rho$, and $(1 - e)\rho = 0$. In the component with unit e, set $z = e + \rho$. The fusion rule gives

$$z^2 - (N + 2)z + e = 0, \qquad z + z^{-1} = (N + 2)e.$$

The second equality uses the inverse $(N + 2)e - z$. The recurrence for $z^r + z^{-r}$, together with $N + 2 = \mathrm{Tr}(\varepsilon)$, yields $z^r + z^{-r} = \mathrm{Tr}(\varepsilon^r)e$.

Since $1 + \rho = (1 - e) + z$ has orthogonal components, $W_r = z^r - e$. Consequently

$$W_r^2 = N_r W_r + (N_r/N) A_G. \tag{17.6}$$

The integer N_r/N is the size of $\ker \pi_r$. Thus

$$\sum_{h \in G_r} \alpha_{\pi_r(h)} = (N_r/N) A_G,$$

and (17.6) is exactly the image of the source fusion relation. The relations involving invertibles follow from the group map and $\alpha_g W_r = W_r$.

The rational calculation proves an integral identity because the fusion basis is free over $\mathbb{Z}$.

For successive periods r, s, the label multipliers multiply to $1 + \varepsilon + \cdots + \varepsilon^{rs-1}$. On the other generator the composite is $(1 + W_r)^s - 1 = (1 + \rho)^{rs} - 1$. This proves composition on every basis element. □

Both roots of the dimension equation are respected:

$$W_r(\varepsilon - 1) = \varepsilon^r - 1, \qquad W_r(\varepsilon^{-1} - 1) = \varepsilon^{-r} - 1.$$

For $K = \mathbb{Q}(\sqrt{5})$, $I = \mathcal{O}_K$, and $\varepsilon = (3 + \sqrt{5})/2$, one has $N = 1$, $N_2 = 5$, and $G_2 \simeq \mathbb{Z}/5$. The map sends every invertible simple at period two to the unit and sends ρ_2 to $1 + 3\rho$. Indeed,

$$(1 + 3\rho)^2 = 10 + 15\rho = 5 + 5(1 + 3\rho).$$

A tensor lift requires maps on multiplicity spaces. Choose the fusion bases of (15.18) and let $\mathscr{F}$ be the additive functor specified by Υ_r. Its tensorator would consist of invertible maps

$$J_{X,Y} : \mathscr{F}(X) \otimes \mathscr{F}(Y) \longrightarrow \mathscr{F}(X \otimes Y)$$

satisfying

$$\begin{aligned} &\mathscr{F}(a_{X,Y,Z}) J_{X\otimes Y,Z}(J_{X,Y} \otimes 1) \\ &\qquad = J_{X,Y\otimes Z}(1 \otimes J_{Y,Z}) a_{\mathscr{F}(X),\mathscr{F}(Y),\mathscr{F}(Z)}. \end{aligned} \tag{17.7}$$

There are also the two unit equations. The finite fusion bases make these polynomial equations with invertibility conditions. The next obstruction uses the tensorator only on invertible objects and the unit channel.

17.5 Quotient maps and their multiplicities

Let $\mathcal{C}_N$ and $\mathcal{C}_M$ have the near-group rules above, with groups G, H of orders N, M, and let $\pi : G \twoheadrightarrow H$ have kernel of order ℓ, so $N = \ell M$. Suppose an additive strong tensor functor F sends α_g to $\alpha_{\pi(g)}$. Write τ for the noninvertible simple in the target and $S = \sum_{h\in H}[\alpha_h]$. Since $\alpha_g \rho = \rho$, the class of $F\rho$ is invariant under all translations of H. Thus

$$[F\rho] = aS + r[\tau], \qquad a, r \in \mathbb{Z}_{\geq 0}.$$

The two coefficients contain all possible multiplicities. No additional simple objects exist in the specified target.

THEOREM 17.5.1 *(Exact fusion-ring obstruction).* A positive unital ring homomorphism with the indicated map on invertible simples exists if and only if there are integers $a \geq 0$, $r > 0$ satisfying

$$r = \ell - 2a, \qquad (M + 4)a(\ell - a) = \ell(\ell - 1). \tag{17.8}$$

Consequently the existence of an additive strong tensor functor with that invertible-sector map requires (17.8). The equations do not alone construct its tensorator.

Proof. In the target $S^2 = MS$, $S\tau = M\tau$, and $\tau^2 = S + M\tau$. Hence

$$(aS + r\tau)^2 = (Ma^2 + r^2)S + (2arM + r^2 M)\tau.$$

The image of the source relation is

$$\ell S + N(aS + r\tau).$$

First $r \neq 0$. Otherwise the positive number aM would solve $d^2 = Nd + N$, whose positive root $(N + \sqrt{N^2 + 4N})/2$ is irrational: $N^2 + 4N$ lies strictly between $(N + 1)^2$ and $(N + 2)^2$ for $N \geq 1$.

Comparing the τ coefficients and dividing by rM gives $r = \ell - 2a$. Substitution in the S coefficient gives the second equation.

Conversely these computations verify every source relation, including the group actions, so the assignment defines the stated ring homomorphism. It is nonnegative and sends the unit to the unit. □

For a proper quotient, $a = 0$ is impossible. For $\ell = 2, 3, 4$, the equations and $r > 0$ have no solutions: at $\ell = 2$ there is no positive $a < \ell/2$. At $\ell = 3$ the only candidate is $a = 1$, which would force $M = -1$. At $\ell = 4$ it forces $M = 0$. In particular, there is no such tensor functor from the $N = 4$ near-group category to the $M = 2$ category along a quotient of their invertible sectors. This obstructs the additive tensor functor itself.

There are nontrivial passing ring tests. For $a = 1$, the equations give

$$M = \ell - 4, \qquad N = \ell(\ell - 4), \qquad r = \ell - 2 \qquad (\ell \geq 5).$$

Thus $N = 12$, $M = 2$, $\ell = 6$ admits the positive ring assignment $\rho \mapsto S + 4\tau$. This passing ring test does not assert existence of every numerical near-group category, and no tensor functor is inferred.

For two given categories, the remaining problem is a finite system of tensorator equations on their multiplicity spaces. Those equations use both associators. The finite receiver of Section 15.6 turns these into matrices, but it does not construct a solution.

For the fixed target $M = 2$, the criterion has a useful arithmetic form:

$$3r^2 = \ell(\ell + 2), \qquad (\ell + 1)^2 - 3r^2 = 1, \qquad a = (\ell - r)/2.$$

In particular, define integers x_j, r_j by $x_j + r_j\sqrt{3} = (2 + \sqrt{3})^j$ and put $\ell_j = x_j - 1$. Then

$$(N, M, \ell, a, r) = (2\ell_j, 2, \ell_j, (\ell_j - r_j)/2, r_j)$$

is a passing based-ring datum for every $j \geq 1$. The first proper cases are $(12, 2, 6, 1, 4)$ and $(50, 2, 25, 5, 15)$.

The recurrence $x_{j+1} = 2x_j + 3r_j$, $r_{j+1} = x_j + 2r_j$ preserves $x_j^2 - 3r_j^2 = 1$. Reduction modulo two gives $\ell_j \equiv r_j$, and $\ell_j \geq r_j$ for $j \geq 1$. These facts prove integrality and nonnegativity of a. These maps specialize the positive period maps of Theorem 17.4.1 to the quadratic unit $2 + \sqrt{3}$. They retain the Pell constraint on the multiplicities.

An additional quick obstruction follows from Frobenius–Perron dimensions. A tensor functor preserves this positive dimension character. Alternatively, this follows here directly by applying the target positive dimension to the source relations. Write $d_N = (N + \sqrt{N^2 + 4N})/2$ and define d_M similarly. They satisfy

$$d_N = aM + rd_M.$$

Unequal quadratic fields $\mathbb{Q}(\sqrt{N^2 + 4N})$ and $\mathbb{Q}(\sqrt{M^2 + 4M})$ prohibit such a map. Equality of these fields is necessary, not sufficient. Here the dimension condition follows directly from the two fusion relations, without a separate categorical reconstruction.

The unit channel also constrains a lift when its multiplicity exceeds one. We use the arithmetic endomorphism presentation of (16.2). Its source group is denoted by G, its noninvertible object by ρ, and its nondegenerate bicharacter by χ. The intertwiners satisfy $U_g U_h = U_{g+h}$ by (15.10). All functors below are linear over a common field F of characteristic zero. For a subgroup $H_0 \subset G$, write

$$H_0^{\perp} = \{g \in G : \chi(g, h) = 1 \text{ for every } h \in H_0\}.$$

PROPOSITION 17.5.2 *(The full unit multiplicity).* Let F be a strong tensor functor and let $H_0 \subset G$ be a subgroup whose invertible objects have image isomorphic to the unit. Suppose

$$a = \dim_F \mathrm{Hom}(1, \mathsf{F}\rho)$$

is finite and positive. Then

$$\chi(g,h)^a = 1 \quad (g,h \in H_0), \qquad aH_0 \subset H_0^{\perp}. \tag{17.9}$$

If H_0 has at most d generators, then

$$|H_0| \mid [G : H_0]a^d. \tag{17.10}$$

Proof. Strictify the target, choose the unit identifications and put $M = \mathsf{F}\rho$. Write $J_{X,Y} : \mathsf{F}X \otimes \mathsf{F}Y \to \mathsf{F}(XY)$ for the tensorator. For $g, h \in H_0$, define invertible maps

$$A_g = J_{\alpha_g,\rho}, \qquad B_h = J^{-1}_{\rho,\alpha_h}\mathsf{F}(U_h).$$

Coherence on $(\alpha_g, \rho, \alpha_h)$ gives

$$J_{\alpha_g,\rho\alpha_h} = J_{\rho,\alpha_h} A_g J^{-1}_{\rho,\alpha_h}.$$

Naturality for $U_h : \rho \to \rho\alpha_h$, together with $\alpha_g(U_h) = \chi(g,h)U_h$, then gives

$$A_g B_h = \chi(g,h) B_h A_g.$$

These maps act by postcomposition on the entire space $\mathrm{Hom}(1, M)$. Taking determinants gives (17.9).

Write $H_0[a]$ for the kernel of multiplication by a on H_0. Its order divides a^d, by the cyclic decomposition of H_0. Moreover aH_0 is a subgroup of $H_0^{\perp}$, whose order is $[G : H_0]$ by nondegeneracy. The identity $|H_0| = |H_0[a]|\,|aH_0|$ proves (17.10). □

In particular, $a = 1$ forces $H_0 \subset H_0^{\perp}$. For period doubling,

$$N_2 = N(N+4), \qquad |\ker \pi_2| = N + 4, \qquad W_2 = S + (N+2)\rho.$$

The unit multiplicity is one, so a tensor lift would require $(N+4)^2 \le N(N+4)$. Their difference is $4(N+4) > 0$. This proves the obstruction in the opening example. For the Fibonacci target, two nonzero scalars would have to satisfy a nontrivial fifth-root commutation relation.

For period maps the kernel has at most two generators. The resulting divisibility condition excludes every even ratio of periods.

THEOREM 17.5.3 *(Even ratios of periods).* Let I be a full rank-two lattice in a real quadratic field and let $\varepsilon > 1$ be a norm-one unit with $\varepsilon I = I$. Put

$$G_r = (\varepsilon^r - 1)^{-1} I/I, \qquad N_r = \varepsilon^r + \varepsilon^{-r} - 2, \qquad N = N_1.$$

Let $\pi_r : G_r \to G_1$ be multiplication by $(\varepsilon^r - 1)/(\varepsilon - 1)$. Assume that the arithmetic near-group categories for the periods in question are given with the nondegenerate bicharacters and endomorphism presentations above. If $r \ge 2$ is even, the positive period ring map of Theorem 17.4.1,

$$\alpha_g \longmapsto \alpha_{\pi_r(g)}, \qquad \rho_r \longmapsto W_r = (1+\rho)^r - 1,$$

has no linear strong tensor lift. The same conclusion holds for $G_{rs} \to G_s$ whenever the ratio r is even, and after any characteristic-zero extension of the coefficient field.

Proof. Put $t = N + 2$, $V_j = \varepsilon^j + \varepsilon^{-j}$, and define $u_{-1} = 0$, $u_0 = 1$ and $u_j = t u_{j-1} - u_{j-2}$ for $j \geq 1$. In the target fusion ring write $S = \sum_{g \in G_1} \alpha_g$. The relations $S^2 = NS$, $S\rho = N\rho$ and $\rho^2 = S + N\rho$ give

$$W_r = a_r S + u_{r-1}\rho, \qquad N a_r = u_{r-1} - u_{r-2} - 1. \tag{17.11}$$

For example, multiplication of W_r by $1 + \rho$, followed by addition of ρ, gives the formula for W_{r+1}. Thus all these multiplicities are integers. Evaluating in the two roots ε, ε^{-1} also gives

$$N a_r = \frac{(\varepsilon^r - 1)(\varepsilon^{r-1} - 1)}{\varepsilon^{r-1}(\varepsilon + 1)} > 0 \qquad (r \geq 2).$$

The kernel H_0 of π_r has order N_r/N and index N in G_r. It is a subgroup of $(\mathbb{Q}/\mathbb{Z})^2$, so it has at most two generators. A lift would have unit multiplicity a_r.

Proposition 17.5.2 would therefore make

$$\frac{N^2 a_r^2}{N_r} = \frac{V_{r-1} - 2}{N + 4} \tag{17.12}$$

an integer. The equality follows by inserting the preceding formula and $N_r = (\varepsilon^r - 1)^2/\varepsilon^r$.

But $V_0 = 2$, $V_1 = t$ and $V_j = tV_{j-1} - V_{j-2}$. Modulo $N + 4$, this gives $V_j \equiv 2(-1)^j$. For even r the numerator on the right of (17.12) is congruent to -4. Since $N + 4 \geq 5$, it is not divisible by $N + 4$.

Replacing ε by ε^s gives the assertion at base period s. The unit multiplicity and the root-of-unity commutator relations are unchanged by extension of coefficients. □

For an odd ratio $r = 2k + 1$, the same quotient is

$$\frac{V_{2k} - 2}{N + 4} = N u_{k-1}^2.$$

Thus every odd ratio passes this determinant test. In the Pell family above, $j = 2m$ gives

$$\ell_j = 6r_m^2, \qquad a_j = r_m(3r_m - x_m), \qquad \frac{2a_j^2}{\ell_j} = 4r_m^2 - 2x_m r_m + \frac{1}{3},$$

whereas $j = 2m + 1$ gives $\ell_j = (x_m + 3r_m)^2$, $a_j = r_m(x_m + 3r_m)$ and $2a_j^2/\ell_j = 2r_m^2$. For the standard Pell lattice, the first odd ratio has a further obstruction: coherence relates the two projective kernel actions.

Lemma 17.5.4 *(Reciprocal kernel cocycles).* In Proposition 17.5.2, suppose the target unit has endomorphism field F. Write $J_{X,Y} : \mathsf{F}X \otimes \mathsf{F}Y \to \mathsf{F}(XY)$ for the tensorator. Choose $\mathsf{F}\alpha_g = 1$ for $g \in H_0$ and write $c(g, h) \in F^\times$ for the tensorator on (α_g, α_h). Put

$$T_h = J_{\rho,\alpha_h}, \qquad A_g = J_{\alpha_g,\rho}, \qquad B_h = T_h^{-1}\mathsf{F}(U_h).$$

Then c is a scalar 2-cocycle and

$$\begin{aligned} A_g A_h &= c(g, h) A_{g+h}, \\ B_g B_h &= c(g, h)^{-1} B_{g+h}, \\ A_g B_h &= \chi(g, h) B_h A_g. \end{aligned}$$

These identities hold on $\mathrm{Hom}(1, \mathsf{F}\rho)$.

Proof. Coherence on three invertible objects gives the cocycle identity. Coherence on $(\alpha_g, \alpha_h, \rho)$ gives the first operator identity, since $\alpha_h \rho = \rho$. For the second, the source has

$$(U_g \otimes 1_{\alpha_h}) U_h = U_{g+h}.$$

Naturality and coherence give, respectively,

$$\mathsf{F}(U_g \otimes 1) T_h = J_{\rho\alpha_g, \alpha_h} \mathsf{F}(U_g), \qquad J_{\rho\alpha_g, \alpha_h} T_g = c(g,h) T_{g+h}.$$

Consequently $\mathsf{F}(U_{g+h}) = c(g,h) T_{g+h} B_g B_h$. Cancelling T_{g+h} proves the second identity. The third is the relation used in Proposition 17.5.2. Postcomposition restricts all three to the unit channel. □

PROPOSITION 17.5.5 *(The third period of the standard Pell lattice).* For $I = \mathbb{Z}[\sqrt{3}]$ and $\varepsilon = 2 + \sqrt{3}$, the positive period map $G_3 \to G_1$ has no linear strong tensor lift between the specified arithmetic categories. The conclusion holds after any characteristic-zero extension of coefficients.

Proof. Extend the field to an algebraic closure. Here $|G_3| = 50$ and $1 + \varepsilon + \varepsilon^2 = 5\varepsilon$. Thus the kernel is

$$H_0 = (\tfrac{1}{5} I)/I \simeq (\mathbb{Z}/5)^2,$$

with basis $\varepsilon/5, 1/5$. Formula (17.11) gives $W_3 = 5S + 15\rho$, so a lift would have a five-dimensional unit channel.

On this kernel the arithmetic Gaussian is given in Radchenko–Wheeler, Section 4.4, p. 20:

$$Q\big((k\varepsilon + l)/5\big) = \zeta^{k^2 - kl + l^2}, \qquad \zeta = e^{2\pi i/5}.$$

Hence $\chi(g,h) = \zeta^{g^{\mathrm{t}} K h}$ with $K = \left(\begin{smallmatrix} 2 & -1 \\ -1 & 2 \end{smallmatrix}\right)$ over $\mathbb{F}_5$.

The commutator of a scalar cocycle on H_0 is an alternating bicharacter. It therefore has the form $c(g,h)c(h,g)^{-1} = \zeta^{v \det(g,h)}$ for some $v \in \mathbb{F}_5$. By Lemma 17.5.4, the operators $A_g B_h$ give a projective representation of $H_0 \oplus H_0$ with alternating commutator matrix

$$\Omega_v = \begin{pmatrix} vJ & K \\ -K & -vJ \end{pmatrix}, \qquad J = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}.$$

Its Pfaffian is $-v^2 - 3$, which is nonzero in $\mathbb{F}_5$: $2 = -3$ is not a square. The commutator form is nondegenerate.

Choose a symplectic basis for this four-dimensional form. The corresponding operators form two independent Weyl pairs of order five. Rescale their scalar fifth powers to one. The two commuting clock operators then diagonalize, and the two shift operators carry each joint eigenspace through twenty-five distinct weights of equal dimension. Every nonzero representation consequently has dimension divisible by twenty-five. This contradicts the five-dimensional unit channel. □

Question 17.5.6. For the arithmetic categories attached to $\varepsilon = 2 + \sqrt{3}$, which odd periods $j \geq 3$ admit a linear strong tensor lift of the positive period map? Its noninvertible image is $a_j S + r_j \tau$, where $a_j = (\ell_j - r_j)/2$ and the integers ℓ_j, r_j are defined above. Construct invertible maps on the finite multiplicity bimodules satisfying the unit and associator equations, or exhibit an obstruction. For $I = \mathbb{Z}[\sqrt{3}]$, Proposition 17.5.5 makes $j = 5$ the first remaining case.

17.6 Multiplicative norms on coefficients

The preceding obstructions concern additive strong tensor functors between the specified fusion categories. Two multiplicative constructions remain available. The first acts on invertible modules. The second tensors an indexed family of algebras and bimodules.

Norms of invertible modules

Let R be a commutative ring and let E/R be finite étale of constant rank d. For an invertible E-module L define the invertible R-module

$$N_{E/R}(L) = \det_R(L) \otimes_R \det_R(E)^{-1}. \tag{17.13}$$

The source and target are the Picard groupoids of invertible modules and their isomorphisms. Their monoidal operation is tensor product.

Theorem 17.6.1 *(Tensor and tower coherence of the norm).* The construction (17.13) is strong symmetric monoidal:

$$N(L \otimes_E M) \simeq N(L) \otimes_R N(M), \qquad N(E) \simeq R.$$

For finite etale towers $R \to E \to F$, it has coherent comparisons $N_{F/R} \simeq N_{E/R} N_{F/E}$. All these maps commute with arbitrary base change on this finite etale domain.

Proof. After an etale splitting, $E = R^d$ and $L = (L_1, \dots, L_d)$. Formula (17.13) becomes the tensor product of the lines L_i. A permutation of sheets has the same determinant sign in $\det_R(L)$ and $\det_R(E)$, so the signs cancel. Thus the local tensor comparison is invariant under every sheet permutation.

For a tower, split all sheets at once. Either norm is the tensor product over the same final sheets, grouped first by their fibers over E or directly over R. Associativity and symmetry of tensor products identify these expressions and every longer grouping. They are invariant under changes of splitting and hence descend by faithful flat descent. The same sheetwise description proves base change and all tensor and tower coherences. □

On automorphisms of the unit line, this is $u \mapsto \det_R(m_u)$, the multiplicative norm of units. The determinant polynomial on all elements is not additive. For $E = R \times R$, it is $(a, b) \mapsto ab$. The two orthogonal idempotents have norm zero while their sum has norm one. An additive functor on all modules cannot induce this map on endomorphisms of the unit. A transfer on a Hall or fusion category therefore needs its own construction or a specified multiplicative subcategory.

For comparison, a finite scalar norm has an exact normalized tower identity. If $\pi : G \twoheadrightarrow H$ is a surjection of finite groups and u has values in a commutative group of units, set

$$N_\pi(u)(h) = \prod_{\pi(g)=h} u(g), \qquad \mathcal{N}_\pi(u)(h) = N_\pi(u)(h)/N_\pi(u)(1_H).$$

For $G \xrightarrow{\pi} H \xrightarrow{\rho} K$ one has

$$\mathcal{N}_\rho(\mathcal{N}_\pi(u)) = \mathcal{N}_{\rho\pi}(u). \tag{17.14}$$

Every fiber of ρ has cardinality $|\ker \rho|$. The intermediate denominator therefore occurs to the same power in every fiber product. Final normalization cancels it, proving (17.14). The group identity here is the reference point for normalization.

The indexed tensor norm on coefficients

An indexed tensor norm has a different target and is nonadditive. Fix a field k and a finite set S. For dg algebras B_s, E_s, D_s over k and composable dg bimodules ${}_{B_s}P_{sE_s}$ and ${}_{E_s}Q_{sD_s}$, define

$$N_S(B_s) = \bigotimes_{s\in S} B_s, \qquad N_S(P_s) = \bigotimes_{s\in S} P_s.$$

Fix an order temporarily to write formulas. The symmetric dg tensor comparison makes different orders canonically equivalent, with their Koszul signs. The left and right actions on the tensor of bimodules are the ordered tensor actions.

THEOREM 17.6.2 *(Composition of indexed norms).* There is a coherent derived comparison

$$\left(\bigotimes_s P_s\right) \otimes^{\mathbb{L}}_{\bigotimes_s E_s} \left(\bigotimes_s Q_s\right) \simeq \bigotimes_s (P_s \otimes^{\mathbb{L}}_{E_s} Q_s).$$

It preserves regular bimodules, arbitrary finite towers of indexing sets, and permutations of the sheets. It does not assert additivity in the repeated input P of $P \mapsto P^{\otimes S}$.

Proof. Use free bar resolutions or K-flat representatives. On homogeneous tensors the comparison is

$$(\otimes_s p_s) \otimes (\otimes_s q_s) \longmapsto (-1)^{\epsilon} \otimes_s (p_s \otimes q_s), \qquad \epsilon = \sum_{s<t} |q_s||p_t|.$$

Balancing on sheet s becomes precisely balancing over E_s after this permutation. The tensor differential commutes with a Koszul permutation. The same permutation applied to the common multibar compares the derived tensors. Its realizations agree because finite tensors over a field preserve the required colimits and because geometric realizations over multiple simplicial indices commute.

For three interfaces, the two routes make the same final permutation of all factors. Thus their signs agree. Regular bimodules give the unit comparison. Grouping a finite set into fibers and then grouping those fibers leaves the final tensor and its permutation unchanged, proving tower coherence. □

Over a characteristic-zero field, this construction descends along a finite étale algebra. Choose a splitting cover with sheet set S. The symmetric tensor action of sheet permutations gives descent data for the algebras and bimodules.

For invertible modules in degree zero, it recovers the Picard norm, with normalization $\det(f_*L) \otimes \det(f_*\mathcal{O})^{-1}$ for the finite étale map f. On arbitrary objects it is polynomial rather than additive. For example,

$$(P \oplus Q)^{\otimes S} \cong \bigoplus_{U\subseteq S} \left(\bigotimes_{s\in U} P\right) \otimes \left(\bigotimes_{s\notin U} Q\right),$$

with factors kept in sheet order. The mixed summands exhibit the failure of additivity.

Let $\mathscr{A}$ be a fixed singular background over k, as in Chapter 16. To obtain interfaces, apply the relative realization after taking this coefficient norm:

$$N_S(B_s) \longmapsto \mathscr{A} \otimes N_S(B_s), \qquad N_S(P_s) \longmapsto \mathscr{A} \otimes N_S(P_s).$$

Theorem 17.6.2 and Theorem 8.2.2 give its relative interface composition. The construction retains one copy of $\mathscr{A}$. An identification of $\mathscr{A}^{\otimes S}$ with $\mathscr{A}$ is not among its maps.

Sheet permutations act on the coefficient tensor. They supply no exchange of positive geometric word factors. The target is the relative envelope with the indexed coefficient algebra. Its comparison with another period's arithmetic fusion category is an additional construction.

17.7 Integral transport and residue fields

The integral presentation of Proposition 15.3.3 also transports. For a fixed period, put $\mathcal{S} = O_L[1/N]$. The field automorphism $\sigma_{\mathfrak{a}}$ preserves this ring, and all four generator formulas are defined over it.

Proposition 17.7.1. The map $\Theta_{\mathfrak{a}}$ restricts to a semilinear isomorphism of the integral Leavitt presentations over $\mathcal{S}$. It preserves their endomorphisms, displayed splittings, cups, caps and marked network equations. For a prime ideal $\mathfrak{q} \subset \mathcal{S}$, it induces an isomorphism between the reductions at $\mathfrak{q}$ and $\sigma_{\mathfrak{a}}(\mathfrak{q})$, over the induced residue-field isomorphism.

Proof. The map permutes the generator labels and conjugates their coefficients. Each normalized coefficient is a unit in $\mathcal{S}$, and its conjugate is the corresponding coefficient for $\mathfrak{a}^{-1}I$. The inverse label map and inverse field automorphism give the inverse integral presentation map.

All the stated equations are identities between finite expressions over $\mathcal{S}$. Their validity follows either from the defining relations or from the free normal form of Proposition 15.3.3. Reducing these expressions preserves every identity. The semilinear map carries the ideal $\mathfrak{q}B_I$ onto $\sigma_{\mathfrak{a}}(\mathfrak{q})B_{\mathfrak{a}^{-1}I}$, so it descends to the claimed isomorphism. □

This statement concerns the presentations and their displayed maps. Intertwiner spaces are kernels of linear equations. Their dimensions can increase after reduction, so semisimplicity and the full list of simple objects require a separate argument. The localization excludes primes dividing N. An integral model at those primes requires an additional construction.

A finite collection of periods can be treated over a common number field containing their coefficients and every chosen normalization. Inverting the product of their N_r gives a common ring for the displayed formulas. The Artin ideals must satisfy the coprimality conditions for each period. No single finite ray field is asserted for all periods simultaneously.

17.8 The remaining tensor comparison

The constructions have distinct domains. Reciprocity gives semilinear equivalences on a marked family. Orbit norms give compatible maps of parameter algebras. Picard norms and indexed tensor norms give multiplicative maps on their specified coefficient categories. The positive period ring map retains both dimension characters, while its tensorator must solve (17.7).

For the standard lattice $\mathbb{Z}[\sqrt{3}]$, every even period ratio and period three are excluded by the preceding proofs. At period five the proposed image is

$$W_5 = 76S + 209\rho, \qquad N_5 = 722, \qquad |\ker \pi_5| = 361.$$

Its determinant test passes: $N^2 76^2/722 = 32$. The reciprocal kernel relations and the full associator equation remain to be solved on these multiplicity spaces. For other lattices, the restricted arithmetic Gaussian must also be determined before applying the period-three argument.

Question 17.8.1. Construct a multiplicative correspondence between the marked arithmetic fusion systems whose scalar evaluation is the normalized orbit norm. Specify its coefficient category, supported field operations, unit and comparison with the indexed norm. Does it preserve the arithmetic junctions and their full collision diagrams?

The parameter-algebra maps already realize the scalar norm in every arity. The question asks for its comparison with the marked fusion objects and their fields.

Chapter 18

Intrinsic geometric and automorphic comparison

A local Hecke polynomial determines two eigenvalues. It does not determine an automorphic representation, the extensions between representations, or the category on which the Hecke operators act. For example, the functor

$$D(k[t]) \longrightarrow D(k[t]) \times D(k[t]), \qquad M \longmapsto (M, 0),$$

is fully faithful and respects a faithful scalar action on the target. Its image misses every nonzero object in the second factor. This elementary example separates the scalar comparison from categorical reconstruction.

The arithmetic constructions of the preceding chapters provide operators, coefficient algebras, marked interfaces and their composition maps. An intrinsic realization must identify these data with independently defined geometric or automorphic objects. This chapter constructs the formal and local comparisons that enter that problem. It retains the deformation groupoids, central actions, extension classes and tensor transitions needed to pass between them.

The coefficients matter throughout. Smooth representations with characteristic-zero coefficients away from the residue characteristic have Bernstein blocks and Weil–Deligne parameters. Smooth p-power-torsion representations have a different spectral recipient, built from étale (φ, Γ)-modules. Global determinant deformations use one fixed coefficient ring at every place. Each comparison below specifies the regime in which its maps are defined.

18.1 Marked objects and categorical recognition

Let $\mathscr{D}$ be an ∞-category of arithmetic data. An object may contain a coefficient algebra, selected modules, Hecke or Galois actions, intertwiners, a distinguished state and a scalar evaluation on a specified domain. Morphisms preserve these markings. Let $\mathscr{R}$ be a category of proposed geometric realizations and let $U : \mathscr{R} \to \mathscr{D}$ retain the data. Write $\mathscr{D}^{\simeq}$ for its maximal ∞-groupoid, and similarly for $\mathscr{R}$.

Definition 18.1.1. For $d \in \mathscr{D}$, the space of marked realizations is

$$\mathrm{Real}_U(d) = \mathrm{hofib}_d\big(\mathscr{R}^{\simeq} \xrightarrow{U^{\simeq}} \mathscr{D}^{\simeq}\big).$$

A point consists of $r \in \mathscr{R}$ and an equivalence $U(r) \simeq d$, with their higher identifications.

Nonemptiness expresses existence. Contractibility expresses uniqueness with coherent identifications. A functorial realization requires a functor $S : \mathscr{D} \to \mathscr{R}$ and an equivalence $US \simeq \mathrm{id}_{\mathscr{D}}$. Objectwise choices do not define S on noninvertible morphisms. When the desired comparison is a map, its realizations instead retain that map in the appropriate arrow category.

This definition applies to several different arithmetic problems. The relative singular models retain a chosen geometric background. The marked fusion models also retain their associator, duality and distinguished arithmetic junction. A global automorphic realization must in addition preserve its ramified and

archimedean actions, coefficient topology and evaluation functional. A scalar identity obtained after evaluation supplies one consequence of such a map.

Coefficients and retained operations

A coefficient change must be a map in the stated coefficient category. For example,

$$(\mathbb{Z}/\ell^r) \otimes_{\mathbb{Z}} \mathbb{Q} = 0, \qquad \left(\varprojlim_r \mathbb{Z}/\ell^r\right) \otimes_{\mathbb{Z}} \mathbb{Q} = \mathbb{Q}_\ell.$$

Thus rationalization before completion destroys this coefficient tower. Likewise, over $\mathbb{F}_p$, the big Witt vector with only $a_p = 1$ is nonzero although all its ghosts $\sum_{d|n} d\, a_d^{n/d}$ vanish. The integral operations require their original coordinates.

Even an equivalence of underlying categories need not preserve a chosen central action. Give $D(k)$ the two $k[t]$-actions $t = 0$ and $t = 1$. Its identity equivalence cannot intertwine them: the proposed equality on the object k would be $0 = 1$. The action and its specified compatibility are therefore part of the realization datum.

Comparison on generators

THEOREM 18.1.2 *(Comparison on compact generators).* Let $\mathcal{C}, \mathcal{D}$ be presentable stable ∞-categories, and let $F : \mathcal{C} \to \mathcal{D}$ be exact and colimit-preserving. Let $\{P_i\}_{i \in I}$ be a set of compact generators of $\mathcal{C}$. Here generation means that their smallest full stable subcategory closed under all small colimits is $\mathcal{C}$. Assume each $F(P_i)$ is compact and that the maps of mapping spectra

$$\mathrm{Map}_{\mathcal{C}}(P_i, P_j) \longrightarrow \mathrm{Map}_{\mathcal{D}}(F(P_i), F(P_j))$$

are equivalences for all i, j. Then F is fully faithful. It is an equivalence if the objects $F(P_i)$ also generate $\mathcal{D}$.

Proof. Fix i. Compactness and exactness imply that both mapping-spectrum functors in the comparison, with second variable X, preserve coproducts and finite colimits. They therefore preserve all colimits between stable categories. The objects X where the comparison is an equivalence form a localizing subcategory of $\mathcal{C}$. It contains every P_j, so it is all of $\mathcal{C}$.

Fix X and vary the first argument. Mapping spectra convert colimits in this argument into limits. Hence the objects Y for which

$$\mathrm{Map}_{\mathcal{C}}(Y, X) \longrightarrow \mathrm{Map}_{\mathcal{D}}(F(Y), F(X))$$

is an equivalence form a localizing subcategory containing all P_i. This proves full faithfulness. Its essential image is closed under colimits and finite cones, since diagrams in that image lift through a fully faithful functor. If the image contains generators of $\mathcal{D}$, it is all of $\mathcal{D}$. □

For an E-linear differential graded enhancement, the hypothesis is a quasi-isomorphism on each derived Hom complex induced by the chosen functor. An equality of dimensions or a match in degree one is weaker. Use the augmentation modules $k = k[t]/(t)$ and $k = (k[\epsilon]/(\epsilon^2))/(\epsilon)$. Then k has $\mathrm{Ext}^1(k,k) = k$ over both $k[t]$ and $k[\epsilon]/(\epsilon^2)$. Over $k[t]$, its length-one free resolution makes all higher Ext groups zero. Over the dual numbers, the periodic resolution with differential multiplication by ϵ gives $\mathrm{Ext}^n(k,k) = k$ for every $n \geq 0$.

The local categorical Langlands question requires the actual source subcategory, spectral support condition, comparison functor, and objects P_i. Frobenius parameters and invariant vectors supply inputs for this question. A categorical equivalence follows only after the derived Hom and generation hypotheses have been established on those categories.

18.2 Determinants and local parameter spaces

A representation gives characteristic polynomials after every scalar extension. A determinant polynomial law retains these compatible polynomials even when no free representation has been chosen. Its definition works in characteristic two, where a trace alone does not contain every characteristic coefficient.

Definition 18.2.1 *(Chenevier determinant and associated trace).* Let R be a commutative ring, Γ a group and $d \geq 1$. An R-valued determinant of dimension d is a multiplicative, homogeneous polynomial law of degree d from $R[\Gamma]$ to R. Thus it specifies maps $D_A : A[\Gamma] \to A$ for every commutative R-algebra A, natural in A, with $D_A(1) = 1$, $D_A(xy) = D_A(x)D_A(y)$ and $D_A(ax) = a^d D_A(x)$. Write

$$D_{R[t]}(t - x) = \sum_{j=0}^{d} (-1)^j \Lambda_j(x) t^{d-j}.$$

The associated trace is the R-linear map $T = \Lambda_1$. The notation (T, D) retains this dependence. The characteristic polynomial gives the Cayley–Hamilton relations in the quotient by their coefficients after polynomial base change. These relations need not hold in $R[\Gamma]$ itself. For a profinite Γ and a topological coefficient ring, continuity means that all characteristic-polynomial coefficient functions on Γ are continuous.

Proposition 18.2.2 *(determinantal deformation rings).* Let k be a finite field of characteristic p_0, and put $W = W(k)$. Fix a continuous residual determinant $\bar{D}$ of dimension d of a profinite group Γ. On finite local W-algebras A with residue field k, let $\mathcal{D}_\Gamma(A)$ be the set of continuous determinants lifting $\bar{D}$. This covariant functor is prorepresented by a profinite local W-algebra R_Γ^{Ch}:

$$\mathcal{D}_\Gamma(A) = \mathrm{Hom}_{W,\mathrm{cont}}(R_\Gamma^{\mathrm{Ch}}, A).$$

Assume that every open subgroup has only finitely many continuous homomorphisms to $\mathbb{Z}/p_0\mathbb{Z}$.

This is Mazur's finiteness condition, and it makes the ring complete Noetherian. A closed deformation condition represented by a quotient is imposed by that quotient. The representing formal space is $\mathrm{Spf}\, R_\Gamma^{\mathrm{Ch}}$. For $\Gamma = G_{\mathbb{Q},S}$ with finite S, and for local Galois groups in characteristic zero, the finiteness condition holds. If the residual representation is absolutely irreducible and defined over k, determinant deformations agree with its representation deformations up to strict equivalence.

Attribution. Chenevier, arXiv:0809.0415, §1.1 and §1.10 define polynomial laws and their characteristic coefficients. Proposition 3.3, p. 42, proves prorepresentability. Example 3.6 and Proposition 3.7, p. 43, give the finiteness assertions. Example 3.4 and Theorem 2.22 give the absolutely irreducible comparison. Bellaïche–Chenevier, *Families of Galois representations and Selmer groups*, Chapter 1, provides the related deformation-theoretic setting. A chosen local condition must be shown to define the quotient used in any particular application. □

The Frobenius parameter stack

Let E be a field of characteristic zero and let $d \in E^\times$. For an E-algebra A, consider a rank-two projective A-module V with an automorphism F satisfying $\wedge^2 F = d\ \mathrm{id}_{\wedge^2 V}$. Isomorphisms intertwine F. No trivialization of $\wedge^2 V$ is part of the data. This defines the quotient stack

$$\mathcal{U}_d = [Y_d / GL_2], \qquad Y_d = \operatorname{Spec} E[x_{11}, x_{12}, x_{21}, x_{22}]/(x_{11}x_{22} - x_{12}x_{21} - d),$$

where GL_2 acts by conjugation. It is the algebraic parameter stack for an unramified rank-two Weil representation with chosen generator acting by F.

Put $t = \operatorname{tr} F$. The regular semisimple open substack $\mathcal{U}_d^{\mathrm{rs}}$ is defined by $t^2 - 4d \neq 0$. The ordered eigenvalue scheme and diagonal torus are

$$T_d = \operatorname{Spec} E[a, a^{-1}, (a^2 - d)^{-1}], \qquad T = \mathbb{G}_m^2.$$

The involution w sends a to d/a and exchanges the factors of T.

PROPOSITION 18.2.3 *(Eigenvalues and eigenline automorphisms).* There is an equivalence

$$\mathcal{U}_d^{\mathrm{rs}} \simeq [T_d / (T \rtimes \langle w \rangle)],$$

where T acts trivially on T_d. The scheme of unordered eigenvalues is

$$U_d = \operatorname{Spec} E[t, (t^2 - 4d)^{-1}].$$

It has dimension one. Over an algebraically closed field, each geometric object of $\mathcal{U}_d^{\mathrm{rs}}$ has automorphism group $\mathbb{G}_m^2$.

Proof. After a finite étale base change, the polynomial $X^2 - tX + d$ has distinct roots a, b, with $b = d/a$. The endomorphisms

$$e_a = \frac{F - b}{a - b}, \qquad e_b = \frac{F - a}{b - a}$$

are complementary idempotents. Their images are rank-one projective modules, and F acts on them by a and b. Conversely, two line bundles with these scalar actions give (V, F).

Changing their frames gives the T-action. Exchanging their order gives the involution. Descent gives the stated quotient stack.

The map $a \mapsto t = a + d/a$ identifies the unordered roots. Its coordinate extension satisfies $a^2 - ta + d = 0$. Inverting $t^2 - 4d$ makes this a finite étale double cover with the stated involution. The invariant ring is $E[t, (t^2 - 4d)^{-1}]$. Each automorphism preserves the two eigenspaces and scales them independently. □

The atlas Y_d has dimension three, since the determinant equation has nonzero differential on invertible matrices. Thus $\mathcal{U}_d$ has dimension $3 - 4 = -1$ as an algebraic stack. Its eigenvalue scheme has a different dimension and omits stabilizers. If a trivialization of $\wedge^2 V$ is required, the quotient uses SL_2 instead. Its regular semisimple stabilizer is $\mathbb{G}_m$. These are distinct moduli conventions.

An unramified deformation ring

Let O be a complete discrete valuation ring of mixed characteristic, with finite residue field k of characteristic p. Fix a nonarchimedean local field L. Write G_L for its absolute Galois group and I_L for inertia, so $G_L/I_L \simeq \widehat{\mathbb{Z}}$. Fix $\overline{F} \in GL_2(k)$ and $d \in O^\times$ lifting $\det \overline{F}$.

A test algebra is a local Artinian O-algebra A with residue field k. An unramified framed deformation sends arithmetic Frobenius to $F_A \in GL_2(A)$, with $F_A \bmod \mathfrak{m}_A = \overline{F}$ and $\det F_A = d$. Here arithmetic Frobenius acts on a residue field by its cardinality power. Inertia acts trivially.

Proposition 18.2.4 *(Framed deformations and distinct residual roots).* Choose a matrix lift $F_0 \in M_2(O)$ of $\overline{F}$. The framed deformation functor is represented by

$$R_d^{\square} = O[[X_{11}, X_{12}, X_{21}, X_{22}]]/(\det(F_0 + X) - d).$$

This ring is formally smooth of relative dimension three. Suppose additionally that $\overline{F} = \operatorname{diag}(\bar{a}, \bar{b})$, with $\bar{a} \neq \bar{b}$.

Choose $a_0 \in O^\times$ lifting $\bar{a}$ and put $b_0 = d/a_0$. Then

$$R_d^{\square} \simeq O[[x, y, z]], \qquad F = \begin{pmatrix} a_0 + x & y \\ z & (d + yz)/(a_0 + x) \end{pmatrix}.$$

Strict conjugacy classes of these deformations are represented by $O[[u]]$. The corresponding ordered eigenvalues are $a = a_0 + u$ and $b = d/a$.

Proof. Every test algebra is finite. A matrix in its finite group $GL_2(A)$ defines a unique continuous homomorphism from $\widehat{\mathbb{Z}}$. Thus specifying F_A is equivalent to specifying the unramified representation. The matrix entries and determinant equation give the first ring.

At least one cofactor of $\overline{F}$ is nonzero. The derivative in the corresponding matrix coordinate is a unit. Solving for that coordinate proves formal smoothness and leaves three parameters. In the displayed diagonal case, $a_0 + x$ is a unit and the determinant equation solves directly for the lower-right entry.

For each F_A, Hensel lifting gives the unique characteristic root a reducing to $\bar{a}$. The other root is $b = d/a$. Since $a - b$ is a unit, the projectors above split A^2 into two free rank-one eigenspaces. Their bases can be chosen to reduce to the standard residual bases.

The resulting change of basis is the identity modulo $\mathfrak{m}_A$, so it is a strict conjugation. Two diagonal lifts are strictly conjugate exactly when their ordered roots agree. The choice of $a - a_0 \in \mathfrak{m}_A$ therefore represents the set of strict conjugacy classes. □

The last ring represents classes, not the deformation groupoid. For a diagonal lift, strict automorphisms contain $(1 + \mathfrak{m}_A)^2$. A quotient stack retains these automorphisms. The construction concerns unramified lifts only. A crystalline lifting condition or a larger Emerton–Gee component requires its own map and coefficient conventions.

18.3 Ordinary quotients and characteristic-zero types

Fix $p \geq 5$. Let $E/\mathbb{Q}_p$ be finite, with integer ring O, uniformizer ϖ, and finite residue field k. Put $G = G_{\mathbb{Q}_p}$ and let $I \subset G$ be inertia. Fix a continuous representation $\bar{\rho} : G \to \mathrm{GL}_2(k)$, a basis of k^2, and a continuous character $\delta : G \to O^\times$ lifting $\det \bar{\rho}$.

Give an Artinian local O-algebra A with residue field k the discrete topology. A framed lift is a continuous homomorphism $\rho_A : G \to \mathrm{GL}_2(A)$ reducing to the specified matrix representation $\bar{\rho}$.

Framed lifts are not divided by conjugation. The framed deformation ring $R^{\square}$ is a complete Noetherian local O-algebra with universal representation $\rho^{\square}$.

Its existence is the framed representability statement in (Kisin, *The structure of potentially semi-stable deformation rings*, §1.2). Set

$$R = R^{\square,\delta} = R^{\square}/\overline{(\det \rho^{\square}(g) - \delta(g) : g \in G)}.$$

The bar denotes closure in the maximal-ideal topology. This quotient represents framed lifts of determinant δ. Write its universal matrices as

$$\rho_R(g) = \begin{pmatrix} a_g & b_g \\ c_g & d_g \end{pmatrix}.$$

Assume a chosen residual quotient $\bar{q} : k^2 \twoheadrightarrow k(\bar{\eta})$ is unramified. Here $k(\bar{\eta})$ is the one-dimensional representation with character $\bar{\eta}$, and unramified means $\bar{\eta}|_I = 1$. Choose the basis so that $\bar{q} = (0, 1)$. Then

$$\bar{\rho}(g) = \begin{pmatrix} \bar{\alpha}(g) & * \\ 0 & \bar{\eta}(g) \end{pmatrix}, \qquad \bar{\alpha} = \bar{\delta}\bar{\eta}^{-1}.$$

An ordinary lift relative to $\bar{q}$ is a framed lift together with a free rank-one quotient lifting $\bar{q}$, on which inertia acts trivially. Quotients are identified up to an equivariant target isomorphism. Each such quotient has a unique normalized row $q = (t, 1)$, where $t \in \mathfrak{m}_A$. Its character is allowed to vary with A.

PROPOSITION 18.3.1 *(explicit ordinary deformation equations).* Suppose $\bar{\alpha} \neq \bar{\eta}$. Choose $g_0 \in G$ with $\bar{\alpha}(g_0) \neq \bar{\eta}(g_0)$. There is a unique $t_0 \in \mathfrak{m}_R$ satisfying

$$b_{g_0} t_0^2 + (d_{g_0} - a_{g_0}) t_0 - c_{g_0} = 0. \tag{18.1}$$

Let $J_{\mathrm{ord}} \subset R$ be the closed ideal generated by

$$\begin{aligned} b_g t_0^2 + (d_g - a_g) t_0 - c_g \quad & (g \in G), \\ t_0 b_h + d_h - 1 \quad & (h \in I). \end{aligned}$$

Then $R^{\mathrm{ord}} = R/J_{\mathrm{ord}}$ represents ordinary lifts relative to $\bar{q}$. The quotient line is uniquely determined by the framed representation. Thus forgetting the quotient gives a closed immersion $\operatorname{Spf} R^{\mathrm{ord}} \hookrightarrow \operatorname{Spf} R$.

Proof. The polynomial in (18.1) vanishes at zero modulo $\mathfrak{m}_R$. Its derivative there is $\bar{\eta}(g_0) - \bar{\alpha}(g_0) \neq 0$. Completeness and Hensel's lemma give the unique root t_0. For completeness, successive correction modulo powers of $\mathfrak{m}_R$ solves a linear equation with this invertible coefficient.

These corrections converge in R. If two roots lie in $\mathfrak{m}_R$, their difference times $b_{g_0}(t + t') + d_{g_0} - a_{g_0}$ is zero. The second factor is a unit, so the roots agree.

For a row $q = (t, 1)$, stability of its kernel under $\rho_A(g)$ is equivalent to

$$q\rho_A(g) = \eta_A(g)q, \qquad \eta_A(g) = tb_g + d_g,$$

where the matrix entries are specialized to A. The first component is exactly $b_g t^2 + (d_g - a_g)t - c_g = 0$. Since $\eta_A(g)$ reduces to $\bar{\eta}(g) \neq 0$, it is a unit. Surjectivity of q and multiplication of the matrices show that η_A is a character. It is continuous because ρ_A is continuous. The equations indexed by I make it unramified.

Every ordinary quotient satisfies the equation for g_0. The uniqueness argument over the Artinian local ring A forces t to be the image of t_0. The remaining equations are precisely the images of J_{ord}. Conversely, a map $R^{\mathrm{ord}} \to A$ gives the quotient $(t_0, 1)$ with these properties.

Both constructions commute with local O-algebra maps of Artinian coefficient rings. The construction also applies to complete Noetherian local coefficient rings by passage to their Artinian quotients. The normalized rows are compatible by uniqueness. □

The kernel of this quotient is freely generated by $(1, -t_0)$. Consequently every ordinary lift has an exact sequence

$$0 \longrightarrow A(\delta\eta_A^{-1}) \longrightarrow A^2_{\rho_A} \longrightarrow A(\eta_A) \longrightarrow 0, \qquad \eta_A|_I = 1. \tag{18.2}$$

Indeed the action on the kernel is multiplication by $a_g - b_g t_0$, and the determinant is the product of the two characters. The sequence need not split. To prescribe an unramified lift $\eta : G \to O^\times$, add the equations $t_0 b_g + d_g = \eta(g)$ for $g \in G$.

Remark 18.3.2 *(coincident residual characters).* Without $\bar\alpha \neq \bar\eta$, the quotient must be retained as part of the deformation problem. That problem is still represented by

$$R[[t]]/\overline{\big(b_g t^2 + (d_g - a_g)t - c_g \ (g \in G), \quad t b_h + d_h - 1 \ (h \in I)\big)}.$$

Here t maps into the maximal ideal of each coefficient ring. The same row calculation proves the assertion.

For the trivial residual representation and trivial determinant, take the constant trivial lift to $k[u]/(u^2)$. The rows $(au, 1)$ for $a \in k$ give distinct ordinary quotient lines lifting $(0, 1)$. Thus the forgetful map need not be injective on deformation functors when the residual characters coincide.

Hodge types on characteristic-zero lifts

The ordinary equations make sense over Artinian coefficient rings. Hodge and inertial types require characteristic-zero period modules. For a continuous representation V on a finite-dimensional vector space over a finite extension E'/E, put

$$D_{\mathrm{dR}}(V) = (B_{\mathrm{dR}} \otimes_{\mathbb{Q}_p} V)^G.$$

Here B_{dR} is Fontaine's filtered de Rham period field.

The representation is de Rham when $\dim_{E'} D_{\mathrm{dR}}(V) = \dim_{E'} V$. We use filtration degrees as Hodge–Tate weights, so the cyclotomic character ε has weight -1. A type $\mathbf{h} = \{h_1, h_2\}$ prescribes the dimensions of $\mathrm{gr}^j D_{\mathrm{dR}}(V)$. Equivalently, Kisin's cocharacter is the conjugacy class of $z \mapsto \mathrm{diag}(z^{-h_1}, z^{-h_2})$.

Let $B_{\mathrm{cris}} \subset B_{\mathrm{st}}$ be Fontaine's crystalline and semistable period rings. For a finite extension $K'/\mathbb{Q}_p$ with maximal unramified subfield K'_0, set

$$D_{\mathrm{st},K'}(V) = (B_{\mathrm{st}} \otimes_{\mathbb{Q}_p} V)^{G_{K'}}, \qquad D_{\mathrm{cris},K'}(V) = (B_{\mathrm{cris}} \otimes_{\mathbb{Q}_p} V)^{G_{K'}}.$$

The representation is potentially semistable, respectively potentially crystalline, when for some K' the corresponding module is free of rank $\dim_{E'} V$ over $K'_0 \otimes_{\mathbb{Q}_p} E'$. Its potentially semistable period module is

$$D_{\mathrm{pst}}(V) = \varinjlim_{K'} D_{\mathrm{st},K'}(V).$$

Inertia acts linearly on this module over $\overline{\mathbb{Q}}_p^{\mathrm{nr}} \otimes_{\mathbb{Q}_p} E'$.

An inertial type is a continuous representation $\tau : I \to \mathrm{GL}_2(E)$ with open kernel which extends to the Weil group. The representation V has this type when its inertia representation on $D_{\mathrm{pst}}(V)$ is isomorphic to τ after scalar extension. Here $\overline{\mathbb{Q}}_p^{\mathrm{nr}}$ is the maximal unramified extension of $\mathbb{Q}_p$ inside its chosen algebraic closure. This is the period-module action, not the inertia action on V.

Choose E large enough to define τ and the Hodge type. Kisin constructs quotients $R_{\mathrm{pst}}^{\square,\mathbf{h},\tau}$ and $R_{\mathrm{pcris}}^{\square,\mathbf{h},\tau}$ of $R^{\square}$. Their characteristic-zero quotients impose the potentially semistable and potentially crystalline type conditions on finite local characteristic-zero coefficient algebras. In particular, their field-valued points specify lifts of these types. These are Kisin's Theorems 1.2.1–1.2.2, pp. 6–7.

For $\star \in \{\mathrm{pst}, \mathrm{pcris}\}$ define the actual fixed-determinant intersection ring and its generic fiber by

$$S_\star = R_\star^{\square,\mathbf{h},\tau} \otimes_{R^{\square}} R, \qquad X_\star = \operatorname{Spec} S_\star[1/p].$$

Both factors are quotient rings, so this tensor product is an ordinary quotient of $R^{\square}$. It is already complete and Noetherian. A continuous map $S_\star \to \mathcal{O}_{E'}$ gives a framed lattice of determinant δ whose rational representation has the indicated type.

Conversely, choose a frame of such a lattice reducing to the given residual frame. Kisin's factorization criterion applies over E'. The defining ideal then vanishes in the torsion-free ring $\mathcal{O}_{E'}$, giving the required integral map. Here coefficient extensions carry a fixed residue-field embedding, and all integral maps are continuous local $\mathcal{O}$-algebra maps.

The scheme $X_\star$ also retains the infinitesimal structure of the intersection. No flatness or reducedness of $S_\star$ is needed for this construction. Incompatible determinant and type conditions can give an empty generic fiber.

The schematic closure of the generic fiber in $\operatorname{Spec} S_\star$ is defined by the p-power torsion ideal. Its coordinate ring is $S_\star/S_\star[p^\infty]$, where $S_\star[p^\infty] = \{x : p^n x = 0 \text{ for some } n\}$. This quotient is p-torsion-free, hence flat over the discrete valuation ring $\mathcal{O}$. It has no effect after inverting p, but can change the special fiber. The integral intersection and its generic fiber must therefore remain distinct.

Under the distinguished quotient hypothesis, define

$$X_\star^{\mathrm{ord}} = \operatorname{Spec}\big((S_\star/J_{\mathrm{ord}}S_\star)[1/p]\big), \qquad X_\star^{\mathrm{rest}} = X_\star \setminus X_\star^{\mathrm{ord}}.$$

The first is a closed subscheme and the second its open complement. This gives a two-piece decomposition within the specified lifting space. The ordinary condition is relative to the chosen residual quotient $\bar{q}$.

COROLLARY 18.3.3 *(ordinary lifts of a prescribed type).* A continuous point $S_\star \to \mathcal{O}_{E'}$ lies in the ordinary piece precisely when its framed lattice has an unramified quotient lifting $\bar{q}$. On this piece its rational representation has an exact sequence

$$0 \longrightarrow E'(\delta\eta^{-1}) \longrightarrow V \longrightarrow E'(\eta) \longrightarrow 0, \qquad \eta|_I = 1,$$

and has the prescribed Hodge and inertial types.

Proof. Factoring through R^{ord} is equivalent to the ordinary quotient property by the proposition. Apply (18.2) and invert p. The quotient $R_\star^{\square,\mathbf{h},\tau}$ imposes the type. If the equations vanish only after inverting p, they already vanish in the torsion-free ring $\mathcal{O}_{E'}$. □

For the potentially Barsotti–Tate problem in the Tate-module convention, take $\star = \mathrm{pcris}$ and $\mathbf{h} = \{-1, 0\}$, with a specified inertial type. The dual convention has weights $\{0, 1\}$. Other Hodge types require other quotient rings. These spaces do not give an exhaustive decomposition of all residual points.

They describe lifts above a fixed residual representation. For example, with $a = p - 1$, the representations $1 \oplus \varepsilon$ and $\varepsilon^a \oplus \varepsilon^{1-a}$ have the same reduction and determinant. Their Hodge–Tate multisets are $\{0, -1\}$ and $\{1 - p, p - 2\}$, respectively.

18.4 A local categorical realization

The formal lifting spaces above have natural maps into a spectral stack at the coefficient prime. The determinant identification belongs to this stack. It is more structure than the determinant value used for the Frobenius quotient stack.

To compare these deformation spaces with categorical local Langlands, fix a continuous central character $\zeta : \mathbb{Q}_p^\times \to O^\times$. Use local reciprocity sending a uniformizer to geometric Frobenius, and require the already fixed determinant to satisfy $\delta = \zeta \varepsilon^{-1}$ as a Galois character. These are the conventions of (Dotto–Emerton–Gee, arXiv:2603.26887, §1.3, p. 8).

Let $\mathcal{A}_\zeta$ be smooth $\mathrm{GL}_2(\mathbb{Q}_p)$ representations on p-power torsion O-modules with central character ζ. Let $\mathcal{X}_\delta$ classify rank-two projective étale (φ, Γ)-modules with a determinant identification. This identification is an isomorphism with the rank-one module attached to δ. Morphisms preserve this isomorphism.

This is the fiber-product definition in (Dotto–Emerton–Gee, arXiv:2603.26887, Definition C.1.1, p. 265). The Dotto–Emerton–Gee functor is

$$F : D(\mathcal{A}_\zeta) \longrightarrow \mathrm{Ind}\, D^b_{\mathrm{coh}}(\mathcal{X}_\delta).$$

It is exact, colimit-preserving and fully faithful (Dotto–Emerton–Gee, arXiv:2603.26887, Theorem 1.1.1 and its following paragraph, p. 3).

The functor has an actual kernel. Write $O[[G]]_\zeta$ for the completed group algebra with central character ζ, where $G = GL_2(\mathbb{Q}_p)$. Dotto–Emerton–Gee construct a pro-coherent right $O[[G]]_\zeta$-module $\mathcal{L}_\infty$ on $\mathcal{X}_\delta$, and on the bounded finitely presented source their functor is

$$F(\pi) = \mathcal{L}_\infty \otimes^{\mathbb{L}}_{O[[G]]_\zeta} \pi.$$

The right action has a specified variance.

The initial Colmez construction has left central character $\zeta \varepsilon^{-2}$. Twisting by $(\zeta^{-1}\varepsilon) \circ \det$ changes this to ζ^{-1}. Precomposition with $g \mapsto g^{-1}$ then gives the right ζ-action.

On a smooth formal chart $\mathrm{Spf}\, A$, the kernel comes from the compatible systems attached to the étale modules over A/I^n. Their coefficient base change and descent construct the global pro-coherent object. Bounded coherence of the displayed tensor and full faithfulness are separate theorems of that construction. Their locators are Definitions 5.1.31–5.1.33, Proposition 5.3.23 and Theorem 5.5.1. A symbol for the tensor product alone would prove neither assertion.

Let $\bar\theta$ be the residual pseudorepresentation of $\bar\rho$. Complete $\mathcal{X}_\delta$ along the fiber over $\bar\theta$. This classifies Galois representations deforming that pseudorepresentation, with the specified determinant identification (Dotto–Emerton–Gee, §1.1.6, p. 4). The universal representation defines a morphism

$$\mathrm{Spf}\, R \longrightarrow \widehat{\mathcal{X}}_{\delta,\bar\theta} \longrightarrow \mathcal{X}_\delta$$

as follows.

Reduce ρ_R modulo each power of its maximal ideal. Over each finite coefficient ring, apply the equivalence between continuous Galois representations and étale (φ, Γ)-modules. Retain the determinant

identification sending the wedge of the two frame vectors to 1 in the character module of δ. The construction preserves tensor products and base change. See Dotto–Emerton–Gee, Appendix C.2, especially (C.2.1)–(C.2.2), p. 268, and Remark C.2.17, p. 272.

The compatible objects define the displayed formal morphism. Their residual pseudorepresentation is $\bar{\theta}$, so the map factors through the indicated completion. A change of basis preserving the determinant identification gives an isomorphism in that stack. Scalar automorphisms ± 1 remain.

The ordinary and type quotients give morphisms into this diagram. For the type quotients these are the maps from $\mathrm{Spf}\, S_\star$. The ordinary intersection uses $\mathrm{Spf}(S_\star/J_{\mathrm{ord}}S_\star)$. These are morphisms of formal moduli problems, whereas $X_\star$ denotes the separately defined scheme after inverting p. They do not identify the source formal schemes with the stack, which retains automorphisms.

An ordinary or potentially Barsotti–Tate comparison must specify full stable source and target subcategories. Essential surjectivity first requires a proof that F restricts between them. The deformation maps alone do not specify these categories or their generators. The functor on the entire target is not an equivalence (Dotto–Emerton–Gee, arXiv:2603.26887, Remark 1.1.2, p. 3). This statement does not decide equivalence on a specified smaller target.

PROPOSITION 18.4.1 *(generation criterion for a restricted functor).* Let $\mathcal{C}, \mathcal{D}$ be presentable stable ∞-categories. Suppose an exact colimit-preserving fully faithful functor $F_0 : \mathcal{C} \to \mathcal{D}$ is supplied. If objects $P_i \in \mathcal{C}$ have images generating $\mathcal{D}$ under colimits, shifts and cofibers, then F_0 is an equivalence.

Proof. Full faithfulness makes the essential image a full subcategory equivalent to $\mathcal{C}$. Every diagram in that image can therefore be lifted to $\mathcal{C}$. Preservation of colimits makes its colimit in $\mathcal{D}$ another image object. Exactness gives closure under shifts and cofibers. The essential image contains the specified generators and hence all of $\mathcal{D}$. □

The local arithmetic construction needed for this criterion is the identification of $F(P_i)$ with actual spectral objects, together with a proof of target generation. If lifting conditions overlap, their union must generate all required extension objects. A direct-sum assembly additionally requires orthogonality. Neither modularity of a lift nor a ring of scalar actions establishes these categorical properties.

Line and quotient conventions. The ordinary lifting problem just constructed retains an unramified *quotient*. Its kernel has character $\delta\eta^{-1}$ and need not be unramified. An ordinary-line condition instead asks for an unramified subrepresentation.

Dualizing a quotient of V gives an unramified subrepresentation of $V^\vee$, with determinant δ^{-1}. It does not identify the two conditions on the same V. Any use of the line convention in the comparison below must specify this dualization or another proved flag comparison, including the central-character and Hodge-sign changes.

Smooth objects with the required central character

Suppose the local residual rank-two representation is unramified at p, and use the determinant convention $\det \bar{\rho} = \chi\bar{\varepsilon}^{-1}$. Under geometric reciprocity, $\bar{\varepsilon}(u) = \bar{u}$ for $u \in \mathbb{Z}_p^\times$ and $\bar{\varepsilon}(p) = 1$. Consequently $\chi(u) = \bar{u}$. An induction from two unramified characters has a different central character on units. The following induction gives actual objects in the required torsion category.

PROPOSITION 18.4.2 *(central-character-compatible smooth source objects).* Fix a finite extension of $\mathbb{Q}_p$ with integer ring O and residue field k. Choose a continuous lift $\zeta : \mathbb{Q}_p^\times \to O^\times$ of χ. Under geometric reciprocity, set $\delta = \zeta\varepsilon^{-1}$, where ε is the p-adic cyclotomic character. Let A be a finite local

Artinian O-algebra with residue field k. Write ζ_A for the induced character, and choose an unramified character $\eta_A : \mathbb{Q}_p^\times \to A^\times$.

Put $G = GL_2(\mathbb{Q}_p)$ and let B be its upper triangular subgroup. The unnormalized smooth induction

$$I_A = \mathrm{Ind}_B^G(\zeta_A \eta_A^{-1} \otimes \eta_A)$$

consists of locally constant $f : G \to A$ satisfying

$$f\left(\begin{pmatrix} a & b \\ 0 & d \end{pmatrix} g\right) = \zeta_A(a)\eta_A(a)^{-1}\eta_A(d) f(g), \qquad (g_0 f)(g) = f(g g_0).$$

It is a nonzero smooth p-power-torsion O-representation with central character ζ. It has no $GL_2(\mathbb{Z}_p)$-fixed vectors. In particular, no square-root modulus factor is used over A.

Proof. The finite coefficient characters have open kernels. Choose a principal congruence subgroup $K_m \subset GL_2(\mathbb{Z}_p)$ so that the inducing character θ_A of B is trivial on $B \cap K_m$. Define $f(bk) = \theta_A(b)$ on BK_m and zero outside. Two factorizations differ by $B \cap K_m$, so this is well-defined. The image of K_m in the Hausdorff space $B\backslash G$ is compact and open, hence closed as well.

The resulting zero extension is locally constant and $f(1) = 1$. Restrict a locally constant induced function to the compact group $GL_2(\mathbb{Z}_p)$. A finite clopen partition refines its local constancy neighborhoods. It is therefore fixed on the right by some sufficiently small open subgroup. This proves smoothness.

The ring A is killed by a power of p, so the same is true of I_A. A central scalar x acts by $\zeta_A(x)\eta_A(x)^{-1}\eta_A(x) = \zeta_A(x)$. Choose a unit u whose reduction is not 1. The element $\zeta_A(u) - 1$ is a unit of A. If a vector were fixed by $GL_2(\mathbb{Z}_p)$, it would be annihilated by this unit, hence vanish. □

A determinant twist cannot turn an unramified principal series into this residual central-character family when p is odd. On the cyclic group $\mathbb{F}_p^\times$, such a twist changes the central exponent by $2a$. The required exponent is 1. The congruence $2a = 1 \pmod{p-1}$ has no solution. This remains an obstruction after coefficient extension and, by reduction, for the finite rings A. The characteristic-zero unramified invariant-vector calculation has a different central-character carrier.

Let C_{ind} be the stable colimit closure of these induced objects in $D(\mathcal{A}_\zeta)$. It is a well-defined source category. To identify it with an ordinary comparison category one must identify its spectral image and generators, including the chosen ordinary flag. An invariant line and an invariant quotient are distinct conditions.

18.5 Quadratic induction and ordinary lifting spaces

A quadratic global induction can become reducible at a nonsplit local place. The local character determines this behavior. Ordinary lifting conditions require further data: a residual quotient line, a determinant, and a characteristic-zero lifting space. These data specify the local objects whose images under a categorical Langlands functor must be compared.

Restriction of a quadratic induction

Let $K/\mathbb{Q}$ be quadratic. Fix a place v of $\mathbb{Q}$ and compatible decomposition groups. Let L be a coefficient field, and let $\psi : G_K \to L^\times$ be continuous. Here G_F denotes the absolute Galois group of a field F, and L is equipped with its specified field topology. All representation spaces carry the corresponding finite-dimensional topology. Induction from an open subgroup of finite index means ordinary algebraic induction, with its induced continuous action.

If v splits in K, the double-coset decomposition gives

$$\operatorname{Ind}_{G_K}^{G_{\mathbb{Q}}} \psi\Big|_{G_{\mathbb{Q}_v}} \simeq \psi_w \oplus \psi_{w'},$$

where w, w' are the two places above v. The two local characters can coincide. If v is nonsplit, there is one place w above v, and the same decomposition gives

$$\operatorname{Ind}_{G_K}^{G_{\mathbb{Q}}} \psi\Big|_{G_{\mathbb{Q}_v}} \simeq \operatorname{Ind}_{G_{K_w}}^{G_{\mathbb{Q}_v}} \psi_w.$$

These formulas follow by separating functions according to their support on the double cosets $G_K \backslash G_{\mathbb{Q}} / G_{\mathbb{Q}_v}$. There are two cosets in the split case and one in the nonsplit case.

To determine the second representation, let H be an open normal subgroup of index two in a profinite group G. Choose $s \in G \setminus H$. For a continuous character $\chi : H \to L^\times$, put

$$\chi^s(h) = \chi(s^{-1}hs), \qquad c = \chi(s^2).$$

On the induced basis $e_1 = 1 \otimes 1$, $e_2 = s \otimes 1$, the action is

$$\rho(h) = \begin{pmatrix} \chi(h) & 0 \\ 0 & \chi^s(h) \end{pmatrix}, \qquad \rho(s) = \begin{pmatrix} 0 & c \\ 1 & 0 \end{pmatrix}. \tag{18.3}$$

PROPOSITION 18.5.1 *(local irreducibility criterion).* If $\chi \neq \chi^s$, then $\operatorname{Ind}_H^G \chi$ is absolutely irreducible. If $\chi = \chi^s$, its reducibility over L is equivalent to the existence of a root of $T^2 - c$ in L.

Suppose $\chi = \chi^s$ and $b^2 = c$ with $b \in L$. There is a continuous extension $\widetilde{\chi} : G \to L^\times$ with $\widetilde{\chi}|_H = \chi$ and $\widetilde{\chi}(s) = b$. If $\operatorname{char} L \neq 2$, then

$$\operatorname{Ind}_H^G \chi \simeq \widetilde{\chi} \oplus (\widetilde{\chi}\, \omega_{G/H}),$$

where $\omega_{G/H}$ is trivial on H and sends s to -1. In characteristic two the induced representation is a nonsplit self-extension of $\widetilde{\chi}$.

Proof. When the characters differ, choose $h \in H$ with $\chi(h) \neq \chi^s(h)$. Any invariant line over an algebraic closure must be one of the two eigenspaces of $\rho(h)$. The matrix $\rho(s)$ interchanges them, so neither is G-stable.

When the characters agree, H acts by scalars. A G-stable line therefore exists precisely when $\rho(s)$ has an eigenvalue in L. Its characteristic and minimal polynomials are both $T^2 - c$. The prescribed values of $\widetilde{\chi}$ respect conjugation by s and the relation $s^2 \in H$, hence define a character.

It is continuous because H is open and χ is continuous. In characteristic different from two the two roots $b, -b$ are distinct, which gives the displayed direct sum. In characteristic two the minimal polynomial is $(T - b)^2$. The matrix is not scalar, so its unique eigenline has no invariant complement. □

Thus over an algebraically closed field, local irreducibility in the nonsplit case is equivalent to $\psi_w \neq \psi_w^s$. Inertness and ramification alone do not decide this equality. Over a smaller coefficient field, an invariant character can instead give an irreducible representation which becomes reducible after scalar extension. Over coefficient rings the matrices in (18.3) still define induction. The field criterion applies after specialization and does not assert an integral direct-sum decomposition.

For a ramified quadratic extension of $\mathbb{Q}_p$ with $p \geq 5$, the ramification index is two, so the extension is tame. A characteristic-zero inducing character can still be nontrivial on wild inertia. For a continuous character valued in $\overline{\mathbb{F}}_p^{\times}$ with the discrete topology, its image is finite of order prime to p. Its restriction to wild inertia is therefore trivial. Since the quadratic extension is tame, wild inertia lies in the inducing subgroup and acts trivially on the induced residual representation.

Example 18.5.2 *(an inert place with reducible restriction).* Let L_0 be the splitting field of $X^3 - 2$. Eisenstein's criterion at 2 and the discriminant -108 give $\mathrm{Gal}(L_0/\mathbb{Q}) = S_3$. The quadratic subfield is $K = \mathbb{Q}(\sqrt{-3})$. Over $\overline{\mathbb{F}}_5$, induction of a nontrivial character of A_3 gives an absolutely irreducible representation of S_3. Complex conjugation is a transposition, so this representation is odd.

The prime 5 is unramified in L_0, and

$$X^3 - 2 = (X - 3)(X^2 + 3X + 4) \pmod 5.$$

The quadratic discriminant is 3, which is nonsquare modulo 5. Frobenius is consequently a transposition. Also $-3 = 2 \pmod 5$ is nonsquare, so 5 is inert in K. The local representation factors through the order-two decomposition group and splits into its $+1$ and -1 Frobenius eigenspaces.

Lemma 18.5.3 *(restriction of a dihedral residual representation).* For a quadratic induction, the split restriction is the sum of the two local characters, which can coincide. At a nonsplit place the restriction is induced from the local quadratic subgroup. Over an algebraically closed coefficient field, it is irreducible exactly when its two conjugate characters differ. Ramification of the quadratic extension alone specifies no Hodge type. At $p \geq 5$ that quadratic extension is tame, and a discrete mod-p character is trivial on wild inertia.

Proof. The double-coset decomposition, matrix computation and characteristic-two case in Proposition 18.5.1 prove these statements. The inert prime 5 example shows why inertness alone cannot imply irreducibility. A comparison with the Colmez Montreal functor, including its actual block and coefficient category, remains additional arithmetic data. It is not a consequence of the restriction formula. □

18.6 Residual parameters and deformation objects

The complex parameters of residual automorphic representations and the mod-p parameters of a deformation stack have different coefficient fields. Their comparison requires more than the same two-dimensional notation. Even over $\mathbb{C}$, the two SL_2 factors in a local Arthur parameter have different roles.

Definition 18.6.1 *(The non-tempered parameter).* At a finite place, use the domain $W_F \times SL_2(\mathbb{C})_{\mathrm{D}} \times SL_2(\mathbb{C})_{\mathrm{A}}$. The parameter takes values in $GL_2(\mathbb{C})$. Here W_F is the Weil group, the factor marked D is the Deligne factor, and the factor marked A is the additional Arthur factor. The trivial-character rank-two non-tempered parameter is

$$\psi_1(w, g_{\mathrm{D}}, g_{\mathrm{A}}) = g_{\mathrm{A}}. \tag{18.4}$$

The associated Langlands parameter is obtained by substituting $\mathrm{diag}(|w|^{1/2}, |w|^{-1/2})$ in the Arthur factor. This convention records its non-tempered exponents.

Definition 18.6.2 *(The monodromy parameter).* On the same domain, the standard rank-two Deligne parameter, regarded as an Arthur parameter trivial on its additional factor, is

$$\psi_0(w, g_{\mathrm{D}}, g_{\mathrm{A}}) = g_{\mathrm{D}}. \tag{18.5}$$

The distinction from (18.4) lies in which factor acts. Restricting both displays to an unnamed SL_2 would erase that distinction. A determinant twist changes the Weil part and does not exchange the two factors.

Remark 18.6.3 *(Local and global classification).* Arthur's parameter formalism separates the Deligne and Arthur factors. His endoscopic classification concerns orthogonal and symplectic groups, with GL_n classification as input. The residual classification for GL_n is the theorem of Moœglin–Waldspurger. For global data one can specify a formal cuspidal datum $\mu \boxtimes \nu_2$, where ν_2 is the standard two-dimensional representation.

This notation does not construct a global Langlands group or a map to a residual-characteristic stack. Packet assertions must specify twists, central character and local-global realization. In particular, (18.5) does not construct an automorphic representation Steinberg at every finite place.

The direct sum of the trivial and mod-p cyclotomic characters admits several independent cyclotomic extension directions. Their dimensions, and the automorphisms of their deformations, depend on the prime. These data determine what a comparison with a distinguished extension class must preserve. The constructions below give the continuous local deformation groupoids, explicit Kummer classes, and a formal family integrating those classes.

First-order deformations and their automorphisms

Fix a separable closure K^{sep} of $K = \mathbb{Q}_p$, and put $\Gamma = \mathrm{Gal}(K^{\mathrm{sep}}/K)$, with its profinite topology. Let $k/\mathbb{F}_p$ be a finite field with the discrete topology. Choose a primitive pth root ζ_p, with $\zeta_2 = -1$, and define

$$g(\zeta_p) = \zeta_p^{\omega(g)}, \qquad \omega : \Gamma \longrightarrow \mathbb{F}_p^{\times} \longrightarrow k^{\times}.$$

Write $k(r)$ for the one-dimensional k-representation with character ω^r.

In particular, $\omega = 1$ when $p = 2$. Fix the ordered basis e_1, e_2 of $V = k^2$, and set

$$\rho_0(g) = \begin{pmatrix} 1 & 0 \\ 0 & \omega(g) \end{pmatrix}, \qquad \mathfrak{a} = \mathrm{End}_k(V), \qquad \mathfrak{a}_0 = \ker(\mathrm{tr} : \mathfrak{a} \to k).$$

Write E_{ij} for the matrix sending e_j to e_i and the other basis vector to zero. The action on $\mathfrak{a}$ is $gX = \rho_0(g) X \rho_0(g)^{-1}$. All cochains and representations are continuous.

For a finite discrete Γ-module N, use the inhomogeneous cochains $C^n(\Gamma, N) = \mathrm{Map}_{\mathrm{cts}}(\Gamma^n, N)$, with $C^0(\Gamma, N) = N$. Their differential is

$$\begin{aligned}(df)(g_1, \dots, g_{n+1}) = {} & g_1 f(g_2, \dots, g_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i f(g_1, \dots, g_i g_{i+1}, \dots, g_{n+1}) \\ & + (-1)^{n+1} f(g_1, \dots, g_n).\end{aligned}$$

Thus $dX(g) = gX - X$ and $dc(g,h) = gc(h) - c(gh) + c(g)$. Write $Z^1(\Gamma, N) = \ker(d : C^1 \to C^2)$, $B^1(\Gamma, N) = dN$, and $H^i(\Gamma, N) = H^i(C^\bullet(\Gamma, N))$.

Set $A = k[\epsilon]/(\epsilon^2)$, with the discrete topology. A framed deformation is a continuous representation $\rho : \Gamma \to \mathrm{GL}_2(A)$ reducing to ρ_0 in the specified basis. Morphisms preserve this entire A-basis. A residual-marked unframed deformation is a free rank-two A-module with a continuous Γ-action and a specified identification of its reduction with V. Its morphisms induce the identity on V.

Proposition 18.6.4 *(Continuous first-order groupoids).* Framed deformations form the discrete groupoid on $Z^1(\Gamma, \mathfrak{a})$. Residual-marked unframed deformations form the action groupoid

$$[Z^1(\Gamma, \mathfrak{a})/\mathfrak{a}], \qquad X : c \longmapsto c - dX.$$

Its isomorphism classes form $H^1(\Gamma, \mathfrak{a})$. The automorphism group of each object is the additive group $H^0(\Gamma, \mathfrak{a})$.

Proof. Every framed lift has a unique expression

$$\rho_c(g) = (1 + \epsilon c(g))\rho_0(g).$$

Multiplication gives

$$\rho_c(g)\rho_c(h) = \big(1 + \epsilon(c(g) + gc(h))\big)\rho_0(gh).$$

The homomorphism condition is therefore $dc = 0$. A basis lifting e_1, e_2 identifies any residual-marked deformation with such a matrix representation.

Two such choices differ by $1 + \epsilon X$, and

$$(1 + \epsilon X)\rho_c(g)(1 - \epsilon X) = \rho_{c-dX}(g).$$

The quotient and automorphism statements follow from this equality. An automorphism fixes c exactly when $dX = 0$. □

If the residual marking is forgotten, the residual centralizer also acts. Write

$$C = \{B \in \mathrm{GL}_2(k) : B\rho_0(g) = \rho_0(g)B \text{ for all } g\}.$$

Every permissible change of basis is $(1 + \epsilon X)B$, and its action is

$$c \longmapsto BcB^{-1} - dX.$$

Thus the acting group is $\mathfrak{a} \rtimes C$.

For odd p, the character ω is nontrivial and C is the group of invertible diagonal matrices. For $p = 2$, it is $\mathrm{GL}_2(k)$. The stabilizer of c consists of the pairs satisfying $BcB^{-1} - dX = c$. At $c = 0$, this is $H^0(\Gamma, \mathfrak{a}) \rtimes C$.

A formal scheme, viewed as a groupoid-valued functor, has only identity automorphisms at its points. It cannot represent these unframed groupoids, which retain nonzero infinitesimal automorphisms. This assertion concerns the groupoids, rather than representability of their sets of isomorphism classes.

Determinant character and determinant identification

Fixing a determinant character restricts the objects of a deformation problem. Choosing an identification of determinant representations also restricts its morphisms. To separate these conditions, fix

$$\delta_\eta(g) = \omega(g)(1 + \epsilon\eta(g)), \qquad \eta \in Z^1(\Gamma, k).$$

Here the action on k is trivial, so η is a continuous additive homomorphism.

For a character $\delta : \Gamma \to A^\times$, write $A(\delta)$ for the free rank-one module with that action. The constant determinant lift has $\eta = 0$. The identity

$$\det \rho_c(g) = \omega(g)(1 + \epsilon \operatorname{tr} c(g))$$

holds in every characteristic.

PROPOSITION 18.6.5 *(The two fixed-determinant groupoids).* For the constant lift $\delta_0 = \omega$, the residual-marked deformation groupoid with fixed determinant character is

$$\mathcal{D}_{\mathrm{char}}(A) = [Z^1(\Gamma, \mathfrak{a}_0)/\mathfrak{a}].$$

Fix the residual orientation $e_1 \wedge e_2$. If objects include an identification $\lambda : \det(V_A) \xrightarrow{\sim} A(\omega)$ lifting that orientation, and arrows preserve λ, the groupoid is

$$\mathcal{D}_{\det}(A) = [Z^1(\Gamma, \mathfrak{a}_0)/\mathfrak{a}_0].$$

Both groupoids have isomorphism classes $H^1(\Gamma, \mathfrak{a}_0)$. Their automorphism groups are respectively $H^0(\Gamma, \mathfrak{a})$ and $H^0(\Gamma, \mathfrak{a}_0)$.

Proof. The fixed-character equation is $\operatorname{tr} c = 0$. Every strict conjugation preserves the determinant, and $\operatorname{tr}(dX) = 0$. This proves the first groupoid formula. For the second, choose a lifted basis with $\lambda(e_1 \wedge e_2) = 1$. Such a basis exists because

$$\det : 1 + \epsilon\mathfrak{a} \longrightarrow 1 + \epsilon k$$

is surjective: $\operatorname{diag}(1 + \epsilon t, 1)$ has determinant $1 + \epsilon t$. Changes between these bases satisfy $\operatorname{tr} X = 0$, which proves the second formula.

The trace admits the Γ-equivariant splitting

$$k \longrightarrow \mathfrak{a}, \qquad t \longmapsto tE_{11}.$$

Indeed, E_{11} is invariant and has trace one. Hence $\mathfrak{a} = \mathfrak{a}_0 \oplus kE_{11}$ and $d\mathfrak{a} = d\mathfrak{a}_0$, including when $p = 2$. The two orbit sets are therefore $H^1(\Gamma, \mathfrak{a}_0)$. The equations $dX = 0$, with the respective trace restrictions, give the stated automorphism groups. □

For a general η, the cocycle $c_\eta(g) = \eta(g)E_{11}$ has trace η. The object spaces are therefore the affine translates $c_\eta + Z^1(\Gamma, \mathfrak{a}_0)$, with the same gauge formulas. A determinant-compatible framing requires $\lambda(e_1 \wedge e_2) = 1$, and gives the discrete groupoid on $Z^1(\Gamma, \mathfrak{a}_0)$ when $\eta = 0$. If a full framing and an independent determinant identification are both retained, the discrete object set is instead $Z^1(\Gamma, \mathfrak{a}_0) \times k$: the second coordinate records $\lambda(e_1 \wedge e_2) = 1 + \epsilon t$. For a chosen determinant identification, forgetting the residual marking allows residual changes in $C \cap \mathrm{SL}_2(k)$.

The coefficient decomposition is

$$\mathfrak{a} = kE_{11} \oplus kE_{22} \oplus k(-1)E_{12} \oplus k(1)E_{21},$$
$$\mathfrak{a}_0 = k(E_{11} - E_{22}) \oplus k(-1)E_{12} \oplus k(1)E_{21}.$$

At $p = 2$, the diagonal trace-zero generator is I, and every summand has trivial action. At $p = 3$, the two off-diagonal characters coincide, but their matrix subspaces remain distinct.

The first-order tangent groupoid is presented by the two-term complex

$$[\mathfrak{a} \xrightarrow{-d} Z^1(\Gamma, \mathfrak{a})] \quad \text{in degrees } [-1, 0].$$

Its degree -1 cohomology records automorphisms and its degree 0 cohomology records deformation classes. This is the truncation through degree zero of $C^\bullet(\Gamma, \mathfrak{a})[1]$, with the cohomological shift convention $(C[1])^i = C^{i+1}$ and shifted differential $-d$. Thus $H^2(\Gamma, \mathfrak{a})$ occurs in degree one of the full shifted complex.

For a determinant identification, replace $\mathfrak{a}$ by $\mathfrak{a}_0$. For the fixed-character problem alone, the two-term complex is $[\mathfrak{a} \xrightarrow{-d} Z^1(\Gamma, \mathfrak{a}_0)]$. Identifying any full cochain complex with the tangent complex of a specified derived stack requires an equivalence of the underlying moduli problems.

Kummer classes at every prime

The lower-left summand has an explicit arithmetic description. For $a \in K^\times$, choose $\beta_a \in K^{\mathrm{sep}}$ with $\beta_a^p = a$, and define

$$\frac{g(\beta_a)}{\beta_a} = \zeta_p^{\kappa_a(g)}, \qquad \kappa_a(g) \in \mathbb{F}_p \subset k.$$

The action on roots of unity gives

$$\kappa_a(gh) = \kappa_a(g) + \omega(g)\kappa_a(h).$$

This cocycle is continuous, since β_a and ζ_p lie in a finite Galois extension. Replacing β_a by $\zeta_p^r \beta_a$ changes it by the coboundary $dr(g) = \omega(g)r - r$.

Proposition 18.6.6 *(Explicit cyclotomic cohomology).* The Kummer map gives an isomorphism

$$(\mathbb{Q}_p^\times / \mathbb{Q}_p^{\times p}) \otimes_{\mathbb{F}_p} k \xrightarrow{\sim} H^1(\Gamma, k(1)), \qquad [a] \otimes 1 \longmapsto [\kappa_a].$$

For odd p, a basis is $[\kappa_p]$, $[\kappa_{1+p}]$. For $p = 2$, a basis is $[\kappa_2]$, $[\kappa_{-1}]$, $[\kappa_5]$. The dimensions are respectively two and three.

Proof. Multiplication of roots makes the Kummer map additive modulo pth powers. If $\kappa_a = dr$, replacing β_a by $\zeta_p^{-r}\beta_a$ makes it invariant. Hence a is a pth power in K. Conversely, Hilbert 90 implies that every continuous μ_p-valued cocycle is $g(\beta)/\beta$ for some $\beta \in (K^{\mathrm{sep}})^\times$. Then $\beta^p \in K^\times$. This proves the isomorphism over $\mathbb{F}_p$.

The required Hilbert 90 statement reduces to a finite Galois extension L/K through which the cocycle factors. If z_σ is a multiplicative cocycle for $\mathrm{Gal}(L/K)$, choose $a \in L$ so that

$$b = \sum_\sigma z_\sigma \sigma(a) \neq 0.$$

Such an a exists by linear independence of distinct field automorphisms. The cocycle identity gives $\tau(b) = z_\tau^{-1} b$.

Consequently $z_\tau = \tau(b^{-1})/b^{-1}$, as required. This is the proof of Milne, *Class Field Theory*, Proposition II.1.22, p. 67. A basis of the finite extension $k/\mathbb{F}_p$ decomposes each continuous cochain into finitely many coordinate cochains. Tensoring with k therefore commutes with cohomology.

For odd p, the multiplicative decomposition is

$$\mathbb{Q}_p^\times = p^{\mathbb{Z}} \times \mu_{p-1} \times (1 + p\mathbb{Z}_p).$$

The valuation supplies the first factor. Hensel lifting of the distinct nonzero residues supplies the roots of unity in the second factor. The pth-power map on μ_{p-1} is bijective.

The logarithm and exponential give inverse homomorphisms

$$\log : 1 + p\mathbb{Z}_p \xrightarrow{\sim} p\mathbb{Z}_p.$$

For $x, y \in p\mathbb{Z}_p$, the estimates

$$v_p(x^n/n) \geq n - v_p(n), \qquad v_p(y^n/n!) \geq n - v_p(n!)$$

prove convergence of the logarithm and exponential, using $v_p(n!) \leq n/(p-1)$. Their formal inverse and product identities pass to these convergent series. Logarithm carries pth powers to $p^2\mathbb{Z}_p$, and $\log(1+p) \equiv p \pmod{p^2}$. Thus valuation and the principal-unit quotient give the basis $[p]$, $[1+p]$.

At $p = 2$, each odd unit has a unique sign making it congruent to one modulo four. Hence

$$\mathbb{Q}_2^\times = 2^{\mathbb{Z}} \times \{1, -1\} \times (1 + 4\mathbb{Z}_2).$$

The preceding convergence estimates, with input valuation at least two, give $\log(1 + 4\mathbb{Z}_2) = 4\mathbb{Z}_2$. Squaring becomes multiplication by two, and $\log(5) \equiv 4 \pmod{8}$. The valuation, sign, and principal-unit factors give the independent classes $[2]$, $[-1]$, $[5]$. □

In particular, $p = 3$ gives the basis $[\kappa_3]$, $[\kappa_4]$. The choice of ζ_p identifies μ_p with $\mathbb{F}_p(1)$. Changing it rescales all numerical cocycles by one nonzero scalar. The intrinsic classes take values in $\mu_p \otimes_{\mathbb{F}_p} k$.

The unit classes form an arithmetic subspace, and valuation gives an exact sequence

$$0 \longrightarrow (\mathbb{Z}_p^\times/(\mathbb{Z}_p^\times)^p) \otimes_{\mathbb{F}_p} k \longrightarrow H^1(\Gamma, k(1)) \xrightarrow{v_p} k \longrightarrow 0.$$

The unit subspace has dimension one for odd p and two for $p = 2$. The specified uniformizer p supplies the splitting $1 \mapsto [\kappa_p]$. The quotient itself does not specify a splitting.

There is also an unramified condition. If $I \subset \Gamma$ is inertia, define its subspace as

$$H^1_{\mathrm{ur}}(\Gamma, k(1)) = \operatorname{im}\bigl(H^1(\Gamma/I, k(1)^I) \to H^1(\Gamma, k(1))\bigr).$$

For odd p, this is zero: $\mathbb{Q}_p(\zeta_p)/\mathbb{Q}_p$ is totally ramified of degree $p-1$, since $((1+T)^p - 1)/T$ is Eisenstein at p. Thus $k(1)^I = 0$.

At $p = 2$, the unramified subspace is the line $k[\kappa_5]$. Indeed, $(1 + \sqrt{5})/2$ satisfies $x^2 - x - 1 = 0$, whose reduction is separable and irreducible over $\mathbb{F}_2$. It therefore generates the unramified quadratic extension. Since $\Gamma/I \cong \widehat{\mathbb{Z}}$, its continuous additive characters into k form a one-dimensional k-space.

An explicit formal family

Each cyclotomic cocycle defines both an extension of residual representations and a tangent direction at their split sum. For $b \in Z^1(\Gamma, k(1))$, set

$$r_b(g) = \begin{pmatrix} 1 & 0 \\ b(g) & \omega(g) \end{pmatrix}.$$

The line ke_2 is invariant, and the quotient is trivial. Thus r_b gives an exact sequence

$$0 \longrightarrow k(1) \longrightarrow E_b \longrightarrow k \longrightarrow 0.$$

Conversely, a vector-space splitting of any such extension gives this matrix form. Changing the splitting changes b by a coboundary. Consequently

$$\operatorname{Ext}^1_{\mathrm{Rep}_k^{\mathrm{cts}}(\Gamma)}(k, k(1)) \cong H^1(\Gamma, k(1)),$$

where the category consists of finite-dimensional discrete continuous k-representations. The order of the two endpoint characters is part of this identification.

The coefficient inclusion $u \mapsto uE_{21}$ and projection onto the lower-left entry commute with the cochain differential. They induce an injection with a specified left inverse

$$j : H^1(\Gamma, k(1)) \hookrightarrow H^1(\Gamma, \mathfrak{a}_0).$$

The class $j([b])$ is represented by $\rho_{\epsilon b}(g) = \left(\begin{smallmatrix} 1 & 0 \\ \epsilon b(g) & \omega(g) \end{smallmatrix}\right)$.

Theorem 18.6.7 *(Formal cyclotomic family).* Set $d = 2$ and $(a_1, a_2) = (p, 1 + p)$ for odd p. For $p = 2$, set $d = 3$ and $(a_1, a_2, a_3) = (2, -1, 5)$. Choose the Kummer cocycles above and set

$$R_{\mathrm{gal}} = k[[t_1, \ldots, t_d]], \qquad u(g) = \sum_{i=1}^{d} t_i \kappa_{a_i}(g).$$

With the maximal-ideal topology on R_{gal}, the matrices

$$\rho_{R_{\mathrm{gal}}}(g) = \begin{pmatrix} 1 & 0 \\ u(g) & \omega(g) \end{pmatrix}$$

define a continuous representation reducing to ρ_0, with determinant ω and the standard determinant identification. Its tangent map is injective, with image $j(H^1(\Gamma, k(1)))$.

Proof. The cocycle equation for u is exactly the lower-left entry of $\rho_{R_{\mathrm{gal}}}(gh) = \rho_{R_{\mathrm{gal}}}(g)\rho_{R_{\mathrm{gal}}}(h)$. The finitely many cocycles factor through a common finite Galois quotient, so the representation is continuous for the maximal-ideal topology. Its determinant and reduction follow from the diagonal entries.

Give each Artinian local k-algebra B with residue field k the discrete topology. Use the same residual-marked deformation definition on free rank-two B-modules. A continuous local homomorphism $R_{\mathrm{gal}} \to B$ specializes these matrices to a deformation. This is compatible with homomorphisms between such algebras and therefore defines a map from the functor of points of Spf R_{gal} to the determinant-identified deformation groupoid.

A tangent homomorphism sends t_i to ϵx_i. Its class is $j(\sum_i x_i[\kappa_{a_i}])$. The Kummer basis and the left inverse of j prove injectivity. □

Changing β_{a_i} to $\zeta_p^{r_i}\beta_{a_i}$ adds dr_i to the corresponding cocycle. Set $s = \sum_i t_i r_i$. Conjugation by $1 - sE_{21}$ carries the old formal family to the new one, since its lower-left entry changes by ds. This calculation holds over R_{gal}, without a first-order truncation. The formal family therefore changes by an explicit isomorphism under these root choices.

This family fixes both diagonal characters and a line and quotient. It is not asserted to represent the full deformation problem. At $p = 2$, the underlying residual representation is trivial, and its unmarked form has no preferred decomposition into two lines. The inclusion through E_{21} uses the stated frame or flag. For odd p, the two distinct character subspaces are intrinsic, although their scalar coordinates still depend on the chosen bases.

Dimensions and comparison maps

The Kummer calculation determines one direct summand without local duality. The full dimension table also uses finite-module local duality and the local Euler characteristic theorem. These are Milne,

Arithmetic Duality Theorems, Corollary I.2.3, p. 28, and Theorem I.2.8, p. 31. For a finite-dimensional continuous $k[\Gamma]$-module N, they imply

$$h^2(N) = h^0(N^\vee(1)), \qquad h^0(N) - h^1(N) + h^2(N) = -\dim_k N,$$

where $h^i(N) = \dim_k H^i(\Gamma, N)$ and $N^\vee = \mathrm{Hom}_k(N, k)$.

The field trace pairing identifies the underlying finite-module dual with the additive module of $N^\vee(1)$. The Euler formula follows by substituting $|N| = p^{[k:\mathbb{F}_p]\dim_k N}$ into $\chi(\Gamma, N) = (\mathbb{Z}_p : |N|\mathbb{Z}_p)^{-1}$. Both theorems apply at $p = 2$, since the base field has characteristic zero. For $N = k(r)$, they give

$$h^1(k(r)) = 1 + \mathbf{1}_{\omega^r=1} + \mathbf{1}_{\omega^{1-r}=1}.$$

The matrix decomposition and $\dim B^1(\Gamma, N) = \dim N - h^0(N)$ now give

	$p \geq 5$	$p = 3$	$p = 2$
$h^1(k)$	2	2	3
$h^1(k(1))$	2	2	3
$h^1(k(-1))$	1	2	3
$h^0(\mathfrak{a})$	2	2	4
$h^0(\mathfrak{a}_0)$	1	1	3
$h^1(\mathfrak{a})$	7	8	12
$h^1(\mathfrak{a}_0)$	5	6	9
$\dim Z^1(\Gamma, \mathfrak{a})$	9	10	12
$\dim Z^1(\Gamma, \mathfrak{a}_0)$	7	8	9
$h^2(\mathfrak{a})$	1	2	4
$h^2(\mathfrak{a}_0)$	1	2	3

These dimensions concern the unrestricted local continuous problem. A crystalline, finite-flat, ordinary, or global Selmer condition requires its own definition before imposing a further subspace.

The explicit formal family supplies a local Galois target for a comparison. A specified nonzero Kummer class selects a one-parameter subfamily. The unit condition selects a line for odd p and a plane at $p = 2$. To identify an analytic residue line with one of these lines, construct a map carrying the residue to the specified nonzero cohomology class.

A coherent extension requires further categorical data. Suppose an exact k-linear functor from $\mathrm{Rep}_k^{\mathrm{cts}}(\Gamma)$ to an abelian category has identified images of k and $k(1)$. It sends E_b to an extension with those endpoints. An exact functor between specified stable categories instead sends its associated triangle to a triangle. Either construction gives a map on extension classes.

An isomorphism requires a calculation of that map, including its kernel and image. A tangent vector alone does not define two coherent objects or a functor between their categories. On $\mathrm{Spec}\, k[t]$, for instance, the tangent space at zero is k, whereas $\mathrm{Ext}^1(k[t], k[t]) = 0$. For the residue module k_0, the resolution

$$0 \longrightarrow k[t] \xrightarrow{t} k[t] \longrightarrow k_0 \longrightarrow 0$$

instead gives $\mathrm{Ext}^1(k_0, k_0) = k$. Thus the endpoints of a coherent extension are indispensable.

A comparison from a complex representation category also requires arithmetic coefficient data. There is no unital field map $k \to \mathbb{C}$, since it would carry $p \cdot 1_k = 0$ to $p \cdot 1_{\mathbb{C}} \neq 0$. There is no unital map in

the reverse direction either, since p is invertible in $\mathbb{C}$. Reduction requires an integral coefficient ring and an integral object or stable lattice. A residue-field map to k must then induce the required map on extension classes. A global Galois comparison additionally requires a ramification set, local conditions, and the restriction maps into the local cohomology computed here.

Finally, scalar twisting gives

$$(1 \oplus \omega) \otimes \omega^{-1} = \omega^{-1} \oplus 1.$$

This is $1 \oplus 1$ only at $p = 2$. At $p = 3$, exchanging summands identifies it with the original representation. For any scalar character χ, conjugation gives $\mathrm{Ad}(\rho_0 \otimes \chi) = \mathrm{Ad}(\rho_0)$, while the determinant changes by χ^2. Hence a scalar twist need not preserve a fixed-determinant fiber, and no extra determinant twist enters the adjoint cochain formulas.

The formal stack and its framed presentation

The local deformation groupoids above retain the residual representation and its automorphisms. At the split cyclotomic point, the residual-marked determinant-identified groupoid has

$$\pi_0 \mathcal{D}_{\det}(k[\epsilon]/(\epsilon^2)) = H^1_{\mathrm{cts}}(\Gamma, \mathrm{ad}^0(1 \oplus \omega)).$$

Here π_0 means the set of isomorphism classes, with its vector-space structure from the cocycle description. Fixing only the determinant character gives the same isomorphism classes at this split point, but retains the larger automorphism group $H^0(\Gamma, \mathfrak{a})$. This distinction follows from the equivariant trace splitting through E_{11}, including in characteristic two.

For the Emerton–Gee moduli problem, a framed lifting ring supplies a versal presentation of the formal deformation groupoid. Emerton–Gee, Proposition 3.6.3, p. 76, identifies its self-fiber product using the change-of-basis group completed along the residual centralizer. The pointed formal problem instead uses completion along the identity. It does not replace the unframed groupoid by a formal scheme with no automorphisms. A derived enhancement, wild-inertia conditions and an identification with its full tangent complex require the corresponding moduli comparison. The computed local complex retains this requirement.

Tangent complexes and spectral extension classes

A tangent direction describes deformation of one point. An extension between two sheaves requires two objects and a category of morphisms. To express the proposed comparison, suppose a derived stack $\mathcal{X}$ over k has been specified, with a cotangent complex $\mathbb{L}_{\mathcal{X}}$ admitting the dual used below. At a point x, set $T_x = R\,\mathrm{Hom}_k(x^*\mathbb{L}_{\mathcal{X}}, k)$. Its degree-zero cohomology is the first-order tangent space, while degree minus one records infinitesimal automorphisms. Write $\mathbb{T}^1_x = H^0(T_x)$ for this convention.

Suppose in addition that a spectral category $\mathcal{A}_{\mathrm{sp}}$ has been constructed, with objects $\mathcal{O}_{\mathrm{St}}$ and $\mathcal{O}_{\mathbf{1}}$ and specified support. These names alone do not define sheaves. For example, an ind-coherent category with nilpotent singular support requires a derived stack for which its singularity space and the specified nilpotent subset are defined. The desired comparison is

$$L_{\mathrm{cyc}} \longrightarrow \mathrm{Ext}^1_{\mathcal{A}_{\mathrm{sp}}}(\mathcal{O}_{\mathrm{St}}, \mathcal{O}_{\mathbf{1}}), \qquad L_{\mathrm{cyc}} \subseteq \mathbb{T}^1_{x_{\mathrm{cyc}}}.$$

Here the subspace L_{cyc}, its dimension and the displayed map are constructions still required. A cotangent calculation does not identify this Ext group between two different sheaves.

Remark 18.6.8 *(The reverse spectral comparison).* For a point x_{triv} representing $1 \oplus 1$, the opposite orientation asks for a specified subspace $L_{\mathrm{triv}} \subseteq \mathbb{T}^{1}_{x_{\mathrm{triv}}}$ and a map

$$L_{\mathrm{triv}} \longrightarrow \mathrm{Ext}^{1}_{\mathcal{A}_{\mathrm{sp}}}(\mathcal{O}_{\mathbf{1}}, \mathcal{O}_{\mathrm{St}}).$$

The two endpoints and their support must be constructed in this category. The explicit scalar-twist calculation above does not identify this problem with the cyclotomic problem at odd primes. At $p = 2$, equality of the residual representations still does not choose the two sheaves or the map. An Arthur parameter over $\mathbb{C}$ supplies neither spectral comparison by itself.

18.7 Blocks, extensions and geometric support

A local categorical comparison must specify its block algebra and its spectral support. The ordinary center, the full endomorphism algebra of a generator and the deformation ring are different objects. Their distinctions persist even when every simple object has the expected parameter.

Characteristic-zero Bernstein decomposition

THEOREM 18.7.1 *(Bernstein–Deligne).* Let G be a connected reductive p-adic group and fix an algebraically closed coefficient field k of characteristic zero. Let $\mathrm{Mod}_G^{\mathrm{sm}}$ denote its smooth representations over k. This category decomposes as a product:

$$\mathrm{Mod}_G^{\mathrm{sm}} = \prod_{\mathfrak{s} \in \mathfrak{B}(G)} \mathrm{Block}_{\mathfrak{s}},$$

Here $\mathfrak{B}(G)$ is the set of inertial equivalence classes of supercuspidal supports. The decomposition is realized by a central idempotent decomposition of the Bernstein center $Z(\mathrm{Mod}_G^{\mathrm{sm}}) = \prod_{\mathfrak{s}} Z_{\mathfrak{s}}$ into a product of integral domains.

Attribution. Bernstein–Deligne (1984), in the proceedings *Representations of reductive groups over a local field*. For the block decomposition and torsor of unramified twists modulo self-twists, see also Helm, arXiv:1201.1874, Theorems 3.4–3.5, pp. 7–8. □

PROPOSITION 18.7.2 *(central-character fibers of Bernstein blocks).* Let k be algebraically closed of characteristic zero, and let $\chi : Z(G) \to k^{\times}$ be a smooth central character. For a Bernstein block $\mathcal{B}_{\mathfrak{s}}$, put

$$\mathcal{B}_{\mathfrak{s}}^{\chi} = \{M \in \mathcal{B}_{\mathfrak{s}} : z|_M = \chi(z)\,\mathrm{id}_M \text{ for every } z \in Z(G)\}.$$

Then

$$\mathrm{Rep}_k^{\mathrm{sm},\chi}(G) \simeq \prod_{\mathfrak{s}} \mathcal{B}_{\mathfrak{s}}^{\chi},$$

with zero factors omitted.

Let $\delta_z \in Z_{\mathfrak{s}}$ denote the central operation supplied by $z \in Z(G)$, and let

$$I_{\mathfrak{s},\chi} = (\delta_z - \chi(z) : z \in Z(G)) \subseteq Z_{\mathfrak{s}}.$$

The ring $Z_{\mathfrak{s}}/I_{\mathfrak{s},\chi}$ acts on $\mathcal{B}_{\mathfrak{s}}^{\chi}$. This is a fiber condition inside the block.

Proof. Each Bernstein projector commutes with the action of $Z(G)$. Thus every component of an object with central character χ again has that central character. Conversely, a family of block objects reconstructs a smooth representation by its direct sum, and the sum satisfies the same scalar equations. This proves the categorical decomposition.

The generators of $I_{\mathfrak{s},\chi}$ act as zero on the indicated subcategory, so the central action factors through the quotient. No claim that taking the categorical center commutes with this quotient is needed. □

For $G = GL_2(F)$, fix a uniformizer ϖ and normalized parabolic induction. In the unramified principal-series block write $a = \eta_1(\varpi)$, $b = \eta_2(\varpi)$ for its two unramified inducing characters, so $t = a + b$ and $d = ab$. The modulus character in normalized induction is trivial on scalar matrices. Consequently the central operation of $u \in O_F^\times$ is 1, and that of ϖ is d, in the ring $k[t, d, d^{-1}]$.

These equalities hold as central operations: their values on all supercuspidal supports are respectively 1 and ab, and the block ring is reduced. If χ is unramified, put $c = \chi(\varpi) \in k^\times$. Then $I_{\mathfrak{s},\chi} = (d - c)$ and the fiber has the quotient scalar action $k[t, d, d^{-1}]/(d - c)$. It is nonzero, for instance on any irreducible constituent of the normalized induction of the unramified characters with values 1, c at ϖ.

If χ is ramified, choose $u \in O_F^\times$ with $\chi(u) \neq 1$. The relation $1 - \chi(u)$ is an invertible scalar, so the quotient and the fixed-character fiber category are zero. Thus fixing central character neither selects a whole Bernstein block nor gives a nonzero fiber in every block.

The exact Bernstein projectors extend degreewise to ordinary complexes of smooth characteristic-zero representations. They preserve quasi-isomorphisms because they are exact, and therefore act on the derived category. This elementary extension does not identify that category with a separately defined geometric Hecke category.

For $GL_2(F)$, take algebraically closed characteristic-zero ℓ-adic coefficients with $\ell \neq p$. Use compatible reciprocity and induction normalizations. The ordinary Bernstein center then identifies with scalar functions on the continuous Weil parameter stack. This includes residue primes two and three.

The four inertial cases retain different parameter rings: irreducible inertia, two fixed characters, an interchanged pair, and scalar inertia. They cannot be recovered from a Frobenius matrix with its inertia action discarded. The ring construction and its full coefficient hypotheses are in Proposition 116.2.2.

That scalar image need not exhaust the center of the spectral category. Scalar GL_2 acts trivially on the parameter coordinates, but equivariant coherent objects retain central weights. After Ind-completion, projections to these weight factors give central operations. A determinant twist changes weight by two.

The weight-zero projector separates this operation from scalar multiplication. See Proposition 116.2.5. Choosing one weight removes this particular obstruction, without proving a categorical equivalence.

The coefficient-prime block algebra

Use the coefficient and reciprocity conventions of Paškūnas, *The image of Colmez's Montreal functor*. Here $p \geq 5$, $G = GL_2(\mathbb{Q}_p)$, and O is a finite extension's integer ring with residue field k. Fix a full central character ζ. Let $\mathcal{A}_\zeta^{\mathrm{lfin}}$ be the smooth O-torsion representations which are locally of finite length: each vector generates a finite-length $O[G]$-module.

A block $\mathcal{B}$ is a connected component of the extension relation on irreducible objects, allowing extensions in both directions. Let $J_\mathcal{B}$ be the injective envelope of the sum of its irreducibles. Its Pontryagin dual $P_\mathcal{B} = J_\mathcal{B}^\vee$ is a projective generator of the corresponding compact category. Put

$$E_\mathcal{B} = \mathrm{End}(P_\mathcal{B}) = \mathrm{End}_G(J_\mathcal{B})^{\mathrm{op}}.$$

Endomorphisms use ordinary composition. This is a pseudocompact ring, with topology given by its finite-length quotients. The functor $\tau \mapsto \mathrm{Hom}(P_\mathcal{B}, \tau^\vee)$ is an anti-equivalence from the block to

compact right $E_{\mathcal{B}}$-modules. The right action is precomposition. These compact modules and the locally finite torsion category are different from the finite-length admissible Banach category.

After a coefficient extension splitting the irreducibles, the four block forms in this theorem are as follows. The first is a supersingular singleton. The second consists of

$$\mathrm{Ind}_B^G(\chi_1 \otimes \chi_2\omega^{-1}), \qquad \mathrm{Ind}_B^G(\chi_2 \otimes \chi_1\omega^{-1}), \qquad \chi_1\chi_2^{-1} \notin \{1, \omega, \omega^{-1}\}.$$

The third is the singleton $\mathrm{Ind}_B^G(\chi \otimes \chi\omega^{-1})$.

The fourth consists of

$$\eta \circ \det, \qquad \mathrm{Sp} \otimes (\eta \circ \det), \qquad \mathrm{Ind}_B^G(\omega \otimes \omega^{-1}) \otimes (\eta \circ \det).$$

Here ω is the residual cyclotomic character under the paper's class-field convention. The associated semisimple Galois parameters are, respectively, absolutely irreducible, $\chi_1 \oplus \chi_2$, $\chi \oplus \chi$, and $\eta \oplus \eta\omega$. In particular, the last is not scalar when $p \geq 5$.

THEOREM 18.7.3 *(Paškūnas, Theorems 1.5–1.7).* For these blocks the center of $E_{\mathcal{B}}$ is the fixed-determinant pseudodeformation ring $R^{\mathrm{ps},\zeta\varepsilon}_{\mathrm{tr}\,\bar\rho}$. The algebra $E_{\mathcal{B}}$ is finite over its center and, on the stated complement of the reducible locus, is a matrix algebra.

For a supersingular singleton, the full algebra is $R^{\zeta\varepsilon}_{\bar\rho}$. For the generic reducible block, let ρ_1, ρ_2 be the two nonsplit extensions of its distinct characters in opposite directions. Their universal fixed-determinant deformations satisfy

$$E_{\mathcal{B}} \simeq \mathrm{End}_{G_{\mathbb{Q}_p}}(\rho_1^{\mathrm{un}} \oplus \rho_2^{\mathrm{un}}).$$

The corresponding dualized and twisted Montreal images of $J_{\mathcal{B}}$ are the indicated universal representation or sum of the two universal representations.

The compact-module convention is that of the paper's §2. Pontryagin duality reverses the endomorphism ring. Keeping this opposite is necessary when comparing the noncommutative block algebras.

The determinant is $\zeta\varepsilon$ in this theorem. The DEG convention above uses $\zeta\varepsilon^{-1}$ and its specified kernel twist. A comparison must retain the dualizations, twists and reciprocity conventions which relate the two functors.

The same paper's Theorem 1.4 gives a different positive equivalence. Fix an absolutely irreducible admissible unitary non-ordinary Banach representation Π. Take the finite-length block with every irreducible subquotient isomorphic to Π. It is equivalent to finite-length modules over the fixed-determinant deformation ring of its associated characteristic-zero Galois representation. It does not identify every torsion block with one commutative deformation ring.

For a finite sum $P = P_1 \oplus P_2$ of nonzero projective covers of distinct simples, $\mathrm{End}(P)$ contains the orthogonal projection idempotents. It cannot be a commutative local ring. A dimension or regularity calculation for its center therefore does not give that calculation for its full endomorphism algebra.

Generic localization and first-order classes

PROPOSITION 18.7.4 *(extension vanishing over the fraction field).* Let R be a commutative Noetherian domain, let $K = \mathrm{Frac}(R)$, and let M, N be finite R-modules. Then

$$\mathrm{Ext}^1_R(M, N) \otimes_R K \simeq \mathrm{Ext}^1_K(M \otimes_R K, N \otimes_R K) = 0.$$

In particular, the statement applies to a regular local domain. It asserts vanishing at the generic point, not at every regular point.

Proof. Noetherianity gives a free resolution of M with finitely generated terms: take a finite set of generators for each successive kernel. Localization is exact, and homomorphisms from each finite free term commute with localization. Localizing the resulting Hom complex therefore computes the displayed extension group over K. Every short exact sequence of vector spaces over K splits. □

Corollary 18.7.5 *(arithmetic transport on a specified generic fiber).* Suppose an arithmetic block category is exactly equivalent to finite modules over a commutative Noetherian domain R. Assume its specified generic-fiber category corresponds to finite $K = \mathrm{Frac}(R)$-modules. Then generic-fiber extensions vanish. If a spectral locus is also identified with this localization by compatible functors, the same vanishing holds in its corresponding category.

Proof. An exact equivalence identifies extension classes. Apply Proposition 18.7.4 and the stated localization comparison. Neither regularity alone nor flatness alone constructs the arithmetic or spectral equivalence. □

Local self-extensions

Proposition 18.7.6 *(Local self-extensions and conditional arithmetic transport).* For a commutative Noetherian local ring $(A, \mathfrak{m}, k)$, there is a natural isomorphism

$$\mathrm{Ext}^1_A(k,k) \cong \mathrm{Hom}_k(\mathfrak{m}/\mathfrak{m}^2, k).$$

Take distinct simples S, S' in an arithmetic ordinary block, and put $A = A_\rho$. Assume a specified k-linear map identifies $\mathrm{Ext}^1_{\mathrm{Block}_\rho}(S, S')$ with a subspace D_ρ of the displayed dual cotangent space. Then its dimension is $\dim_k D_\rho$. If in addition $\dim_k \mathfrak{m}_\rho/\mathfrak{m}_\rho^2 \le 3$ is established, this gives the bound $\dim_k D_\rho \le 3$. Breuil–Mezard multiplicities alone supply neither this class comparison nor the bound on the embedding dimension.

Proof. Apply $\mathrm{Hom}_A(-,k)$ to $0 \to \mathfrak{m} \to A \to k \to 0$. The restriction $\mathrm{Hom}_A(A,k) \to \mathrm{Hom}_A(\mathfrak{m},k)$ is zero, since $\mathfrak{m}k = 0$, and $\mathrm{Ext}^1_A(A,k) = 0$. Thus the connecting map identifies $\mathrm{Hom}_A(\mathfrak{m},k)$ with $\mathrm{Ext}^1_A(k,k)$. Every such homomorphism kills $\mathfrak{m}^2$, giving the displayed dual cotangent space. Concretely, a functional gives the extension obtained by pushing out $0 \to \mathfrak{m} \to A \to k \to 0$ along $\mathfrak{m} \to k$.

The arithmetic conclusion follows from the separately assumed class comparison. There is no subtraction by a number of defining relations: for $A = k[\epsilon]/(\epsilon^2)$, the embedding dimension is one and $\mathrm{Ext}^1_A(k,k) = k$. This space is annihilated by $\mathfrak{m}$, and is not a nonzero free $A/\mathfrak{m}^2$-module. Every simple module over a commutative local ring is its residue field. Comparison with distinct arithmetic simples therefore requires the specified additional map. □

The reduced total-quotient version also has a precise domain. For a reduced Noetherian ring R, its total quotient ring is a finite product of fields. Localization of finite-module Ext therefore gives vanishing of every positive extension degree over that semisimple ring. Reducedness cannot be replaced by the hypersurface condition. For

$$R = k[[t,u,\epsilon]]/(\epsilon^2),$$

the generic coefficient algebra is $K[\epsilon]/(\epsilon^2)$, with $K = \mathrm{Frac}(k[[t,u]])$. Its simple module has a periodic free resolution with differential ϵ, so $\mathrm{Ext}^1(K,K) = K$.

For a complete local algebra over a discrete valuation ring with uniformizer ϖ, the relative first-order tangent is

$$\operatorname{Hom}_k\bigl(\mathfrak{m}/(\mathfrak{m}^2+\varpi R),k\bigr).$$

The absolute self-extension space uses $\mathfrak{m}/\mathfrak{m}^2$. For $R=O[[x]]$, these dimensions are one and two, respectively. They coincide for a coefficient problem over k, not for every mixed-characteristic deformation problem.

A comparison with an extension between two arithmetic simples must specify both endpoints, the functor or class map, and its normalization. A commutative local ring has only its residue field as a simple module. It does not label several arithmetic simple pairs by itself. Matching one extension dimension gives no higher-product comparison. The polynomial and dual-number examples in Section 18.1 agree in degree one and differ in every higher degree.

Support and compact generation

The localizing subcategory generated by $k=k[t]/(t)$ in $D(k[t])$ disappears after inverting t. The object $k[t]$ survives. Thus a family of image objects can have correct pointwise descriptions and still fail to generate its intended target.

For a quasi-smooth derived scheme X, singular support lies in its scheme of singularities, built from $H^1(T_X)$ over X^{cl}. Its action is the degree-two Hochschild action. It is not a locus inside X defined merely by naming a degree-one Galois class. On derived Artin stacks, the automorphism directions must also be retained when specifying cotangent amplitude and the smooth-local definition of support.

Definition 18.7.7 *(Residual gerbe).* Let x be a point of a locally Noetherian algebraic stack X. Its *residual gerbe* $\mathcal{G}_x$ is the reduced locally Noetherian substack whose underlying space consists of x alone. The inclusion is a monomorphism. This characterizes the gerbe up to its unique equivalence inside X. Existence and uniqueness are The Stacks Project, Tags 06MT and 0H22.

The stabilizers of rank-two parameters give concrete tests. An irreducible representation has scalar centralizer. A distinct split pair has a two-dimensional torus. A scalar representation has GL_2 centralizer.

For a nonsplit self-extension with nilpotent matrix N, the centralizer is $\{aI+bN : a\neq 0\}$. It includes scalar automorphisms and a unipotent subgroup. A rational representative neutralizes its residual gerbe. An arbitrary gerbe need not have such a chosen representative. Determinant twists shift scalar weights by two and do not generate all weights from one of them.

A finite-stratification argument can prove compact generation when the support-compatible recollement functors are supplied. In particular, an extension functor preserves compact objects if its right adjoint preserves filtered colimits. Apply this fact at each stratum, then use the recollement triangles to generate the ambient category. Per-stratum compactness alone does not prove the needed compactness after extension.

At residue primes two and three, a comparison requires the actual block algebra and an enhanced functor into the specified spectral support category. Full derived endomorphisms and target generation must then be compared. One simple object does not imply semisimplicity. A type, an irreducible representation, an inertial class, a deformation point and an irreducible geometric component are different objects. None is substituted for another in this criterion.

A nilpotent local model

Proposition 18.7.8 *(the nilpotent cone in rank two).* Let K be an algebraically closed field of characteristic zero. The nilpotent cone in $\mathfrak{sl}_2(K)$ has dimension two. Its nonzero locus is the regular nilpotent orbit, of codimension one in $\mathfrak{sl}_2(K)$. The zero orbit has dimension zero.

Proof. Write

$$X = \begin{pmatrix} a & b \\ c & -a \end{pmatrix}.$$

Then $X^2 = (a^2 + bc)\mathrm{I}$, so nilpotency is the equation $a^2 + bc = 0$ in $\mathbb{A}^3_K$. On $b \neq 0$ it is parametrized by a, b, with $c = -a^2/b$. The quadric is irreducible: a factorization into linear forms would give a quadratic form of rank at most two, whereas $a^2 + bc$ has rank three.

Thus the cone has dimension two. Every nonzero nilpotent matrix has one Jordan block and is conjugate to $\left(\begin{smallmatrix} 0 & 1 \\ 0 & 0 \end{smallmatrix}\right)$. A conjugating matrix can be rescaled to determinant one because K is algebraically closed. The nonzero locus is therefore one $SL_2(K)$-orbit of dimension two. The remaining orbit is $\{0\}$. □

Remark 18.7.9 *(the arithmetic local model).* This calculation does not determine the dimension of an arithmetic Selmer space. Such a conclusion requires a constructed local-model morphism and its relative dimension. A nonempty transition space cannot be a subspace of both a closed locus and its open complement, since their intersection is empty. In singular-support theory the support condition lies in the scheme of singularities of a quasi-smooth derived space.

It is not, by definition, a locus where the underlying representations have unipotent monodromy. The relevant constructions are Arinkin–Gaitsgory, arXiv:1201.6343, §§2.3, 4.1 and 8.2. §11.1 defines the global nilpotent cone for the geometric local-system stack. An arithmetic analogue requires its own space, singular-support subset and functors.

Filtration length and geometric codimension

Example 18.7.10 *(a Nygaard filtration on a point).* On the prism $(\mathbb{Z}_p, (p))$, take the Frobenius lift $\varphi = \mathrm{id}$. The Nygaard submodules defined by $\varphi(x) \in p^i\mathbb{Z}_p$ are

$$N^{\geq i}\mathbb{Z}_p = p^i\mathbb{Z}_p \quad (i \geq 0), \qquad \mathrm{gr}^i_N\,\mathbb{Z}_p = \mathbb{F}_p.$$

Every nonnegative graded degree is nonzero, although $\operatorname{Spec}\mathbb{F}_p$ has dimension zero. Thus a geometric codimension bound does not by itself truncate the Nygaard filtration in degree two.

For a filtered complex C with decreasing filtration F, the usual cohomological spectral sequence begins with

$$E_1^{a,b} = H^{a+b}(\mathrm{gr}^a_F\, C). \tag{18.6}$$

Convergence of Equation (18.6) to $H^{a+b}(C)$ requires appropriate completeness, exhaustiveness and convergence hypotheses on the filtered complex. A comparison with a cellular filtration additionally requires a filtered chain map and a proof of its effect on graded pieces. The dimension calculation above supplies neither a map nor a spectral-sequence degeneration statement.

Lifting cycles and automorphic hypotheses

Fixed-type cycle theorems supply positive geometric information without identifying categorical generators. In Emerton–Gee's cocharacter notation, the minimal regular type is BT = (1, 0), corresponding to filtration degrees $\{-1, 0\}$ above. For $GL_2(K)$, with $K/\mathbb{Q}_p$ finite and $p > 2$, Theorem 8.6.2 gives the geometric Breuil–Mézard formula for potentially Barsotti–Tate types and arbitrary inertial type.

Write $\mathcal{X}_2^{\mathbf{k}}$ for the component indexed by the Serre weight $\mathbf{k}$. Call $\mathbf{k}$ Steinberg when $k_{\sigma,1} - k_{\sigma,2} = p - 1$ at every embedding. In that case put $\widetilde{k}_{\sigma,1} = \widetilde{k}_{\sigma,2} = k_{\sigma,2}$. The cycles in that formula are

$$\mathcal{Z}_{\mathbf{k}} = \begin{cases} [\mathcal{X}_2^{\mathbf{k}}], & \mathbf{k} \text{ not Steinberg,} \\ [\mathcal{X}_2^{\mathbf{k}}] + [\mathcal{X}_2^{\widetilde{\mathbf{k}}}], & \mathbf{k} \text{ Steinberg.} \end{cases}$$

The special-fiber cycle for a type is the sum of these cycles with the Jordan–Hölder multiplicities of its reduced type. The crystalline and semistable versions use their respective types. The additional component in the Steinberg case is part of the theorem.

The general geometric formula of their Conjecture 8.2.2 has a different scope. Their Theorem 8.1.4 supplies finite cycle support for each fixed regular type. It does not assert smooth divisors or transverse intersections. Nor does a cycle determine a projective generator and all its morphisms. The range $2 \leq k \leq p - 1$ gives dual weights $(0, k - 1)$, including $(0, p - 2)$ at its endpoint. It does not reduce the full supersingular lifting problem to two weights.

There are also positive modularity theorems with specific global hypotheses. For example, Taylor's Theorem A in *On icosahedral Artin representations II* applies to an irreducible continuous $\rho : G_{\mathbb{Q}} \to GL_2(\mathbb{C})$ with $\det \rho(c) = -1$. If its projective image is A_5, impose two further conditions. Its projective inertia image at three has odd order. Its projective decomposition image at five is unramified of order two. Then ρ is modular and its Artin L-function is entire.

This theorem does not give a local compact generator for every residual A_5 block. Potential automorphy, ordinary modularity and local-global compatibility theorems retain their residual, regularity, cyclotomic-irreducibility and local hypotheses. Potential automorphy alone supplies no tower of cyclic extensions for descent. Cyclic descent requires the actual invariance and descent data at each step. The finite-field PSL_2 and PGL_2 image cases and overlaps of lifting loci also remain in a proposed coverage argument.

A categorical comparison can use these results after constructing the relevant image objects and supports. For any collection of overlapping lifting conditions, take the localizing closure of the actual image objects, including their extensions. A direct-sum decomposition additionally requires orthogonality. The generator criterion then applies on this specified category. It does not infer coverage from a list of arithmetic names.

18.8 Geometric Hecke categories and spectral actions

Several geometric constructions realize a full representation category or a distinguished subcategory. Their coefficient theories and geometric spaces are part of their statements. The equal-characteristic affine flag, the Weil–Deligne parameter stack and the p-adic determinant-identified stack give different recipients for an arithmetic comparison.

Bundles and elementary modifications

Every finite projective $\mathbb{Z}$-module is free. A finite projective module is a direct summand of a finite free module. A submodule of a free module over the principal ideal domain $\mathbb{Z}$ is free. Thus the groupoid of

rank-two bundles on Spec $\mathbb{Z}$ has one isomorphism class, with automorphism group $GL_2(\mathbb{Z})$. This is a statement about bundles over that base. It does not identify their moduli functor on every test scheme with a constant classifying stack.

Elementary modifications still occur. The inclusion $p\mathbb{Z} \oplus \mathbb{Z} \subset \mathbb{Z}^2$ has quotient $\mathbb{F}_p$ and becomes an isomorphism away from p. The existence of these lattice correspondences is compatible with freeness of both endpoint bundles. Their convolution, its sheaf realization and its scalar function are separate constructions.

The affine flag and Springer correspondences

Let G be a split reductive group over an algebraically closed field k, and fix $\ell \neq \operatorname{char} k$. Use constructible $\overline{\mathbb{Q}}_\ell$-complexes on the equal-characteristic affine flag spaces of $G(k((t)))$. Let I be an Iwahori subgroup, I° its pro-unipotent radical, and $T = I/I^\circ$. Write D_{II} for the I-equivariant derived category on $G(k((t)))/I$. Write $D_{I^\circ I}$ for the I°-equivariant category on this same space. Finally, $D^{\mathrm{un}}_{I^\circ I^\circ}$ is the category on $G(k((t)))/I^\circ$ with I°-equivariance on the left and unipotent T-monodromy on the right.

Let $\check{G}$ be the Langlands dual group over $\overline{\mathbb{Q}}_\ell$, with Lie algebra $\check{\mathfrak{g}}$. Its Grothendieck and Springer resolutions are

$$\widetilde{\mathfrak{g}} = \{(\mathfrak{b}, x) : x \in \mathfrak{b}\}, \qquad \widetilde{\mathcal{N}} = \{(\mathfrak{b}, x) : x \in \operatorname{rad}(\mathfrak{b})\}.$$

Set

$$\mathrm{St} = \widetilde{\mathfrak{g}} \times_{\check{\mathfrak{g}}} \widetilde{\mathfrak{g}}, \qquad \mathrm{St}' = \widetilde{\mathfrak{g}} \times_{\check{\mathfrak{g}}} \widetilde{\mathcal{N}}.$$

For a map to $\check{\mathfrak{g}}$, the subscript $\mathcal{N}$ on coherent sheaves denotes set-theoretic nilpotent support.

Theorem 18.8.1 *(Bezrukavnikov).* There are equivalences

$$D^{\mathrm{un}}_{I^\circ I^\circ} \simeq D^b \mathrm{Coh}^{\check{G}}_{\mathcal{N}}(\mathrm{St}),$$
$$D_{I^\circ I} \simeq D^b \mathrm{Coh}^{\check{G}}(\mathrm{St}'),$$
$$D_{II} \simeq \mathrm{DGCoh}^{\check{G}}\big(\widetilde{\mathcal{N}} \times^{\mathbb{L}}_{\check{\mathfrak{g}}} \widetilde{\mathcal{N}}\big).$$

The first and third preserve convolution. The middle equivalence preserves both convolution actions. With the corresponding Iwahori–Whittaker conditions, one also has the module-category equivalences

$$D^I_{\mathrm{IW}} \simeq D^b \mathrm{Coh}^{\check{G}}(\widetilde{\mathcal{N}}), \qquad D^{I^\circ,\mathrm{un}}_{\mathrm{IW}} \simeq D^b \mathrm{Coh}^{\check{G}}_{\widetilde{\mathcal{N}}}(\widetilde{\mathfrak{g}}).$$

They preserve the respective actions above.

These are Theorems 1–2 of *On two geometric realizations of an affine Hecke algebra*. The Whittaker character is nondegenerate on the finite simple-root quotients and trivial on the affine-root quotient, with the left and right conventions of that paper. The monodromic convolution category in the first line need not contain a unit. The Iwahori category in the third line is unital. The derived fiber product in that line retains its higher Tor. The two other displayed Steinberg products have their ordinary scheme descriptions under the stated resolution hypotheses.

In particular, the Springer-resolution category is a module category, and the Iwahori category has a Steinberg carrier. The Iwahori derived category is not the bounded derived category of its perverse heart in general. Passing to functions over a finite field also requires Frobenius structures and the sheaf–function map. These are substantive parts of any comparison with an arithmetic Hecke category.

Coherent Springer objects

Let H be reductive over $L = \overline{\mathbb{Q}}_\ell$ or $\mathbb{C}$. Let $\widehat{\mathcal{N}}$ be the formal completion of its Lie algebra along the nilpotent cone, and let $\mu : \widetilde{\mathcal{N}} \to \widehat{\mathcal{N}}$ be the Springer map followed by completion. Use H_{gr} for H together with the dilation action, and let $\mathcal{L}$ denote derived loops. The coherent Springer object is

$$\mathcal{S}_H = (\mathcal{L}\mu)_* \mathcal{O}_{\mathcal{L}(\widetilde{\mathcal{N}}/H_{\mathrm{gr}})} \quad \text{on } \mathcal{L}(\widehat{\mathcal{N}}/H_{\mathrm{gr}}).$$

THEOREM 18.8.2 *(Ben-Zvi–Chen–Helm–Nadler).* The full derived endomorphism algebra of $\mathcal{S}_H$ is the affine Hecke algebra $\mathcal{H}_H$, concentrated in degree zero. Tensoring with $\mathcal{S}_H$ defines a fully faithful functor

$$D(\mathcal{H}_H) \longrightarrow \mathrm{IndCoh}\big(\mathcal{L}(\widehat{\mathcal{N}}/H_{\mathrm{gr}})\big)$$

whose image is generated by $\mathcal{S}_H$. It is compatible with parabolic induction. The anti-spherical module maps to the projection of the dualizing object onto this Springer subcategory.

For $q \in L^\times$ not a root of unity, let

$$\mathcal{L}^u_{q,H} = [\{(g, N) : N \in \mathcal{N},\ gNg^{-1} = qN\}/H]$$

be the unipotent parameter stack and let $\mathcal{S}_{q,H}$ be the corresponding coherent specialization. There is a fully faithful functor

$$\mathrm{Perf}(\mathcal{H}_{q,H}) \longrightarrow \mathrm{Coh}(\mathcal{L}^u_{q,H})$$

defined by $\mathcal{S}_{q,H}$. It takes the anti-spherical module to $\mathcal{O}_{\mathcal{L}^u_{q,H}}$ and preserves the parabolic induction correspondences.

The assertions are Theorems 1.7 and 1.9 of *Coherent Springer theory and categorical Deligne–Langlands*. At a non-root of unity the affine Hecke algebra has finite cohomological dimension, so its perfect and bounded coherent derived categories agree in this statement. The formal derived loop carrier before specialization and the classical reduced q-parameter stack are different objects. In particular, the unspecialized anti-spherical image is the stated projection of a dualizing object.

For GL_n, the same work gives a larger positive comparison. Let F be a nonarchimedean local field and $\mathcal{L}_{F,M}$ the stack of continuous Weil–Deligne parameters for a Levi subgroup M of GL_n, over $\mathbb{C}$. It retains formal deformation spaces of parameters. Theorem 1.12 gives full embeddings

$$D(\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(M(F))) \longrightarrow \mathrm{IndCoh}(\mathcal{L}_{F,M}).$$

They send irreducible cuspidal representations to the parameter skyscraper sheaves prescribed by local Langlands, and commute with parabolic induction through its pull–push correspondence. These properties characterize the supplied embeddings. No equivalence with their whole ind-coherent targets is asserted.

The spectral action on the Fargues–Fontaine curve

Let F have residue cardinality q, let ℓ differ from its residue characteristic, and let L be a field over $\mathbb{Q}_\ell(\sqrt{q})$. For a reductive group G/F, write $\widehat{G}$ for its dual. The parameter stack $[Z^1(W_F, \widehat{G})_L/\widehat{G}]$ uses continuous Weil cocycles and the specified Weil action on $\widehat{G}$. It is not generally quasi-compact.

Fargues–Scholze, Corollary X.1.3, constructs an action

$$\mathrm{Perf}([Z^1(W_F, \widehat{G})_L/\widehat{G}]) \curvearrowright D_{\mathrm{lis}}(\mathrm{Bun}_G, L)^\omega.$$

Here Bun_G is the bundle stack on the Fargues–Fontaine curve, and ω denotes compact objects of the indicated category of lisse sheaves. The action is compactly supported: on each object it factors through parameters trivial on some sufficiently small open subgroup of wild inertia. Its restrictions along the representation functors recover the Hecke actions, functorially in every finite set of legs.

For integral coefficients, their Theorem X.0.1 also imposes $\ell \nmid |\pi_1(\widehat{G})_{\mathrm{tor}}|$. The rational action is a theorem. The equivalence formulated in their Conjecture X.1.4 is a further assertion about a Whittaker-generated functor and its right adjoint. Neither statement changes D_{lis} into coherent sheaves on Bun_G, or identifies the parameter stack with the coefficient-prime stack $\mathcal{X}_\partial$.

Factorization and Whittaker equivalences

The critical-level comparison has a stronger factorization form. Use a reductive group on a smooth characteristic-zero curve. With the twisting conventions of *Proof of the geometric Langlands conjecture II*, Theorem 6.1.4 gives

$$\mathrm{KL}(G)_{\mathrm{crit}} \simeq \mathrm{IndCoh}^*(\mathrm{Op}_{\check{G}}^{\text{mon-free}})$$

as factorization categories. Here KL is the spherical critical Kac–Moody category.

A monodromy-free oper consists of a local system extending to the disk, together with its oper structure on the punctured disk. It is not an unrestricted monodromic local system. Corollary 6.1.9 proves that this functor is strictly unital. The regular-oper structure object maps to the critical vacuum.

At nondegenerate levels, Campbell–Dhillon–Raskin construct the spherical and affine-flag DG equivalences

$$\mathrm{Whit}_\kappa^{\mathrm{sph}} \simeq \widehat{\check{\mathfrak{g}}}_{\check{\kappa}}\text{-mod}^{L^+\check{G}}, \qquad \mathrm{Whit}_\kappa^{\mathrm{aff}} \simeq \widehat{\check{\mathfrak{g}}}_{\check{\kappa}}\text{-mod}^{\check{I}}.$$

The left categories are twisted Whittaker D-modules on the affine Grassmannian and flag variety. The right categories are Harish–Chandra DG module categories for the displayed affine Lie algebra and subgroup. The dual level uses the critical shifts of their §2.7.

Their good-level hypothesis has a concrete form. On each simple factor an irrational level is good. For a rational level $\kappa^\circ = (-h^\vee + a/b)\kappa_{\mathrm{bas}}$, with $(a,b) = 1$, the denominator b must be coprime to

type	A_n	B_n	C_n	D_n	E_6	E_7	E_8	F_4	G_2
$n(\mathfrak{g})$	1	2	2	2	6	6	30	6	6.

This is Proposition 3.4.5. These DG equivalences in that paper set aside the factorization enhancement. They are not a theorem about arbitrary quantum parameters on an arithmetic base.

Gaitsgory–Lysenko's small local equivalence has a third precise recipient. Choose their geometric metaplectic datum on a smooth curve. Let q be its restricted Weyl-invariant root-of-unity quadratic form, and H the associated dual datum. Fix the required trivialization at the marked point.

Retain the nondegeneracy and sheaf-theory hypotheses of that datum. Nondegeneracy means that $q(\alpha)$ has order different from one for every coroot α of G, as in Definition 2.3.4. Their graded Hecke category is formed using the metaplectic Satake action of $\mathrm{Rep}(H)$ and restriction to its Cartan T_H. Theorem 19.2.5 identifies it with the renormalized category of factorization modules:

$$\mathrm{Hecke}^\bullet(\mathrm{Whit}_{q,x}(G)) \simeq \left(\Omega_q^{\mathrm{small}}\text{-FactMod}\right)^{\mathrm{ren}}.$$

The renormalization retains the specified Artinian structure and compact objects. Replacing it by the unrenormalized category changes the statement. The allowed sheaf theories include the stated D-module, constructible and ℓ-adic settings. The factorization-category strengthening is distinguished in their §0.4.5 from the categorical theorem they formulate.

These are geometric positive comparisons with specified units, levels and enhancements. A value p^{-s} in a Hecke spectrum does not identify their quantum parameter with an arithmetic one. An arithmetic use requires the coefficient and operation-preserving map, including its collision and unit data.

18.9 Normalized intertwining for unramified principal series

An Eisenstein comparison must distinguish the normalization of an intertwining operator from its passage to a category of representations. For unramified principal series over a nonarchimedean field, the operator can be computed on every locally constant vector. The computation also determines its poles and its degenerations.

Let F be a finite extension of $\mathbb{Q}_p$. Write O for its ring of integers, ϖ for a uniformizer, and $q = |O/\varpi O|$. Normalize $|\varpi| = q^{-1}$ and the additive Haar measure by $\mathrm{vol}(O) = 1$. Fix an additive character $\psi : F \to \mathbb{C}^\times$ that is trivial on O and nontrivial on $\varpi^{-1}O$.

The operator below does not depend on ψ. This choice fixes the additive convention for subsequent local-factor comparisons. All representations and function spaces have coefficients in $\mathbb{C}$.

Put $G = \mathrm{GL}_2(F)$, $K = \mathrm{GL}_2(O)$, and let B be the upper triangular subgroup. For unramified smooth characters $\chi_1, \chi_2 : F^\times \to \mathbb{C}^\times$, let $I(\chi_1, \chi_2)$ consist of locally constant functions $f : G \to \mathbb{C}$ satisfying

$$f\left(\begin{pmatrix} a & b \\ 0 & d \end{pmatrix} g\right) = |a/d|^{1/2} \chi_1(a)\chi_2(d) f(g).$$

The action is right translation, $(\pi(g)f)(h) = f(hg)$. Thus $I(\chi_1, \chi_2)$ is normalized smooth induction.

Set

$$z = \frac{\chi_1(\varpi)}{\chi_2(\varpi)}, \qquad w = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \qquad n(x) = \begin{pmatrix} 1 & x \\ 0 & 1 \end{pmatrix}.$$

For $|z| < 1$, define

$$(M_z f)(g) = \int_F f(wn(x)g)\, dx. \tag{18.7}$$

The target is $I(\chi_2, \chi_1)$. The subscript z specifies the ratio parameter. The source and target characters remain part of the operator's data.

The compact picture and ball averages

Restriction to K identifies every $I(\chi_1, \chi_2)$ with

$$V = C^\infty(X; \mathbb{C}), \qquad X = (B \cap K)\backslash K = \mathbb{P}^1(F).$$

Here C^∞ means locally constant. The identification of X sends a matrix to its bottom row, up to scalar. It follows from $G = BK$ and the triviality of unramified characters on $O^\times$.

A primitive row has at least one unit coordinate. For primitive representatives $u, v \in O^2$, define

$$\rho([u], [v]) = |\det(u, v)|.$$

This function is independent of the primitive representatives and is invariant under the right action of K. Let ν be the K-invariant probability measure on X.

For $n \geq 1$, reduction modulo ϖ^n gives a finite set

$$X_n = \mathbb{P}^1(O/\varpi^n O), \qquad |X_n| = (q+1)q^{n-1}.$$

Let $V_n \subset V$ be the functions that factor through X_n. Put $V_0 = \mathbb{C}\mathbf{1}$ and $H = L^2(X, \nu)$, with inner product linear in the first variable. The orthogonal projection $E_n : H \to V_n$ averages over each reduction fiber.

The projection E_0 is global averaging. The fibers are the balls $\rho(x, y) \le q^{-n}$, each of measure

$$b_n = \frac{1}{(q+1)q^{n-1}}.$$

Every locally constant function factors through some X_n. Consequently $V = \bigcup_{n\ge 0} V_n$ is dense in H.

Define mutually orthogonal finite-dimensional spaces

$$H_0 = V_0, \qquad H_n = V_n \cap V_{n-1}^{\perp} \quad (n \ge 1).$$

Then

$$V = \bigoplus_{n\ge 0}^{\mathrm{alg}} H_n, \qquad H = \widehat{\bigoplus}_{n\ge 0} H_n.$$

In particular, $\dim H_1 = q$ and $\dim H_n = (q+1)(q-1)q^{n-2}$ for $n \ge 2$.

Lemma 18.9.1 *(Integral kernel and meromorphic continuation).* For $|z| < 1$, the integral in (18.7) converges absolutely. It defines a smooth G-intertwiner. In the compact picture it is

$$M_z = (1 + q^{-1})E_0 + (z - q^{-1}) \sum_{n\ge 1} z^{n-1} E_n. \tag{18.8}$$

The series converges in operator norm on H.

On the orthogonal summands it acts by

$$M_z|_{H_0} = c(z), \qquad c(z) = \frac{1 - q^{-1}z}{1 - z}, \qquad M_z|_{H_n} = \frac{(z - q^{-1})z^{n-1}}{1 - z} \quad (n \ge 1).$$

These formulas give a meromorphic continuation on every V_N. On every nonzero V_N, its only pole in $z \in \mathbb{C}^\times$ is the simple pole at $z = 1$. Here meromorphic continuation means continuation on each finite level, not a family of bounded operators on H for all parameters.

Proof. Let $x_0 = [(0, 1)]$. For $|x| \le 1$, the matrix $wn(x)$ belongs to K. For $|x| > 1$, the factorization

$$wn(x) = \begin{pmatrix} -x^{-1} & 1 \\ 0 & x \end{pmatrix} \begin{pmatrix} 1 & 0 \\ x^{-1} & 1 \end{pmatrix}$$

shows that the inducing factor on $|x| = q^n$ is $q^{-n}z^n$. The shell has additive measure $(1 - q^{-1})q^n$. Since compact-picture functions are bounded, the tail is dominated by $a \sum_{n\ge 1} |z|^n$ for a finite constant a. The same argument applies to each right translate of f.

The integral commutes with right translations. Changing x to $x + y$ proves invariance under left multiplication by $n(y)$. For $a, d \in F^\times$, use

$$wn(x) \begin{pmatrix} a & 0 \\ 0 & d \end{pmatrix} = \begin{pmatrix} d & 0 \\ 0 & a \end{pmatrix} wn(xd/a).$$

The substitution $u = xd/a$ contributes $|a/d|$.

The resulting factor is $|a/d|^{1/2}\chi_2(a)\chi_1(d)$, which is the target induction law. Right local constancy is preserved by the integral. Thus M_z is the stated smooth intertwiner.

The chart $[(1, x)]$, $x \in O$, has measure $q(q+1)^{-1}dx$. The chart $[(y, 1)]$, $y \in \varpi O$, has the same density. For example, reduction modulo ϖ^N divides either chart into sets of additive measure q^{-N} and ν-measure $((q+1)q^{N-1})^{-1}$. This proves the density assertion on locally constant functions.

In the second chart, the substitution $y = x^{-1}$ has Jacobian $dx = |y|^{-2}dy$. On $|y| = q^{-n}$, the resulting density in the raw integral is $q^n z^n\, dy$. Thus its kernel, relative to ν, has value $1 + q^{-1}$ when $\rho(x_0, y) = 1$, and value $(1+q^{-1})q^n z^n$ when $\rho(x_0, y) = q^{-n}$. The diagonal has measure zero. Right K-equivariance gives the same radial kernel about every point.

For $\rho(x, y) = q^{-m}$, telescope the kernel as

$$(1+q^{-1})\left[1 + \sum_{n=1}^{m}\left(q^n z^n - q^{n-1}z^{n-1}\right)\right].$$

Integration of the nth ball indicator is $b_n E_n$. Since $(1+q^{-1})b_n = q^{-n}$, its coefficient is $(z - q^{-1})z^{n-1}$. Absolute convergence justifies the sum and proves (18.8). The projection norms are one, so the series also converges in operator norm.

On H_0, every E_n acts as the identity. On H_m, $m \geq 1$, the projection E_n is zero for $n < m$ and is the identity for $n \geq m$. Summing the geometric series gives the displayed eigenvalues. Each V_N is a finite sum of these spaces.

The rational formulas therefore give its meromorphic continuation. At $z = 1$, every numerator has nonzero value $1 - q^{-1}$. The pole is simple on every nonzero summand. □

Normalization, composition, and domains

The spherical vector is $\mathbf{1} \in H_0$. The scalar in the preceding lemma equals the unramified local ratio

$$c(z) = \frac{L(0, \chi_1\chi_2^{-1})}{L(1, \chi_1\chi_2^{-1})}, \qquad L(u, \chi_1\chi_2^{-1}) = (1 - zq^{-u})^{-1}.$$

Normalizing the spherical vector therefore requires division by $c(z)$. Define the meromorphic family

$$R_z = c(z)^{-1}M_z.$$

THEOREM 18.9.2 *(The normalized unramified intertwiner).* The compact-picture eigenvalues of R_z are

$$r_0(z) = 1, \qquad r_n(z) = z^{n-1}\frac{z - q^{-1}}{1 - q^{-1}z} \quad (n \geq 1). \tag{18.9}$$

The operator is holomorphic on each V_N away from $z = q$. It has a simple pole on every H_n with $n \geq 1$ at $z = q$. The value at $z = 1$ is id_V.

The value at $z = q^{-1}$ is E_0. For $z \notin \{q, q^{-1}\}$, the smooth maps satisfy

$$R_{z^{-1}}R_z = \mathrm{id}_V, \qquad R_z R_{z^{-1}} = \mathrm{id}_V\,.$$

Here the second operator uses the swapped inducing characters.

If χ_1 and χ_2 are unitary, R_z extends uniquely to a unitary intertwiner between their induced Hilbert representations on H. Its Hilbert domain is all of H. In particular, the equal-character point $z = 1$ is regular.

Proof. Division of the preceding eigenvalues by $c(z)$ gives (18.9). This calculation cancels the apparent singularity at $z = 1$. At $z = q$, the denominator has a simple zero and the numerator is nonzero on every H_n, $n \geq 1$. Substitution gives the stated values at 1 and q^{-1}.

For $n \geq 1$, direct cancellation gives

$$r_n(z)r_n(z^{-1}) = \frac{(z - q^{-1})(1 - q^{-1}z)}{(1 - q^{-1}z)(z - q^{-1})} = 1.$$

The identity also holds on H_0. Every smooth vector has finitely many components, so both compositions are defined on all of V at the stated parameters. Intertwining holds first on the convergence domain of the raw integral.

On each smooth vector and each fixed group element, the compact-picture formulas are rational in the two nonzero unramified character values. For a fixed $g \in G$, right translation sends V_N into some V_M independently of the unramified character values. Indeed, an open subgroup of $K \cap gK_Ng^{-1}$ fixes the translated vectors, where $K_N = 1 + \varpi^N M_2(\mathcal{O})$ for $N \geq 1$. On the resulting finite partition of K, the Iwasawa factors have fixed diagonal valuations.

Their character values are Laurent monomials. The integral intertwining identity therefore continues meromorphically. This also proves intertwining at every regular specialization.

If the inducing characters are unitary, $|z| = 1$. Then $|z - q^{-1}| = |1 - q^{-1}z|$, so $|r_n(z)| = 1$ for every n. The orthogonal decomposition of H gives a unique unitary extension. Its inverse has parameter z^{-1}.

For completeness, the induced action preserves the stated Hilbert norm. In the open Bruhat chart put $F_f(x) = f(wn(x))$. For unitary inducing characters, the chart measures above give

$$\|f|_K\|_H^2 = \frac{q}{q+1}\int_F |F_f(x)|^2\,dx.$$

Right translation by $n(y)$ gives $F_f(x + y)$.

Right translation by $\mathrm{diag}(a, d)$ gives

$$|d/a|^{1/2}\chi_1(d)\chi_2(a)F_f(xd/a).$$

Right translation by w, away from $x = 0$, gives

$$|x|^{-1}\chi_1(-x^{-1})\chi_2(x)F_f(x^{-1}).$$

Translations, dilations, and inversion preserve the displayed norm with these factors and their respective Jacobians. These elements generate G.

Each smooth vector has an open stabilizer. Density and unitarity therefore imply strong continuity of the extended action. The smooth equivariance of R_z extends by density to these induced unitary representations. □

For nonunitary parameters, the same compact-picture formulas also specify an operator on a fixed Hilbert space. This assertion does not equip the induced representation with an invariant positive inner product.

Proposition 18.9.3 *(Closed compact-picture realization).* For $z \neq q$, write $h = \sum_{n\geq 0} h_n$ with $h_n \in H_n$. The closure of $R_z|_V$ on H is the normal operator with domain

$$\mathrm{Dom}(\overline{R}_z) = \left\{h \in H : \sum_{n\geq 0} |r_n(z)|^2\|h_n\|^2 < \infty\right\}, \qquad \overline{R}_z h = \sum_{n\geq 0} r_n(z)h_n.$$

The space V is a core. This operator is bounded exactly when $|z| \le 1$. The composition assertions of the preceding theorem hold on V. On the unit circle they hold on all of H.

Proof. The orthogonal sum of scalar operators with the displayed maximal domain is closed and normal. Its adjoint has coefficients $\overline{r_n(z)}$ and the same domain. Truncating the expansion after $n = N$ converges in its graph norm. Thus this maximal operator is the closure of its restriction to V.

Boundedness is equivalent to $\sup_n |r_n(z)| < \infty$. Formula (18.9) proves boundedness for $|z| \le 1$. For $|z| > 1$ and $z \ne q$, the nonzero factor $(z - q^{-1})/(1 - q^{-1}z)$ is fixed and $|z|^{n-1}$ is unbounded. □

Reducibility and the unitary axis

The poles of a normalization and the reducibility of the induced representation are different loci. They can both be determined in the present unramified family.

PROPOSITION 18.9.4 *(Reducibility locus).* The smooth representation $I(\chi_1, \chi_2)$ is reducible exactly when

$$\chi_1\chi_2^{-1} = |\cdot| \quad \text{or} \quad \chi_1\chi_2^{-1} = |\cdot|^{-1}.$$

Equivalently, $z \in \{q^{-1}, q\}$. For $z = q^{-1}$, the regular intertwiner R_z has image H_0 in $I(\chi_2, \chi_1)$ and kernel in $I(\chi_1, \chi_2)$ equal to $\bigoplus_{n\ge1}^{\mathrm{alg}} H_n$. For $z = q$, the swapped regular intertwiner $R_{z^{-1}}$ has image H_0 in $I(\chi_1, \chi_2)$. The stated kernel at $z = q^{-1}$ and image at $z = q$ are nonzero proper invariant subspaces of $I(\chi_1, \chi_2)$.

Proof. The kernel and image assertions follow from (18.9) and the regular intertwining identity. They prove reducibility at the two displayed ratios. Away from these ratios, apply Bernstein–Zelevinsky's irreducibility criterion to the two characters of $\mathrm{GL}_1(F)$. This is *Induced representations of reductive p-adic groups I*, Theorem 4.2, p. 454. The induction conventions are in §1.8(a), p. 444, and §§2.2–2.3, p. 446.

For the upper triangular parabolic, their modulus on the unipotent radical is $|a/d|$, so their square-root factor is the one used here. Every character of $\mathrm{GL}_1(F)$ is irreducible and cuspidal. The criterion excludes exactly the relations $\chi_j = |\cdot|\chi_i$ for distinct i, j. Thus it proves irreducibility on the stated complement. Only this direction of their criterion is used. □

For the symmetric family $\chi_1 = |\cdot|^{s/2}$, $\chi_2 = |\cdot|^{-s/2}$, one has $z = q^{-s}$. The raw integral converges for $\Re(s) > 0$. Its poles occur at

$$s \in \frac{2\pi i}{\log q}\mathbb{Z}.$$

On every smooth finite level, the normalized operator is regular on $\Re(s) \ge 0$.

Its poles occur at

$$s \in -1 + \frac{2\pi i}{\log q}\mathbb{Z},$$

and reducibility occurs at

$$s \in \left(1 + \frac{2\pi i}{\log q}\mathbb{Z}\right) \cup \left(-1 + \frac{2\pi i}{\log q}\mathbb{Z}\right).$$

Neither reducibility locus meets the unitary axis $\Re(s) = 0$. These statements concern local unramified induction. Poles of a global Eisenstein series require a separate global construction.

Example 18.9.5 *(The first nonconstant vectors).* Let $q = 2$ and $z = -1$. The three reduction fibers of $X \to \mathbb{P}^1(\mathbb{F}_2)$ have equal measure. On V_1, the raw integral and normalized operator are

$$M_{-1} = \frac{1}{4}\begin{pmatrix} -1 & 2 & 2 \\ 2 & -1 & 2 \\ 2 & 2 & -1 \end{pmatrix}, \qquad R_{-1} = \frac{1}{3}\begin{pmatrix} -1 & 2 & 2 \\ 2 & -1 & 2 \\ 2 & 2 & -1 \end{pmatrix}.$$

The spherical scalar is $c(-1) = 3/4$.

The normalized matrix fixes constants and negates their orthogonal complement. Its square is the identity. At $z = 1/2$, the normalized matrix is the rank-one averaging projection. At $z = 1$, its continued value is the identity matrix.

The automorphic comparison

A categorical Eisenstein comparison requires categories and functors in addition to these operators. One must specify the coefficient field, the local parameter spaces, and the global automorphic quotient with its central character and level. The global category must carry its Hecke actions and its Eisenstein subcategory. A comparison functor must identify the relevant derived mapping objects and determine its essential image. The shared global induction parameter must also be imposed on local families.

The construction above supplies the full smooth intertwiner and its Hilbert extension only for unramified nonarchimedean induction. Ramified characters and the archimedean place require their own operators, normalizations, and analytic domains. A global restricted product requires compatible distinguished vectors and an explicit global family. The categorical comparison further requires functors implementing these maps and their Weyl coherences. No equivalence of automorphic categories follows from the compact-picture Hilbert isomorphism alone.

The place-indexed operator notation

Definition 18.9.6 *(the raw place-indexed operator).* For a finite local field F_v and unramified characters $\chi = (\chi_1, \chi_2)$, use normalized smooth induction

$$I_v(s, \chi) = \mathrm{Ind}_{B(F_v)}^{GL_2(F_v)}(\chi_1|\cdot|^{s/2} \otimes \chi_2|\cdot|^{-s/2}).$$

Put $\alpha_1 = \chi_1|\cdot|^{s/2}$, $\alpha_2 = \chi_2|\cdot|^{-s/2}$ and $z = \alpha_1(\varpi)/\alpha_2(\varpi)$. With $\chi^w = (\chi_2, \chi_1)$, the notation is

$$M_v(s, \chi) = M_z : I_v(s, \chi) = I(\alpha_1, \alpha_2) \longrightarrow I(\alpha_2, \alpha_1) = I_v(-s, \chi^w).$$

The integral is defined for $|z| < 1$ and continued on each smooth finite level by Lemma 18.9.1.

Definition 18.9.7 *(the normalized place-indexed operator).* On the same source and target, define

$$N_v(s, \chi) = R_z = c(z)^{-1} M_z, \qquad c(z) = \frac{1 - q^{-1}z}{1 - z}.$$

Cancellation and continuation at $z = 1$ are part of Theorem 18.9.2. The expression is not a pointwise product of undefined values there. Its poles, domains and unitary specializations are those proved in that theorem.

18.10 Algebraic parameters for unramified induction

The normalized unramified intertwiner varies with the inducing characters. A category of coefficient complexes records this variation and its Weyl symmetry. Its relation to smooth induction is a functor defined by tensoring with universal smooth induction. The resulting category concerns local algebraic parameters. An automorphic comparison requires further constructions.

Retain the nonarchimedean field F, residue cardinality q, group $G = \mathrm{GL}_2(F)$, and compact subgroup K of the unramified calculation. In particular, $|\varpi| = q^{-1}$ and $\mathrm{vol}(\mathcal{O}) = 1$. Let a, b denote the values at ϖ of the two unramified characters. Their ratio is $z = a/b$. To make both normalized intertwining directions regular and invertible, put

$$A = \mathbb{C}[a^{\pm 1}, b^{\pm 1}, (a - qb)^{-1}, (b - qa)^{-1}], \qquad T = \operatorname{Spec} A.$$

Thus T omits precisely the two divisors $z = q, q^{-1}$. The Weyl group $W = \{1, w\}$ acts through the ring involution $\sigma(a) = b$, $\sigma(b) = a$. The involution exchanges the two inverted divisors. At a complex point (a_0, b_0), define $\chi_{a_0}(x) = a_0^{v_F(x)}$, where $v_F(\varpi) = 1$. The corresponding representation is the normalized induction $I(\chi_{a_0}, \chi_{b_0})$.

The ratio alone determines the normalized operator in the compact picture. It does not determine the representation. Replacing (a_0, b_0) by (ta_0, tb_0) twists the representation by $\chi_t \circ \det$. For example, the central element $\varpi\,\mathrm{id}$ acts by $a_0 b_0$ before the twist and by $t^2 a_0 b_0$ afterwards. Both characters must therefore remain in the parameter space.

Coefficient complexes and their unit

For a ring D, write $\mathcal{D}(D)$ for the stable ∞-category of unbounded cochain complexes of left D-modules, with quasi-isomorphisms inverted. The differential has degree 1. We use $P[1]^n = P^{n+1}$ with differential $-d_P$. For commutative D, tensor products are derived over D. Their symmetry has sign $(-1)^{ij}$ on degrees i, j. Let $\mathrm{Perf}(D)$ be a small skeleton of the full subcategory generated by $D[0]$ under finite sums, shifts, cones, and retracts.

PROPOSITION 18.10.1 *(The coefficient category).* The category $\mathrm{Perf}(A)$ is stable, idempotent complete, and symmetric monoidal under $\otimes^{\mathbf{L}}_A$. There is a canonical equivalence

$$\mathrm{Ind}(\mathrm{Perf}(A)) \simeq \mathcal{D}(A).$$

The compact objects of $\mathcal{D}(A)$ are exactly $\mathrm{Perf}(A)$. The monoidal unit is $A[0]$. The functor

$$e : \mathcal{D}(\mathbb{C}) \longrightarrow \mathcal{D}(A), \qquad U \longmapsto A \otimes_{\mathbb{C}} U$$

is a colimit-preserving symmetric monoidal pointing and preserves compact objects.

Proof. The category of derived modules is stable and presentable. For a commutative ring it identifies symmetric monoidally with modules over the associated discrete ring spectrum. This is Lurie, *Higher Algebra* (2017), Theorem 7.1.2.13, pp. 1212–1213. Its shifts of A detect zero objects, since $\mathrm{Hom}_{\mathcal{D}(A)}(A[-n], P) = H^n(P)$.

These shifts are compact because cohomology commutes with filtered colimits of modules. The module compact-generation theorem identifies their finite stable retract closure with all compact objects and gives the Ind equivalence. See Lurie, *Higher Algebra* (2017), Definition 7.2.4.1 and Proposition 7.2.4.2, pp. 1260–1261. For ordinary rings these are bounded complexes of finitely generated projective modules (The Stacks Project, Tag 07LQ, Lemma 15.80.1 and Proposition 15.80.3).

Tensoring two such complexes gives another such complex. The associativity, unit, and symmetry are those of derived tensor product. Extension of scalars preserves colimits and takes a finite complex of finite-dimensional vector spaces to a finite free complex. Its tensor and unit identities prove the assertion about e. □

A point of T gives the specialization functor $\mathbb{C} \otimes^{\mathbf{L}}_{A,(a_0,b_0)} (-)$. The point module $A/(a - a_0, b - b_0)$ is also perfect. Its length-two Koszul resolution follows because $a - a_0, b - b_0$ form a regular sequence. Indeed, the quotient by the first element is a localization of $\mathbb{C}[b^{\pm 1}]$, and the second element is nonzero there.

The inverted elements remain nonzero at the chosen point. This point module differs from the monoidal unit A. For two distinct points, its tensor product with the other point module is zero, as follows by localizing at their disjoint supports. The unit cannot have this property.

The universal smooth representation

Let $X = (B \cap K)\backslash K$ and $V = C^\infty(X; \mathbb{C})$, where B is the upper triangular subgroup and functions are locally constant. The compact-picture calculation gives $V = \bigoplus_{n \geq 0} H_n$ and $V_N = \bigoplus_{n=0}^{N} H_n$, with $H_0 = \mathbb{C}\mathbf{1}$ and finite-dimensional H_n. Put $E = A \otimes_{\mathbb{C}} V$ and $E_N = A \otimes V_N$. All these modules are in cochain degree zero.

Proposition 18.10.2 *(Induction over the parameter ring).* There is an A-linear smooth action π_A of G on E. Its specialization at (a_0, b_0) is $I(\chi_{a_0}, \chi_{b_0})$. The normalized intertwiner defines an A-linear isomorphism

$$R : E \longrightarrow E^{\mathrm{sw}}, \qquad R|_{A \otimes H_0} = 1, \qquad R|_{A \otimes H_n} = z^{n-1} \frac{z - q^{-1}}{1 - q^{-1} z} \quad (n \geq 1),$$

where E^{sw} has the inducing parameters b, a. Its inverse has the displayed coefficients with z replaced by z^{-1}. The coefficient module E is free and is not compact in $\mathcal{D}(A)$. Every E_N is compact and K-stable.

Proof. Use the universal unramified characters $\chi_a(x) = a^{v_F(x)}$ and $\chi_b(x) = b^{v_F(x)}$ in the induction law. The factor $|x/y|^{1/2}$ is a fixed positive real scalar. For $g \in G$, extend a function from K to $BK = G$ by this law, then translate it on the right by g. Independence of the Iwasawa factorization follows because the characters and modulus are trivial on $B \cap K$. For each fixed g, N, compactness and local constancy give a finite partition on which all diagonal valuations are constant.

The resulting coefficients are Laurent monomials in a, b. Thus $\pi_A(g) E_N \subset E_M$ for some finite M. Right translation satisfies the group law before restriction to K, and consequently defines an action on E. Each vector has an open stabilizer in K. Specializing the induction law proves the fiber assertion.

The stated coefficients belong to A and are units in A. The normalized intertwiner calculation proves the intertwining identity and $r_n(z^{-1}) r_n(z) = 1$. These identities apply over A: for fixed g, N they are finite matrix identities in rational functions of a, b. They hold at every regular complex specialization, hence hold in A. This proves the asserted isomorphism and inverse.

Each E_N is finite free. The decomposition of V makes E free of infinite rank. If E were compact, its identity would factor through some term of $E = \operatorname{colim}_N E_N$. That would express an infinite-rank free module as a retract of a finite-rank module, which is impossible after tensoring with the fraction field of A. The compact-picture K-action preserves each V_N. The full G-action need not preserve these finite levels. □

Let $\mathcal{D}_{\mathrm{sm}}(G, A)$ denote the derived ∞-category of smooth A-linear G-representations. Here smooth means that every vector has an open stabilizer, and G acts trivially on A. Tensoring with the flat module E gives an actual functor

$$\mathcal{F} : \mathcal{D}(A) \longrightarrow \mathcal{D}_{\mathrm{sm}}(G, A), \qquad P \longmapsto E \otimes_A P.$$

It is well-defined on quasi-isomorphisms since E is free over A.

Its specialization is $I(\chi_{a_\circ}, \chi_{b_\circ}) \otimes_{\mathbb{C}} (\mathbb{C} \otimes^{\mathbf{L}}_A P)$. The spherical map $A \to E, c \mapsto c\mathbf{1}$, is K-equivariant. It is generally not G-equivariant when A has trivial G-action. For example, the central element $\mathfrak{Z}$ id acts on E by ab. Thus neither the spherical vector nor the representation E replaces the coefficient category's monoidal unit.

Weyl descent

The involution σ acts on coefficient complexes by restriction of scalars. On the underlying complex the new scalar action is $c \cdot m = \sigma(c)m$. Applying this operation twice is the identity. It preserves derived tensor products and the unit, with their usual canonical identifications. This is a specified coherent action of W on $\mathcal{D}(A)$. Its descent category is the homotopy limit $\mathcal{D}(A)^{hW}$.

PROPOSITION 18.10.3 *(An explicit descent category).* Let $D = A \rtimes W = A \oplus Au$, with multiplication given by $u^2 = 1$ and $uc = \sigma(c)u$ for $c \in A$. There is an equivalence

$$\mathcal{D}(A)^{hW} \simeq \mathcal{D}(D).$$

This category is stable and presentable. An object is compact if and only if its underlying A-complex is perfect. Its symmetric monoidal product is derived tensor over A, with diagonal Weyl action. Its compact monoidal unit is A with $u(c) = \sigma(c)$.

Proof. A strict D-module is an A-module with a semilinear involution θ: $\theta(cm) = \sigma(c)\theta(m)$ and $\theta^2 = 1$. The same description applies to complexes with a chain involution. To identify the derived category with coherent descent, consider the evaluation functor from the homotopy limit to $\mathcal{D}(A)$. It is conservative and has the free-equivariant left adjoint $P \mapsto P \oplus \sigma^* P$ with its permutation action.

Colimits are computed on underlying complexes since σ^* preserves them. In particular, evaluation preserves geometric realizations of split simplicial objects. The monadicity theorem therefore applies (Lurie, *Higher Algebra* (2017), Theorem 4.7.3.5, p. 685). Its monad is $P \mapsto P \oplus \sigma^* P$, with multiplication from W.

This is also the monad of restriction from D-modules to A-modules, whose left adjoint is $D \otimes^{\mathbf{L}}_A (-)$. Restriction is conservative and preserves geometric realizations. The two monadic descriptions prove the equivalence, including all higher coherences.

As a left or right A-module, D is free of rank two. Thus every perfect D-complex becomes perfect over A. Conversely, a D-complex M is a retract of $D \otimes_A M$. The action map is a retraction of the D-linear chain map

$$m \longmapsto \tfrac{1}{2}(1 \otimes m + u \otimes \theta(m)).$$

The relations $uc = \sigma(c)u$ and $\theta^2 = 1$ verify linearity directly. If the underlying A-complex is perfect, extension of scalars makes $D \otimes^{\mathbf{L}}_A M$ perfect over D. The retract is therefore perfect. The compact-object characterization in the coefficient proposition applies to D as well.

The diagonal involution on $M \otimes^{\mathbf{L}}_A N$ is $\theta_M \otimes \theta_N$. Semilinearity makes it well-defined, and the usual tensor constraints are equivariant. The module A with involution σ is the unit and is perfect over A. This proves its compactness after descent. □

The involution is not free on T. Every point (a_0, a_0) is fixed and belongs to T. The modules A with involutions σ and $-\sigma$ specialize there to the trivial and sign representations of W. These are not isomorphic: an intertwining scalar would satisfy $c = -c$. Consequently descent retains stabilizer representations. It cannot be replaced by the category of modules on the coarse orbit space through ordinary pullback, which has trivial stabilizer action on every fiber.

The representation E has its own compatible descent datum. Let $S : E \to E$ apply σ to coefficients and fix V. Define $\Theta = SR$, using the common compact-picture module. Then

$$\Theta(cf) = \sigma(c)\Theta(f), \qquad \Theta^2 = 1, \qquad \Theta\pi_A(g) = \pi_A(g)\Theta.$$

Indeed, $S\pi_A(g) = \pi_A^{\mathrm{sw}}(g)S$ and $R\pi_A(g) = \pi_A^{\mathrm{sw}}(g)R$.

Conjugating R by S replaces z by z^{-1}, so its inverse is obtained. These identities prove all three assertions. Moreover, $\Theta(c\mathbf{1}) = \sigma(c)\mathbf{1}$. For an equivariant coefficient complex (P, θ), the formula $(E \otimes_A P, \Theta \otimes \theta)$ therefore defines equivariant smooth induction. This is a construction of a functor, without an assertion of full faithfulness or essential surjectivity.

A common complex parameter

For the symmetric inducing characters $|\cdot|^{s/2}, |\cdot|^{-s/2}$, the two parameters are $a = q^{-s/2}$ and $b = q^{s/2}$. Here $q^s = \exp(s \log q)$, with the real logarithm of q. The ratio $z = q^{-s}$ has period $2\pi i/\log q$. The ordered pair (a, b) has period $4\pi i/\log q$. A shift by the smaller period changes both character values by -1. This explains why the ratio does not encode the whole family.

Let $\Omega = \{s \in \mathbb{C} : |\operatorname{Re} s| < 1\}$ and $B_\Omega = \mathcal{O}(\Omega)$, treated as an ordinary commutative ring. There is a ring map

$$\phi_q : A \longrightarrow B_\Omega, \qquad a \longmapsto e^{-s \log q/2}, \qquad b \longmapsto e^{s \log q/2}.$$

The inverted factors have no zeros in Ω because $|q^{-s}| = q^{-\operatorname{Re} s}$ lies strictly between q^{-1} and q. Their reciprocals are holomorphic, which proves that the map is defined.

The involution $\tau(h)(s) = h(-s)$ satisfies $\phi_q\sigma = \tau\phi_q$. Derived extension of scalars gives a compact-preserving functor

$$B_\Omega \otimes^{\mathbf{L}}_A (-) : \mathcal{D}(A) \longrightarrow \mathcal{D}(B_\Omega)$$

and an equivariant version on descent categories. The latter sends (P, θ) to the complex with involution $h \otimes p \mapsto \tau(h) \otimes \theta(p)$. All finite-level matrices of E and R pull back to holomorphic matrices.

Evaluating at s gives exactly the smooth representation and normalized operator at $z = q^{-s}$. On $s \in i\mathbb{R}$, the previously constructed Hilbert extension is unitary. No topology on B_Ω or Hilbert completion is part of this scalar-extension functor.

For a finite set of finite places S, allow independent local character parameters and put $A_S = \bigotimes_{v \in S, \mathbb{C}} A_v$. The common symmetric family gives a single map

$$\phi_S : A_S \longrightarrow B_\Omega, \qquad \bigotimes_v f_v \longmapsto \prod_v \phi_{q_v}(f_v).$$

It imposes the same variable s at every place. For $S \subset S'$, scalar extension along $A_S \to A_{S'}$ supplies compatible coefficient functors, and $\phi_{S'}$ restricts to ϕ_S.

Thus these maps also define a map from the filtered union of the rings A_S. They give actual base-change functors for independent local parameters. The compatible Weyl action is the simultaneous swap at all places. An individual local swap generally does not preserve the common family.

For example, with $q_2 = 2$ and $q_3 = 3$, the independent unitary ratios $(z_2, z_3) = (1, -1)$ do not come from any common s. The first equation forces $s = 2\pi i n/\log 2$ for an integer n. The second would give $2n \log 3 = (2m + 1) \log 2$ for an integer m, after changing signs of the indices if necessary. Exponentiation contradicts unique factorization of rational numbers. Thus tensoring independent unitary axes does not impose the global parameter.

After common base change, put $E_{v,\Omega} = B_\Omega \otimes_{A_v} E_v$. Write $R_{v,\Omega}$ for the scalar extension of R_v. The local semilinear involution $\Theta_v = S_v R_v$ induces

$$\Theta_{v,\Omega}(h \otimes f) = \tau(h) \otimes \Theta_v(f).$$

This formula is balanced because $\phi_{q_v} \sigma_v = \tau \phi_{q_v}$.

It squares to the identity, commutes with G_v, and fixes $\mathbf{1}_v$. For finite S, put $E_{S,\Omega} = \bigotimes_{v \in S, B_\Omega} E_{v,\Omega}$. The B_Ω-linear operator $\bigotimes_{v \in S} R_{v,\Omega}$ has target the family with every inducing pair swapped. The semilinear involution on $E_{S,\Omega}$ is instead defined by

$$\Theta_S\Big(\bigotimes_{v \in S} f_v\Big) = \bigotimes_{v \in S} \Theta_{v,\Omega}(f_v).$$

For $S = \varnothing$, set $E_{S,\Omega} = B_\Omega$ and $\Theta_S = \tau$. For nonempty S, moving a scalar between two tensor factors changes both resulting expressions by its image under τ. Thus the displayed map is balanced and τ-semilinear. Applying it twice gives the identity on pure tensors, hence on the whole module.

It commutes with the action of $\prod_{v \in S} G_v$. Insertion of $\mathbf{1}_v$ defines compatible maps as S grows. These maps intertwine Θ_S and $\Theta_{S'}$ because each $\Theta_{v,\Omega}$ fixes the inserted vector. This also holds for the insertion from the empty set, by semilinearity.

The algebraic filtered colimit is the restricted tensor product of these smooth families over finite places, relative to $\mathbf{1}_v$. It therefore inherits a semilinear involution from the maps Θ_S. It carries the restricted product group relative to K_v: outside finitely many places an element belongs to K_v and fixes $\mathbf{1}_v$. Every tensor and every group action is computed at some finite stage. No infinite product of operator norms is needed for this algebraic construction.

The automorphic comparison problem

The common family above fixes the two global inducing characters to be trivial before the powers of the absolute value are inserted. For general inducing characters, their local components must arise from specified Hecke characters, and the Weyl action must also swap that character pair. Independent local characters do not by themselves supply these global data.

An analytic coefficient category still requires a choice of sheaf theory, topology, growth conditions, and derived completion on a complex parameter domain. The ring category $\mathcal{D}(B_\Omega)$ specifies none of those choices. An automorphic target further requires the adelic quotient, central character, level, archimedean factor, and an Eisenstein functor with analytic domains. To compare that target with the parameter category, one must construct the functor on complexes and compare its derived mapping objects and essential image.

Compactness of coefficient complexes does not prove admissibility or finite generation over local Hecke algebras after induction. The local smooth family, its coherent Weyl descent, and common-parameter base change provide the input maps for this comparison. They do not identify a category of automorphic representations.

Remark 18.10.4 *(global normalizations and the pairing comparison).* The local operator $N_v(s,\chi) = R_z$ divides the raw operator by its spherical scalar $c(z)$. A global product requires Hecke characters, compatible spherical insertions, the archimedean and ramified factors, and an analytic continuation on a specified global family. For the trivial level-one Eisenstein datum, put

$$\Lambda(u) = \pi^{-u/2}\Gamma(u/2)\zeta(u), \qquad \xi(u) = \tfrac{1}{2}u(u-1)\Lambda(u).$$

The classical scattering factor is $\Lambda(2u-1)/\Lambda(2u)$, with symmetric induction variable $s = 2u-1$.

The entire-completion ratio instead satisfies

$$\frac{\xi(2u-1)}{\xi(2u)} = \frac{u-1}{u}\frac{\Lambda(2u-1)}{\Lambda(2u)}.$$

The two phases are different. For a general inducing character, the global epsilon product retains its character and additive convention. It is not universally 1.

An operator, a scalar phase and a Plancherel density are different data. The Koszul–Petersson transport requires its actual pairing map and measure identity. If an even measure on the full axis has density $\frac{1}{2}w(t)dt$, pushforward under $t \mapsto |t|$ has density $w(t)dt$ off zero. This folding identity does not determine w.

Definition 18.10.5 *(local degeneration and the regular unitary locus).* For the symmetric unramified family at a finite place, define

$$\Sigma_v^{\mathrm{exc}} = \left(1 + \frac{2\pi i}{\log q_v}\mathbb{Z}\right) \cup \left(-1 + \frac{2\pi i}{\log q_v}\mathbb{Z}\right).$$

These are reducibility parameters. The normalized operator has poles only on the second set and is a projection at the first set. The non-exceptional unitary locus is all of $i\mathbb{R}$. The point 0 is regular and 1 is not on the unitary axis.

Remark 18.10.6 *(local degeneration and global residues).* A residue of a global Eisenstein series is not a pole of every normalized local operator. Its parameter, global quotient and central character must be specified. The local kernel/image sequences at $z = q^{\pm 1}$ are given by Proposition 18.9.4. Comparison of their extension classes with arithmetic deformation data remains a separate coefficient-compatible construction.

18.11 The regular unramified family

The normalized unramified intertwiner loses invertibility at two character ratios. Its cone records the resulting kernels and quotients, including those created by specialization. To define this cone across both ratios, fix the scalar used to clear the denominator.

Let F be a finite extension of $\mathbb{Q}_p$ with ring of integers O, uniformizer ϖ, and residue cardinality q. Set $|\varpi| = q^{-1}$ and normalize additive Haar measure by $\mathrm{vol}(O) = 1$. Put $G = \mathrm{GL}_2(F)$, $K = \mathrm{GL}_2(O)$, and let B be the upper triangular subgroup. The coefficient ring and ratio are

$$R = \mathbb{C}[a^{\pm 1}, b^{\pm 1}], \qquad z = a/b.$$

Every coefficient ring in this local-family construction is an ordinary commutative $\mathbb{C}$-algebra. It has no analytic topology. The universal unramified characters are $\chi_a(x) = a^{v_F(x)}$ and $\chi_b(x) = b^{v_F(x)}$, with $v_F(\varpi) = 1$.

Let $E = I_R(\chi_a, \chi_b)$ be the smooth normalized induction. Its elements are locally constant functions $f : G \to R$ satisfying

$$f\left(\begin{pmatrix} u & v \\ 0 & t \end{pmatrix} g\right) = |u/t|^{1/2} a^{v_F(u)} b^{v_F(t)} f(g).$$

The square root is positive real, and G acts by right translation. Restriction to K identifies its coefficient module with $R \otimes_{\mathbb{C}} V$, where

$$X = (B \cap K)\backslash K = \mathbb{P}^1(F), \qquad V = C^\infty(X; \mathbb{C}).$$

Here C^∞ means locally constant. Indeed, $G = BK$, and the inducing factor is trivial on $B \cap K$. For a fixed $g \in G$, compactness partitions K into finitely many pieces with constant diagonal valuations in an Iwasawa decomposition of kg. Right translation therefore has Laurent polynomial coefficients on every finite space of functions.

This constructs the action over R and proves its compatibility with arbitrary coefficient extension. Every vector is fixed by an open subgroup of K. Define $E^{\mathrm{sw}} = I_R(\chi_b, \chi_a)$ in the same way. These are different G-actions on the same coefficient module.

Let ν be the K-invariant probability measure on X. For $N \geq 1$, let V_N be the functions pulled back from $X_N = \mathbb{P}^1(\mathcal{O}/\varpi^N\mathcal{O})$, and put $V_0 = \mathbb{C}\mathbf{1}$. Averaging on reduction fibers defines projections $P_N : V \to V_N$. Let P_0 be global averaging, and define

$$H_0 = V_0, \qquad H_n = \ker(P_{n-1}|_{V_n}) \quad (n \geq 1).$$

Thus $V = \bigoplus_{n\geq 0} H_n$ and $V_N = \bigoplus_{n=0}^{N} H_n$. Write $H_+ = \bigoplus_{n\geq 1} H_n$. The dimensions are $\dim H_0 = 1$, $\dim H_1 = q$, and $\dim H_n = (q+1)(q-1)q^{n-2}$ for $n \geq 2$. These are K-stable spaces. They need not be G-stable.

The unramified integral calculation fixes the normalization. With $w = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $n(x) = \left(\begin{smallmatrix} 1 & x \\ 0 & 1 \end{smallmatrix}\right)$, it gives

$$M_z f(g) = \int_F f(wn(x)g)\, dx, \qquad c(z) = \frac{1 - q^{-1}z}{1 - z}, \qquad R_z = c(z)^{-1} M_z.$$

The integral is initially defined at complex specializations with $|z| < 1$. Its rational continuation, on each V_N, satisfies

$$R_z|_{H_0} = 1, \qquad R_z|_{H_n} = z^{n-1}\frac{z - q^{-1}}{1 - q^{-1}z} \quad (n \geq 1). \tag{18.10}$$

For clarity, the compact-picture calculation underlying this formula is

$$M_z = (1 + q^{-1})P_0 + (z - q^{-1})\sum_{n\geq 1} z^{n-1} P_n.$$

A reduction fiber at depth n has measure $((q+1)q^{n-1})^{-1}$. For primitive rows $u, v \in \mathcal{O}^2$, set $\rho([u],[v]) = |\det(u,v)|$. The radial integral kernel has successive values $(1 + q^{-1})q^n z^n$ at distance q^{-n}. Subtracting successive values gives the displayed projection coefficients.

On H_m, $m \geq 1$, only the terms $n \geq m$ remain. Their geometric sum is $(z - q^{-1})z^{m-1}/(1 - z)$. On constants the sum is $c(z)$, which proves (18.10). The integral commutes with right translation and exchanges the inducing characters by the substitution $x \mapsto xd/u$ for a diagonal matrix $\mathrm{diag}(u, d)$. Its intertwining identity consequently continues as a rational identity on finite spaces of vectors.

Set

$$\alpha = 1 - q^{-1}z, \qquad \beta = z - q^{-1}, \qquad h = (1 - q^{-1}z)(1 - q^{-1}z^{-1}) = z^{-1}\alpha\beta.$$

The chosen regular map is

$$D = \alpha R_z = (1 - z)M_z : E \longrightarrow E^{\mathrm{sw}}, \qquad D|_{R\otimes H_0} = \alpha, \quad D|_{R\otimes H_n} = z^{n-1}\beta. \tag{18.11}$$

The equalities with meromorphic operators mean equality of rational families. The right-hand coefficients define D over all of R, including $z = 1$. Multiplication by an additional nonunit would change the cone. Thus the scalar in (18.11) is part of the construction.

Example 18.11.1. Let $q = 2$ and $N = 1$. The three residue directions have equal measure. In their characteristic-function basis, put $J = (1)_{i,j=1}^{3}$. The projection onto constants is $P = J/3$, so

$$D_1 = \alpha P + \beta(1 - P) = \frac{1}{2}\begin{pmatrix} z & 1 - z & 1 - z \\ 1 - z & z & 1 - z \\ 1 - z & 1 - z & z \end{pmatrix}, \qquad \det D_1 = (1 - z/2)(z - 1/2)^2.$$

At $z = 1/2$ its value is $J/4$, with kernel the two-dimensional sum-zero space. At $z = 2$ its value is $\frac{3}{2}(1 - P)$, with kernel the constants. At $z = 1$ its value is $\frac{1}{2}\,\mathrm{id}$. The matrix with swapped inducing characters is $D_1(z^{-1})$, and

$$D_1(z^{-1})D_1(z) = (1 - z/2)(1 - z^{-1}/2)\,\mathrm{id}\,.$$

Indeed, both matrices preserve constants and their sum-zero complement. Multiplying the two eigenvalues on either space gives the displayed scalar. The two distinct kernels determine the two support summands of the general cone.

Proposition 18.11.2. The map D is an R-linear smooth G-intertwiner on all of E. Let $D^{\mathrm{sw}} : E^{\mathrm{sw}} \to E$ be the same regular construction with (a, b) replaced by (b, a). Then

$$D^{\mathrm{sw}}D = h\,\mathrm{id}_E, \qquad DD^{\mathrm{sw}} = h\,\mathrm{id}_{E^{\mathrm{sw}}}\,. \tag{18.12}$$

On H_0 the coefficient of D^{sw} is β/z. On H_n, $n \geq 1$, it is $z^{-n}\alpha$. After extension to $R[h^{-1}]$, the normalized operator is $R_z = \alpha^{-1}D$ and its inverse is $(1 - q^{-1}z^{-1})^{-1}D^{\mathrm{sw}}$.

Proof. Every vector has only finitely many H_n components, so (18.11) defines a map on all smooth vectors. For fixed g, N, both sides of the intertwining identity lie in some $R \otimes V_M$. Their coefficients are Laurent polynomials. The rational intertwining identity established above proves their equality in the fraction field of R, hence in R.

Replacing z by z^{-1} gives the stated opposite coefficients. Their products are h on every summand, which proves (18.12). Inverting h inverts both α and β, and the normalized composition follows. □

The ordered pair cannot be replaced by its ratio in the representation data. The central element $\varpi\,\mathrm{id}$ acts by ab. Replacing (a, b) by (ta, tb) leaves z fixed and tensors the representation with $\chi_t \circ \det$. The swap in Proposition 18.11.2 always exchanges the two characters.

18.12 The cone and its coefficient extensions

Use cochain complexes, with differentials of degree 1 and $P[1]^j = P^{j+1}$ with differential $-d_P$. The cone of the map between degree-zero representations is

$$C = \mathrm{Cone}(D) = [\, E \xrightarrow{D} E^{\mathrm{sw}} \,], \qquad C^{-1} = E, \quad C^0 = E^{\mathrm{sw}}.$$

Let $\mathcal{D}_{\mathrm{sm}}(G, R)$ denote the derived category of smooth R-linear representations of G. Its objects are complexes, with quasi-isomorphisms inverted.

The action on coefficients is trivial. The displayed complex is an object of this category. Its terms are free as R-modules.

THEOREM 18.12.1. The map D is injective over R. Writing $Q_{\mathrm{loc}} = \operatorname{coker} D$, the augmentation $C \to Q_{\mathrm{loc}}[0]$ is a G-equivariant quasi-isomorphism. As an (R, K)-module,

$$Q_{\mathrm{loc}} \cong (R/(\alpha)) \otimes H_0 \;\oplus\; (R/(\beta)) \otimes H_+. \tag{18.13}$$

Its support is the disjoint union of the two divisors $z = q$ and $z = q^{-1}$. It is annihilated by h. The two support summands in (18.13) are G-stable.

For every commutative R-algebra S, the complex

$$C_S = [\, S \otimes_R E \xrightarrow{1 \otimes D} S \otimes_R E^{\mathrm{sw}} \,]$$

computes the derived coefficient extension $S \otimes^{\mathbf{L}}_R C$. As S-modules with K-action, its cohomology is

$$H^{-1}(C_S) = (\mathrm{ann}_S\, \alpha) \otimes_{\mathbb{C}} H_0 \oplus (\mathrm{ann}_S\, \beta) \otimes_{\mathbb{C}} H_+,$$
$$H^0(C_S) = (S/\alpha S) \otimes_{\mathbb{C}} H_0 \oplus (S/\beta S) \otimes_{\mathbb{C}} H_+.$$

There is no cohomology in other degrees. Here α, β, z denote their images in S.

Proof. The ring R is a domain. Every eigenvalue in (18.11) is nonzero, so multiplication is injective on each free summand. The direct sum remains injective. Since z is a unit, the image on $R \otimes H_n$ is $\beta(R \otimes H_n)$ for $n \geq 1$. This proves (18.13) and the quasi-isomorphism.

The identity

$$\alpha + q^{-1}\beta = 1 - q^{-2} \tag{18.14}$$

shows that the two defining ideals are comaximal. Both quotient summands are nonzero, so their supports are exactly the stated divisors. Scalar multiplication by $h = z^{-1}\alpha\beta$ kills them. The Chinese remainder idempotents of $R/(\alpha\beta)$ commute with G. Their images therefore give the G-stable support summands. This argument makes no claim that individual H_n are G-stable.

A bounded complex of free coefficient modules computes derived extension of scalars. Tensoring (18.11) with S gives the displayed complex. The factors z^{n-1} remain units. Computing kernels and cokernels of scalar multiplication on each direct summand gives the formulas. □

For a coefficient map $S \to T$, the maps $s \otimes f \mapsto \bar{s} \otimes f$ define a G-equivariant chain map $C_S \to C_T$. They compose strictly, and $T \otimes^{\mathbf{L}}_S C_S \simeq C_T$. These are the specialization maps of this family. In particular, evaluation at a point $x = (a_0, b_0) \in (\mathbb{C}^\times)^2$ gives

$$C_x = [\, I(\chi_{a_0}, \chi_{b_0}) \xrightarrow{D_x} I(\chi_{b_0}, \chi_{a_0}) \,].$$

This statement includes nonflat coefficient maps. The global equality $\ker D = 0$ does not imply $\ker D_x = 0$. The new kernel is $\mathrm{Tor}^R_1(\mathbb{C}_x, Q_{\mathrm{loc}})$. Distinct closed points have no specified specialization map between their fibers. The maps above arise from actual coefficient homomorphisms.

18.13 The representations on the exceptional divisors

The support decomposition permits a full G-equivariant description. Let $J = C^\infty(B\backslash G;\mathbb{C})$ be unnormalized induction of the trivial character, with right translation. Its constant functions form the trivial representation. Define the Steinberg representation here by the quotient

$$\mathrm{St} = J/\mathbb{C}\mathbf{1}.$$

Only this definition is needed below.

Its compact-picture coefficient space is V/H_0. For any invertible coefficient t, write $\chi_t(x) = t^{v_F(x)}$. Define free R-modules with smooth G-action by

$$L_\alpha = R \otimes (\chi_{q^{1/2}b} \circ \det), \qquad L_\beta = (R \otimes_{\mathbb{C}} \mathrm{St}) \otimes (\chi_{q^{1/2}a} \circ \det).$$

The first notation means a rank-one free module on which g acts by $(q^{1/2}b)^{v_F(\det g)}$. The second combines the indicated scalar with the usual action on St.

Theorem 18.13.1. There is an isomorphism of smooth R-linear G-representations

$$Q_{\mathrm{loc}} \cong L_\alpha/\alpha L_\alpha \oplus L_\beta/\beta L_\beta. \tag{18.15}$$

Consequently, in $\mathcal{D}_{\mathrm{sm}}(G,R)$,

$$C \simeq [\, L_\alpha \xrightarrow{\alpha} L_\alpha \,] \oplus [\, L_\beta \xrightarrow{\beta} L_\beta \,], \tag{18.16}$$

with both source terms in degree -1. The equivalence is specified by the augmentations of both sides to (18.15). It remains an equivalence after every derived coefficient extension.

Proof. On $\beta = 0$, the ordered parameters satisfy $b = qa$. The target induction has ordered pair $(b,a) = (qa,a)$. Put $\lambda = q^{1/2}a$. Its normalized induction factor is

$$|u/t|^{1/2}(qa)^{v_F(u)}a^{v_F(t)} = \lambda^{v_F(ut)}.$$

Thus $E^{\mathrm{sw}}|_{\beta=0}$ is J tensored with $\chi_\lambda \circ \det$. The image of D there is precisely the constants, since $\alpha|_{\beta=0} = 1 - q^{-2}$ is nonzero. Taking the quotient gives $L_\beta/\beta L_\beta$. This computation holds over the divisor ring $R/(\beta)$.

On $\alpha = 0$, the ordered pair is $(a,b) = (qb,b)$. The source $E|_{\alpha=0}$ is J tensored with $\chi_{q^{1/2}b} \circ \det$, by the same induction-law calculation. The target has ratio q^{-1}. The regular normalized intertwiner from this target to the source is P_0, by (18.10).

Its image is the constant line in the source, and its kernel is H_+. The map D from the source to the target has image H_+, since all its positive-level coefficients are units on this divisor. Therefore P_0 identifies the cokernel with $L_\alpha/\alpha L_\alpha$. Together with the G-stable support decomposition, this proves (18.15).

Multiplication by α on L_α and by β on L_β is injective. The two displayed complexes are free coefficient resolutions of the corresponding summands of Q_{loc}. Their augmentations and $C \to Q_{\mathrm{loc}}$ give the claimed equivalence. All terms of the two resolutions and of C are coefficient-flat. Hence these resolutions also compute every derived coefficient extension. □

PROPOSITION 18.13.2. At a complex point $x = (a_0, b_0)$, put $z_0 = a_0/b_0$. If $z_0 \notin \{q, q^{-1}\}$, then C_x is acyclic. At the two exceptional ratios, define

$$W_x = \begin{cases} \chi_{q^{1/2}b_0} \circ \det, & z_0 = q, \\ \mathrm{St} \otimes (\chi_{q^{1/2}a_0} \circ \det), & z_0 = q^{-1}. \end{cases}$$

Then $H^{-1}(C_x) \cong W_x \cong H^0(C_x)$ as smooth G-representations.

In the full category $\mathcal{D}_{\mathrm{sm}}(G, \mathbb{C})$,

$$C_x \simeq W_x[1] \oplus W_x.$$

In the compact picture, the kernel and cokernel spaces are H_0 at $z_0 = q$ and H_+ at $z_0 = q^{-1}$. The cokernel means the quotient of the target by the complementary image.

Proof. Outside the two divisors every coefficient of D_x is nonzero, so the map is invertible on V. At $z_0 = q$, the H_0 coefficient is zero and all positive-level coefficients are nonzero. At $z_0 = q^{-1}$ the reverse holds. This computes kernels and cokernels as K-spaces.

Applying coefficient extension to (18.16) identifies the full derived G-objects. On the vanishing divisor the relevant Koszul differential becomes zero. The other differential becomes an invertible scalar, so its complex is contractible. The surviving representation is exactly W_x. □

Remark 18.13.3 *(The central character).* The action on E, E^{sw}, C, and Q_{loc} satisfies

$$\pi(t\,\mathrm{id}) = (ab)^{v_F(t)}\,\mathrm{id} \qquad (t \in F^\times).$$

One may require this identity strictly on every object and complex. It defines a smaller abelian category of smooth representations and its derived category. The cone C, its augmentation to Q_{loc}, and its coefficient specializations belong to that category, with the coefficient character specialized when necessary.

The lifts L_α and L_β have central characters $(qb^2)^{v_F(t)}$ and $(qa^2)^{v_F(t)}$, respectively. These equal $(ab)^{v_F(t)}$ only after imposing their respective divisor equations. Thus (18.16) is an equivalence in the full category stated in Theorem 18.13.1. The universal lifts therefore do not prove a splitting inside the strict universal-central-character category.

At a fixed exceptional complex point, however, the same actual complex C_x does split in the strictly specialized category. The next construction supplies a projective resolution and the two quasi-isomorphisms that establish this assertion. Universal marked-family compatibility remains a separate question.

18.14 STRICT CENTRAL CHARACTER AT A COMPLEX POINT

At an exceptional unramified character ratio, the regular intertwining complex has two nonzero cohomology groups. A splitting must preserve the central character on every representation and every morphism. The lattice tree supplies a projective resolution inside that category and removes the degree-two obstruction.

Use the same local field and operator as above. More explicitly, let F be a finite extension of $\mathbb{Q}_p$. Write O for its ring of integers, ϖ for a uniformizer, and q for its residue cardinality. Normalize $v_F(\varpi) = 1$ and $|\varpi| = q^{-1}$.

Set $G = \mathrm{GL}_2(F)$, with center $Z = F^\times\,\mathrm{id}$. In this fixed-point splitting construction, representations are complex vector spaces with smooth group action: each vector has an open stabilizer. All tensor products are algebraic over $\mathbb{C}$.

Fix $a_0, b_0 \in \mathbb{C}^\times$ with $z_0 = a_0/b_0 \in \{q, q^{-1}\}$. Define $\chi_t(u) = t^{v_F(u)}$ for $t \in \mathbb{C}^\times$. Let $E_x = I(\chi_{a_0}, \chi_{b_0})$ be normalized induction from the upper triangular subgroup B. Thus its locally constant functions satisfy

$$f\left(\begin{pmatrix} u & v \\ 0 & t \end{pmatrix} g\right) = |u/t|^{1/2} \chi_{a_0}(u)\chi_{b_0}(t) f(g), \qquad (\pi(g)f)(h) = f(hg),$$

with the positive square root.

Write $E_x^{\mathrm{sw}} = I(\chi_{b_0}, \chi_{a_0})$. Both representations have central character

$$\zeta(t\,\mathrm{id}) = (a_0 b_0)^{v_F(t)}.$$

Let $\mathcal{A}_\zeta$ be the abelian category of smooth complex G-representations on which every t id acts exactly by this scalar. Its morphisms are G-equivariant linear maps.

Kernels and cokernels in smooth representations preserve the stated identity. Write $\mathcal{D}^b(\mathcal{A}_\zeta)$ for its bounded derived category. Use cochain complexes with differential of degree 1 and $P[1]^j = P^{j+1}$ with differential $-d_P$.

The regular intertwiner is the specialization of $D_z = (1 - q^{-1}z)R_z = (1 - z)M_z$, with additive measure $\mathrm{vol}(O) = 1$ in the raw intertwining integral M_z. The source and target are the ordered inducing pairs and their swaps. The established compact-picture formula is

$$D_z|_{H_0} = 1 - q^{-1}z, \qquad D_z|_{H_n} = z^{n-1}(z - q^{-1}) \quad (n \geq 1).$$

Here H_0 is the constant line on $\mathbb{P}^1(F)$.

For $n \geq 1$, H_n consists of functions on $\mathbb{P}^1(O/\varpi^n O)$ with zero average on every fiber of reduction to level $n - 1$. At level zero, reduction means global averaging. These spaces form the algebraic direct sum of all locally constant functions. The regular map $D_x : E_x \to E_x^{\mathrm{sw}}$ is a smooth G-intertwiner.

The complex under consideration is

$$C_x = [\, E_x \xrightarrow{D_x} E_x^{\mathrm{sw}} \,], \qquad C_x^{-1} = E_x, \quad C_x^0 = E_x^{\mathrm{sw}}. \tag{18.17}$$

Its kernel and cokernel are both isomorphic to

$$W_x = \begin{cases} \chi_{q^{1/2}b_0} \circ \det, & z_0 = q, \\ \mathrm{St} \otimes (\chi_{q^{1/2}a_0} \circ \det), & z_0 = q^{-1}, \end{cases} \tag{18.18}$$

where $\mathrm{St} = C^\infty(B\backslash G; \mathbb{C})/\mathbb{C}\mathbf{1}$ uses unnormalized induction of the trivial character. The operator and these kernel and quotient identifications are the input to the splitting problem. The following construction applies to every two-term complex in $\mathcal{A}_\zeta$.

Removing the fixed central character

Set

$$\lambda = \begin{cases} q^{1/2}b_0, & z_0 = q, \\ q^{1/2}a_0, & z_0 = q^{-1}. \end{cases} \qquad \eta = \chi_\lambda \circ \det.$$

In either case $\lambda^2 = a_0 b_0$. The character η is smooth, and its restriction to Z equals ζ. Let $H = G/Z = \mathrm{PGL}_2(F)$, with the quotient topology.

LEMMA 18.14.1. Twisting by η^{-1} and descending through $G \to H$ gives an exact equivalence

$$\mathcal{A}_\zeta \longrightarrow \mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(H).$$

Its inverse inflates an H-representation and twists by η. Under this equivalence, W_x becomes the trivial representation when $z_0 = q$ and the Steinberg quotient when $z_0 = q^{-1}$.

Proof. For $V \in \mathcal{A}_\zeta$, every central element acts trivially on $V \otimes \eta^{-1}$. Its action therefore factors uniquely through H. If a vector has open stabilizer U in G, the image of UZ is open in H and fixes that vector. Thus the descended action is smooth.

Conversely, inflation of a smooth H-action is smooth, and the twist gives central character ζ. The two constructions are inverse on objects and morphisms. Their underlying vector-space functors are exact. Formula (18.18) gives the final assertion. □

It remains to construct projective resolutions for smooth representations of H. The quotient by the full center is essential: the stabilizers of lattice classes in H are compact.

The lattice tree

An O-lattice in F^2 is the O-span of an F-basis. Vertices are homothety classes $[L]$ of such lattices. Two classes are adjacent if they have representatives satisfying

$$\varpi L \subset M \subset L, \qquad \dim_{O/\varpi O}(M/\varpi L) = 1.$$

This is a symmetric relation on classes. Indeed, the reverse inclusion can be represented by $\varpi M \subset \varpi L \subset M$. The group H acts on this graph by its action on lattice classes.

LEMMA 18.14.2. This graph is a tree. Each vertex has $q + 1$ neighbors.

Proof. The neighbors of $[L]$ are exactly the lines in $L/\varpi L$, so there are $q + 1$. Fix the root $[L_0]$, where $L_0 = Oe_1 \oplus Oe_2$. Each class has a unique representative $L \subset L_0$ with $L \not\subset \varpi L_0$. Multiplication by a unit does not change a lattice, which proves uniqueness. Choose a primitive vector $u \in L$ and complete it to a basis u, v of L_0.

The image of L in L_0/Ou is an ideal $\varpi^n O$. Subtracting an Ou component from a lift of its generator gives

$$L = Ou \oplus O\varpi^n v, \qquad n \geq 0.$$

The integer n is the valuation of the determinant of this normalized lattice relative to L_0. It is independent of the chosen basis and will be its height. Height zero gives the root.

For $n > 0$, the line generated by $\varpi^n v$ in $L/\varpi L$ gives the neighboring lattice $O\varpi u \oplus O\varpi^n v$. After normalization, its height is $n - 1$. Every other line is generated by $u + c\varpi^n v$ for one residue $c \in O/\varpi O$. Its neighboring lattice is

$$O(u + c\varpi^n v) \oplus O\varpi^{n+1} v,$$

which is normalized and has height $n + 1$.

Every neighbor of the root has height one. Thus every positive-height vertex has exactly one neighbor of lower height. Repeated lower-height steps connect it to the root. A cycle would have a maximal-height vertex with two neighbors of lower height, which is impossible. □

An element of H can exchange the endpoints of an edge. Insert a midpoint in each edge to obtain the barycentric subdivision T. Orient each new edge from its lattice vertex to its midpoint. The H-action preserves these two vertex types and therefore preserves the chosen orientations.

Let $v_0 = [L_0]$ and $v_1 = [\mathcal{O}e_1 \oplus \mathcal{O}\varpi e_2]$. Let m_0 be the midpoint between them. The stabilizer K of v_0 is the image of $\mathrm{GL}_2(\mathcal{O})$ in H. It is compact and open.

The stabilizer I of the incidence (v_0, m_0) fixes both v_0 and v_1. In K, it is the inverse image of the stabilizer of a line modulo ϖ, hence compact and open. The class of

$$s = \begin{pmatrix} 0 & 1 \\ \varpi & 0 \end{pmatrix}$$

exchanges v_0 and v_1 and satisfies $s^2 = 1$ in H. The midpoint stabilizer is $J = I \sqcup sI$ and is compact and open.

The action is transitive on lattice vertices, on midpoints, and on the oriented edges of T. The first assertion follows by sending one lattice basis to another. Transitivity on incident pairs follows because K acts transitively on lines modulo ϖ.

Example 18.14.3 *(The first ball when $q = 2$).* The first ball about v_0 is a star with three leaves v_1, v_2, v_3. Write m_i for the midpoint of $v_0 v_i$. The subdivision has seven vertices and six oriented edges $e_i = (v_0, m_i)$ and $f_i = (v_i, m_i)$, for $1 \le i \le 3$. Its boundary map and augmentation are

$$\partial e_i = [m_i] - [v_0], \qquad \partial f_i = [m_i] - [v_i], \qquad \epsilon[v] = 1.$$

Define a linear map h from vertices to edge chains by

$$h[v_0] = 0, \qquad h[m_i] = e_i, \qquad h[v_i] = e_i - f_i.$$

Then

$$\partial h = \mathrm{id} - [v_0]\epsilon, \qquad h\partial = \mathrm{id}\,.$$

Both identities follow by applying the displayed formulas to each basis vector. Thus ∂ has rank six and its image is $\ker \epsilon$. This finite ball is not H-stable. The same finite-path calculation proves exactness for arbitrary finite chains in the entire tree.

Projective cellular chains

For a compact open subgroup $U \subset H$, let $\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$ denote its smooth complex representations. An object is projective if every morphism from it to a quotient lifts through the quotient map. The following property depends on the coefficient field $\mathbb{C}$.

Lemma 18.14.4. Every smooth complex representation of U is projective in $\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$.

Proof. The orbit of any vector under U is finite because its stabilizer is open and U is compact. The orbit spans a finite-dimensional U-submodule. A basis of this submodule has a common open stabilizer. Its normal core is an open normal subgroup, so the action factors through a finite quotient of U.

For an invariant subspace, average a linear projection over the finite quotient to obtain an equivariant projection. Its kernel is an invariant complement. Induction on dimension therefore decomposes this submodule into irreducibles. Hence every smooth U-module is a sum of finite-dimensional irreducible submodules.

Choose a maximal direct sum of such submodules. If it does not contain the whole module, a finite-dimensional submodule contributes a simple summand outside it. That simple summand has zero intersection with the maximal direct sum, a contradiction. Thus the whole module is a direct sum of finite-dimensional irreducibles.

Each such irreducible τ is projective. To verify the lifting property explicitly, let $Y \twoheadrightarrow Z$ be an epimorphism and let $f : \tau \to Z$ be U-equivariant. Choose lifts in Y of the images of a basis of τ and extend them to a linear map $\ell : \tau \to Y$. The U-orbits of these finitely many lifts span a finite-dimensional submodule Y_0.

Choose an open normal subgroup $N \subset U$ acting trivially on both Y_0 and τ. Then

$$\widetilde{f}(v) = \frac{1}{|U/N|} \sum_{u \in U/N} u\, \ell(u^{-1}v)$$

is well-defined, U-equivariant, and lifts f. Only finite-dimensional smooth data are averaged. Finally, morphisms out of a direct sum can be lifted on its summands and then assembled. A direct sum of projectives is therefore projective. □

For $M \in \mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$, define compact induction $\mathrm{c\text{-}Ind}_U^H M$ by finite sums of symbols $[g, m]$, linear in m, with relations

$$[gu, m] = [g, um] \qquad (g \in H,\ u \in U).$$

The group acts by $h[g, m] = [hg, m]$. This is the algebraic finite-support model on H/U, valid because U is open. It is smooth: the stabilizer of $[g, m]$ contains $gU_m g^{-1}$, where U_m is an open stabilizer of m in U. A finite sum has the intersection of finitely many such open stabilizers.

The map determined by $[g, m] \mapsto gf(m)$ gives the adjunction

$$\mathrm{Hom}_H(\mathrm{c\text{-}Ind}_U^H M, V) \cong \mathrm{Hom}_U(M, V|_U).$$

Its inverse restricts a morphism to the symbols $[1, m]$. Restriction is exact, so compact induction takes projectives to projectives. Lemma 18.14.4 applies to every compact open cell stabilizer of T.

For a discrete set Y, write $C_c(Y; \mathbb{C})$ for its finitely supported functions, with basis vectors denoted $[y]$. Let T_0 and T_1 be the vertices and the chosen oriented edges of T. For a smooth H-representation V, define

$$P_1(V) = C_c(T_1; \mathbb{C}) \otimes V, \qquad P_0(V) = C_c(T_0; \mathbb{C}) \otimes V,$$

with diagonal action $g([c] \otimes v) = [gc] \otimes gv$. For an oriented edge $e = (u, m)$, define

$$\partial([e] \otimes v) = ([m] - [u]) \otimes v, \qquad \epsilon([u] \otimes v) = v.$$

Both maps commute with H, and $\epsilon\partial = 0$.

THEOREM 18.14.5. For every smooth complex H-representation V, the sequence

$$0 \longrightarrow P_1(V) \xrightarrow{\partial} P_0(V) \xrightarrow{\epsilon} V \longrightarrow 0 \tag{18.19}$$

is exact and its first two terms are projective smooth H-representations. Consequently,

$$\mathrm{Ext}^j_{\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(H)}(V, U) = 0 \qquad (j \geq 2)$$

for all smooth V, U.

Proof. Fix a root vertex o of T. Let p_v be the finite edge chain along the unique path from o to v. Its coefficient is -1 wherever the path opposes the chosen edge orientation. Then $\partial p_v = [v] - [o]$.

The map $[v] \otimes w \mapsto p_v \otimes w$ gives $\partial h = \mathrm{id} - ([o] \otimes -)\epsilon$. Thus every chain of augmentation zero is a boundary. The augmentation is surjective because $w = \epsilon([o] \otimes w)$. A nonzero finite-support edge cycle would have a leaf in the finite subtree spanned by its support.

At that leaf, its boundary equals the nonzero coefficient of its unique incident supported edge, up to sign. This is impossible, so ∂ is injective. These arguments also apply to vector coefficients and use only finite sums. The root-path contraction proves exactness and is not claimed equivariant.

For a chosen cell c with stabilizer U, the map

$$\text{c-}\operatorname{Ind}_U^H(V|_U) \longrightarrow C_c(Hc;\mathbb{C}) \otimes V, \qquad [g,v] \longmapsto [gc] \otimes gv$$

is an equivariant isomorphism. The relation $[gu, v] = [g, uv]$ verifies that it is well-defined. Its inverse sends $[gc] \otimes w$ to $[g, g^{-1}w]$ and is independent of the representative g. The three cell orbits therefore give

$$P_1(V) \cong \text{c-}\operatorname{Ind}_I^H(V|_I), \qquad P_0(V) \cong \text{c-}\operatorname{Ind}_K^H(V|_K) \oplus \text{c-}\operatorname{Ind}_J^H(V|_J).$$

They are smooth projectives by Lemma 18.14.4 and the compact-induction adjunction. Applying $\operatorname{Hom}(-, U)$ to this projective resolution computes Ext and leaves no terms in degrees $j \geq 2$. □

The constant-coefficient resolution above needs no finite generation or admissibility hypothesis. Its projective terms can have infinite multiplicity. Schneider–Stuhler develop cellular resolutions with coefficient systems of compact-subgroup invariants in *Representation theory and sheaves on the Bruhat–Tits building*. See Section II.2, pp. 121–122, and Theorem II.3.1, p. 123. Here the rank-one tree and constant coefficients give the stated resolution directly.

The obstruction and the splitting maps

Lemma 18.14.1 transports the resolution and projectivity into $\mathcal{A}_\zeta$. For $V \in \mathcal{A}_\zeta$, apply (18.19) to its descended twist $V \otimes \eta^{-1}$, then inflate and tensor every term and map with η. This gives a projective resolution

$$0 \longrightarrow P_1^\zeta(V) \xrightarrow{d} P_0^\zeta(V) \xrightarrow{\epsilon} V \longrightarrow 0$$

inside $\mathcal{A}_\zeta$. In particular, $\operatorname{Ext}^j_{\mathcal{A}_\zeta}(V, U) = 0$ for all $j \geq 2$. Every central element acts by ζ on both projective terms.

Theorem 18.14.6. Let $A \xrightarrow{D} B$ be a morphism in $\mathcal{A}_\zeta$. Place A in degree -1 and B in degree 0, and set $U = \ker D, V = \operatorname{coker} D$. There is an isomorphism

$$[\, A \xrightarrow{D} B \,] \simeq U[1] \oplus V \qquad \text{in } \mathcal{D}^b(\mathcal{A}_\zeta).$$

It can be represented by two explicit quasi-isomorphisms through the cellular projective resolution of V.

Proof. Write $P_1 \xrightarrow{d} P_0 \xrightarrow{\epsilon} V$ for the resolution just constructed. Let $p : B \twoheadrightarrow V$ and $i : U \hookrightarrow A$ be the quotient and kernel maps. Since P_0 is projective, choose a morphism $f_0 : P_0 \to B$ with $pf_0 = \epsilon$. The identity $pf_0 d = \epsilon d = 0$ shows that $f_0 d$ takes values in $\operatorname{im} D$.

Projectivity of P_1 lifts that map through the epimorphism $A \twoheadrightarrow \operatorname{im} D$. Thus there is $f_1 : P_1 \to A$ satisfying

$$Df_1 = f_0 d. \tag{18.20}$$

All objects, quotient maps, and lifts lie in $\mathcal{A}_\zeta$.

Let $P = [\,P_1 \xrightarrow{d} P_0\,]$, in degrees -1, 0. Equation (18.20) defines a chain map

$$\Phi : U[1] \oplus P \longrightarrow [\,A \xrightarrow{D} B\,], \qquad \Phi^{-1}(u, v) = i(u) + f_1(v), \quad \Phi^0 = f_0.$$

The superscripts denote cochain degrees. Since d is injective, $H^{-1}(U[1] \oplus P) = U$ and $H^0(U[1] \oplus P) = V$. The map Φ induces the identity on these groups, using $pf_0 = \epsilon$.

It is therefore a quasi-isomorphism. The augmentation of P gives another quasi-isomorphism

$$\Psi : U[1] \oplus P \longrightarrow U[1] \oplus V, \qquad \Psi^{-1}(u, v) = u, \quad \Psi^0 = \epsilon.$$

The roof

$$[\,A \xrightarrow{D} B\,] \xleftarrow{\Phi} U[1] \oplus P \xrightarrow{\Psi} U[1] \oplus V$$

proves the asserted derived isomorphism. The compact averaging construction in Lemma 18.14.4, followed by compact induction, constructs the required lifts after choices of irreducible summands and linear lifts. No averaging over the noncompact group is used. □

The associated obstruction is the class of the exact two-extension

$$0 \longrightarrow U \xrightarrow{i} A \xrightarrow{D} B \xrightarrow{p} V \longrightarrow 0$$

in $\mathrm{Ext}^2_{\mathcal{A}_\zeta}(V, U)$. Equivalently, it is the connecting morphism $V \to U[2]$ in the cohomological truncation triangle. Theorem 18.14.5 makes this group zero, and the roof above realizes the splitting by actual maps. The construction proves existence and depends on the choices of lifts. No canonical splitting or compatibility between different parameters is asserted.

PROPOSITION 18.14.7 *(The exceptional fibers).* For the exceptional pair fixed in (18.17), there is an isomorphism

$$C_x \simeq W_x[1] \oplus W_x \qquad \text{in } \mathcal{D}^b(\mathcal{A}_\zeta).$$

Its degree-two obstruction vanishes in the strictly fixed-central-character category.

Proof. The kernel and cokernel identifications (18.18) are morphisms inside $\mathcal{A}_\zeta$. Apply Theorem 18.14.6 to the actual map D_x. The resulting roof uses the projective resolution twisted by the stated η, so every term has central character ζ. □

This is a pointwise statement over $\mathbb{C}$. The compact projectivity proof uses division by finite group orders and does not establish a theorem over arbitrary coefficient rings. The character η is fixed at the chosen complex point. Universal-central-character splitting over the ordered-character ring requires a separate construction. So do canonical Weyl-compatible pointwise splittings and a comparison with global Eisenstein categories.

18.15 NORMAL EQUATIONS AND SPECIALIZATION MAPS

The opposite operator provides a direct comparison of these two cohomology groups. Put $T = R/(h)$. Equation (18.12) gives a well-defined map

$$\overline{D^{\mathrm{sw}}} : \mathrm{coker}(D_T) \longrightarrow \ker(D_T), \qquad [y] \longmapsto D_T^{\mathrm{sw}} y.$$

It is an isomorphism of smooth T-linear G-representations.

To prove this, decompose T by the two comaximal ideals. On $\alpha = 0$, its surviving coefficient is $\beta/z = 1 - q^{-2}$ on H_0. On $\beta = 0$, its surviving coefficients are $z^{-n}\alpha$ on H_n, $n \geq 1$. All are units in the corresponding divisor ring. The same isomorphism holds after further coefficient extension from T.

There is also a comparison determined by a chosen equation of one divisor. For $t = \alpha$ or $t = \beta$, let $\overline{R} = R/(t)$. For $x \in \ker D_{\overline{R}}$, choose a lift $\widetilde{x} \in E$. The vector $D\widetilde{x}$ is divisible by t in the free module E^{sw}.

Define

$$\delta_t : \ker D_{\overline{R}} \longrightarrow \operatorname{coker} D_{\overline{R}}, \qquad x \longmapsto [\, D\widetilde{x}/t \,].$$

Changing the lift by tu changes the quotient by Du, so the map is well-defined. Equivariance follows by applying $D\pi(g) = \pi^{\mathrm{sw}}(g)D$ to the chosen lift. This is the connecting map for the coefficient sequence $0 \to R/(t) \xrightarrow{t} R/(t^2) \to R/(t) \to 0$ applied to C. It also identifies the kernel calculated from the free resolution of Q_{loc} with its t-torsion using the resolution $[R \xrightarrow{t} R]$ of $R/(t)$.

The map δ_α has coefficient 1 on H_0. The map δ_β has coefficient z^{n-1} on H_n, $n \geq 1$, evaluated on $\beta = 0$. Thus both are isomorphisms. They are compatible with subsequent extension along the respective divisor.

They satisfy

$$\delta_t \overline{D^{\mathrm{sw}}} = (h/t)|_{t=0}\ \mathrm{id}, \qquad (h/\alpha)|_{\alpha=0} = 1 - q^{-2}, \quad (h/\beta)|_{\beta=0} = q(1 - q^{-2}).$$

Replacing the local equation t by ut, with u a unit, multiplies δ_t by u^{-1} on the divisor. The normal equation is therefore part of this specialization comparison.

18.16 Finite levels and matrix factorizations

The finite spaces V_N retain the integral's compact-level refinement. Set $E_N = R \otimes V_N$ and $E_N^{\mathrm{sw}} = R \otimes V_N$, with their respective induced compact actions. Restriction gives $D_N : E_N \to E_N^{\mathrm{sw}}$ and $D_N^{\mathrm{sw}} : E_N^{\mathrm{sw}} \to E_N$. Inclusions $V_N \hookrightarrow V_{N+1}$ and averaging maps $P_N : V_{N+1} \to V_N$ commute with both operators because they preserve each H_n.

They therefore induce maps of the cones and of their coefficient extensions. The inclusions give

$$C = \operatorname*{colim}_N C_N, \qquad C_N = [E_N \xrightarrow{D_N} E_N^{\mathrm{sw}}].$$

Filtered colimits of modules are exact, so kernels, cokernels, and the displayed coefficient extensions commute with this colimit.

For $N \geq 1$, let $K_N = 1 + \varpi^N M_2(\mathcal{O})$, and set $K_0 = K$. Then $E^{K_N} = E_N$ and $(E^{\mathrm{sw}})^{K_N} = E_N^{\mathrm{sw}}$. Compact averaging is defined over every $\mathbb{C}$-algebra and is exact on smooth representations. Indeed, any finite set of vectors is fixed by an open subgroup, and averaging reduces to a finite sum with invertible denominator.

It follows that $C_N = C^{K_N}$ and $\operatorname{coker} D_N = Q_{\mathrm{loc}}^{K_N}$. Full G-translation can move E_N into a larger E_M. The finite complexes carry K-actions, whereas their colimit carries the full G-action.

A finite-free matrix factorization of $h \in R$ consists of finite-free modules M_0, M_1 and maps $d_0 : M_0 \to M_1$, $d_1 : M_1 \to M_0$ satisfying $d_1 d_0 = h\,\mathrm{id}$ and $d_0 d_1 = h\,\mathrm{id}$. Thus (D_N, D_N^{sw}) is a finite-free K-equivariant matrix factorization of h. Its rank is $\dim V_N$ in each parity. The full pair (D, D^{sw}) has infinite-rank free terms.

PROPOSITION 18.16.1. Each finite-level matrix factorization (D_N, D_N^{sw}) is contractible through K-equivariant maps. Its cokernel is a projective $R/(h)$-module. The ordinary two-term cone C_N is nevertheless nonzero in the derived category for every $N \geq 0$.

Proof. Put $c = 1 - q^{-2}$. Write $d_0 = D_N$, $d_1 = D_N^{\mathrm{sw}}$. A contraction consists of maps $s_0 : M_0 \to M_1$ and $s_1 : M_1 \to M_0$ with $ds + sd = \mathrm{id}$ on the two-parity module. On H_0 take

$$s_1 = c^{-1}, \qquad s_0 = q^{-1} z / c.$$

Then $s_1 d_0 + d_1 s_0 = (\alpha + q^{-1}\beta)/c = 1$. On H_n, $n \geq 1$, take

$$s_1 = q^{-1} z^{-(n-1)} / c, \qquad s_0 = z^n / c.$$

Here $s_1 d_0 + d_1 s_0 = (q^{-1}\beta + \alpha)/c = 1$ as well. All coefficients commute, so the identity also holds on the other parity. These are Laurent coefficients and preserve the K-stable decomposition.

The ring $R/(h)$ is $R/(\alpha) \times R/(\beta)$ by (18.14). The cokernel is free of rank one on the first component and rank $\dim V_N - 1$ on the second. It is therefore projective over their product. As an R-module it is nonzero, since the first component is nonzero. This cokernel is $H^0(C_N)$, which proves the last assertion. □

The contraction above is asserted only for the coefficient modules with K-action. Its diagonal formulas do not establish a contraction commuting with the full G-action. A matrix factorization uses both opposite maps and satisfies $d^2 = h$. The ordinary cone uses only D and has the nonzero cohomology (18.13). These are distinct homological constructions.

The regular intertwiner therefore defines a smooth equivariant degeneration complex on the entire ordered-character torus. Its cohomology consists of a character family on one divisor and a Steinberg quotient family on the other. Its derived fibers and their specialization comparisons are given above. A category comparison for global Eisenstein representations still requires a global target and a functor whose derived mapping objects and essential image are determined. The local degeneration complex supplies no such equivalence by itself.

18.17 Local Yoneda classes and finite exterior products

A local nonsplit principal series defines a degree-one extension between its Steinberg quotient and its constant subrepresentation. At two distinct finite places, the exterior product of these extensions has degree two. An infinite restricted tensor introduces a second condition: its distinguished local vectors must be fixed by the prescribed compact subgroups at almost every place. These two requirements distinguish a finite exterior product of Steinberg representations from an adelic extension of principal series.

The local sequence and its invariant vectors

Fix the coefficient field $\mathbb{C}$. For a finite prime p, put $G_p = GL_2(\mathbb{Q}_p)$, $K_p = GL_2(\mathbb{Z}_p)$, and let B_p be the upper triangular Borel subgroup. Give these groups their usual p-adic topologies. Write $X_p = B_p \backslash G_p \simeq \mathbb{P}^1(\mathbb{Q}_p)$, with its compact quotient topology and right G_p-action. The identification sends a matrix to the line spanned by its bottom row.

Let

$$E_p = C^{\mathrm{lc}}(X_p, \mathbb{C}), \qquad (\rho_p(g)f)(x) = f(xg).$$

Here C^{lc} means locally constant functions, without an analytic completion. This is unnormalized smooth induction of the trivial character of B_p. With normalized induction and $|p|_p = p^{-1}$, its ordered inducing characters are $|\cdot|_p^{-1/2}$ and $|\cdot|_p^{1/2}$. Thus, if symmetric induction is written with characters $(|\cdot|_p^{s/2}, |\cdot|_p^{-s/2})$, this sequence occurs at $s = -1$.

The constants give the exact sequence

$$0 \longrightarrow \mathbb{C} \xrightarrow{i_p} E_p \longrightarrow \mathrm{St}_p \longrightarrow 0, \qquad \mathrm{St}_p = E_p/\mathbb{C}\mathbf{1}_p. \tag{18.21}$$

This is the usual rank-one Steinberg quotient. See Casselman, *Introduction to the Theory of Admissible Representations of p-Adic Reductive Groups*, Section 8.1, p. 70. Every term has trivial central character.

We use $\mathrm{Rep}_{\mathbb{C}}^{\mathrm{sm}}(G_p)$ for the abelian category of all smooth complex representations. Its full subcategory on which the center acts trivially is identified with $\mathrm{Rep}_{\mathbb{C}}^{\mathrm{sm}}(PGL_2(\mathbb{Q}_p))$. Extension groups below specify which of these categories is used.

Lemma 18.17.1. The sequence (18.21) is nonsplit. Moreover,

$$\mathrm{Hom}_{G_p}(E_p, \mathbb{C}) = 0, \qquad \mathrm{Hom}_{G_p}(\mathrm{St}_p, \mathbb{C}) = 0, \qquad \mathrm{St}_p^{K_p} = 0.$$

The same statements hold after passage to $PGL_2(\mathbb{Q}_p)$.

Proof. Consider a G_p-invariant linear functional $\ell : E_p \to \mathbb{C}$. Projective p-adic balls are translates of one another under G_p. Affine transformations relate the balls in $\mathbb{Q}_p$. Inversion relates them to the balls containing infinity. A ball is a disjoint union of p smaller balls.

Consequently the common value c of ℓ on ball indicators satisfies $c = pc$, so $c = 0$. Locally constant functions on X_p are finite linear combinations of these indicators, since X_p is compact and the balls form a clopen basis. Hence $\ell = 0$. A splitting of (18.21) would provide such a functional with $\ell(\mathbf{1}_p) = 1$. A morphism $\mathrm{St}_p \to \mathbb{C}$ would pull back to a morphism $E_p \to \mathbb{C}$, proving the first two assertions.

Every line in $\mathbb{Q}_p^2$ has a primitive integral representative that extends to an integral basis. Thus K_p acts transitively on X_p and $E_p^{K_p} = \mathbb{C}\mathbf{1}_p$. Invariants under a compact open subgroup are exact for smooth complex representations. Indeed, normalized Haar averaging of a smooth vector is a finite sum, and averaging a lift of an invariant vector gives an invariant lift.

Applying invariants to (18.21) gives $\mathrm{St}_p^{K_p} = 0$. This averaging argument is also Casselman, Proposition 2.1.7, p. 20. All actions factor through $PGL_2(\mathbb{Q}_p)$, and the same proof applies there. □

Write α_p for the Yoneda class of (18.21). It is a specified nonzero element of $\mathrm{Ext}^1(\mathrm{St}_p, \mathbb{C})$. No residue operator is needed to define it, and no dimension assertion about that group is required below.

Two finite places and the exterior degree

Let $p \neq q$ be finite primes. External tensor products over $\mathbb{C}$ are written $\boxtimes$ and carry the separate actions of the two groups. Tensoring the two local sequences gives the exact sequence

$$\begin{aligned} 0 \longrightarrow \mathbb{C} \boxtimes \mathbb{C} \xrightarrow{d_2} (E_p \boxtimes \mathbb{C}) \oplus (\mathbb{C} \boxtimes E_q) \xrightarrow{d_1} E_p \boxtimes E_q \\ \longrightarrow \mathrm{St}_p \boxtimes \mathrm{St}_q \longrightarrow 0, \end{aligned} \tag{18.22}$$

where

$$d_2 = (i_p \boxtimes 1, -1 \boxtimes i_q), \qquad d_1(x, y) = (1 \boxtimes i_q)x + (i_p \boxtimes 1)y.$$

Unlike the cochain indexing of the local cone, the following totals use homological degrees and differentials of degree -1.

These signs are the tensor differential for homological complexes, $\partial(x \otimes y) = \partial x \otimes y + (-1)^{\deg x} x \otimes \partial y$. In particular $d_1 d_2 = 0$. The two complexes $[\mathbb{C} \to E_p]$ and $[\mathbb{C} \to E_q]$, in homological degrees $1, 0$, have homology only in degree zero, with values St_p and St_q. Tensoring over a field preserves this assertion. It proves the exactness of (18.22).

The sequence (18.22) is a Yoneda two-extension, not a short exact sequence with these endpoints. Its class is the exterior Yoneda product of α_p and α_q, with the displayed tensor sign convention. The following argument proves that this class is nonzero without replacing either local representation by a finite-dimensional model.

PROPOSITION 18.17.2. Let S be a nonempty finite set of finite primes, $n = |S|$, and $\mathrm{St}_S = \boxtimes_{p \in S} \mathrm{St}_p$. Put $G_S = \prod_{p \in S} G_p$. In $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(G_S)$ one has

$$\mathrm{Ext}^r_{G_S}(\mathrm{St}_S, \mathbb{C}) = 0 \quad (0 \le r < n).$$

The exterior product of the classes α_p is nonzero in $\mathrm{Ext}^n_{G_S}(\mathrm{St}_S, \mathbb{C})$. It is represented by the total tensor of the n sequences (18.21). Both assertions also hold in the category where each local center acts trivially, namely $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(\prod_{p \in S} PGL_2(\mathbb{Q}_p))$.

Proof. For either of the groups G_p and $PGL_2(\mathbb{Q}_p)$, compact induction $\text{c-Ind}^G_K \mathbb{C}$ from a compact open subgroup is projective. A G-map from this compact induction to V is determined by the image of the indicator of K. That image can be any element of V^K. Thus its Hom functor is $V \mapsto V^K$, which is exact by averaging.

Every smooth vector is fixed by a compact open subgroup. Taking one such compact induction for each vector gives enough projectives. Resolutions can therefore use sums of these compact inductions.

Choose such a resolution $P_{p,\bullet} \to \mathrm{St}_p$, with homological indices at least zero. Products of compact open subgroups are compact open, and

$$\left(\text{c-Ind}^G_K \mathbb{C}\right) \boxtimes \left(\text{c-Ind}^H_L \mathbb{C}\right) \simeq \text{c-Ind}^{G \times H}_{K \times L} \mathbb{C}.$$

Both sides are finite-support functions on the product of the relevant discrete coset spaces. Hence the total external tensor of the chosen resolutions is a projective resolution of St_S.

Let $C_{p,\bullet} = (P_{p,\bullet})_{G_p}$ be its coinvariant complex (or use $PGL_2(\mathbb{Q}_p)$ in the fixed-central-character category). For any representation V, a map $V \to \mathbb{C}$ factors uniquely through V_G. It follows that

$$\mathrm{Ext}^r_G(\mathrm{St}_p, \mathbb{C}) \simeq \mathrm{Hom}_{\mathbb{C}}(H_r(C_{p,\bullet}), \mathbb{C}). \tag{18.23}$$

Here the algebraic dual is exact over the field $\mathbb{C}$.

No topological or continuous dual is used. Coinvariants of an external tensor for a product group are the tensor of the coinvariants. Consequently the same argument identifies the product-group Ext with the dual homology of $\bigotimes_{p \in S} C_{p,\bullet}$.

Lemma 18.17.1 and (18.23) imply $H_0(C_{p,\bullet}) = 0$. The Künneth formula for bounded-below complexes of vector spaces gives

$$H_r\left(\bigotimes_{p \in S} C_{p,\bullet}\right) \simeq \bigoplus_{\substack{(r_p) \in \mathbb{Z}^S_{\ge 0} \\ \sum_p r_p = r}} \bigotimes_{p \in S} H_{r_p}(C_{p,\bullet}).$$

For completeness, one can split each vector-space complex as its homology with zero differential plus a contractible complex. Tensoring these splittings proves the formula. For $r < n$, every summand has some $r_p = 0$ and is zero. This proves the vanishing assertion.

Each nonzero class α_p is a nonzero functional on $H_1(C_{p,\bullet})$. Choose a homology element on which it is nonzero. The product functional is nonzero on the tensor of these elements, which lies in degree n. It represents the exterior Yoneda class.

Lift the projective resolution's augmentation to E_p. Its degree-one boundary then factors through $\mathbb{C}$, giving a chain map to $[\mathbb{C} \to E_p]$. The resulting degree-one cocycle represents α_p. Tensoring these chain maps gives exactly the total extension and the product cocycle, with the tensor signs already specified. Thus the exterior class is nonzero.

This proof uses genuinely compact open subgroups even for GL_2. It does not treat compact-mod-center subgroups as compact, and it makes no assertion about vanishing above degree n in the unrestricted GL_2 category. □

18.18 The restricted tensor condition

Let

$$G_f = GL_2(\mathbb{A}_f) = \prod_p{}'(G_p, K_p).$$

Its restricted-product topology has neighborhoods of the identity that contain $\prod_{p\notin S} K_p$ for some finite S. A usual algebraic restricted tensor representation uses nonzero distinguished vectors $e_p \in V_p^{K_p}$ for all but finitely many p. Its vectors are finite linear combinations of tensors whose factors equal e_p almost everywhere. For $g = (g_p) \in G_f$, both $g_p \in K_p$ and the distinguished factor condition hold almost everywhere, making the coordinate action well-defined.

Proposition 18.18.1. The local representations St_p do not admit a nonzero restricted tensor representation with the standard hyperspecial pointings at almost every finite prime. More generally, suppose a smooth G_f-representation V has factorizations $V \simeq \mathrm{St}_p \otimes W_p$ for every finite p. If G_p acts only on the first factor, then $V = 0$.

Proof. The required pointing space is zero at every prime by Lemma 18.17.1. For the second assertion, a vector in a smooth G_f-representation is fixed by an open subgroup. That subgroup contains K_p for every p outside a finite set. But the stipulated factorization implies

$$V^{K_p} = \mathrm{St}_p^{K_p} \otimes W_p = 0.$$

This equality follows from averaging on the first tensor factor, or from writing any tensor as a finite sum with linearly independent second factors. Thus the vector is zero. □

Choosing Iwahori-fixed vectors at infinitely many places does not supply these hyperspecial pointings. The restricted product relative to those Iwahori subgroups is a different subgroup and topology. No passage to an unspecified completed tensor product is part of this construction.

For a finite set S, a genuine smooth adelic representation is

$$\mathrm{St}_S^{(f)} = \left(\boxtimes_{p\in S} \mathrm{St}_p\right) \boxtimes \left(\bigotimes_{p\notin S}{}' \mathbb{C}\right),$$

where each omitted place uses the trivial representation and vector 1. It is inflation from G_S under the continuous projection $G_f \to G_S$. The extension of Proposition 18.17.2 inflates with it and remains nonzero: restriction along the inclusion $G_S \hookrightarrow G_f$ is exact and recovers the original Yoneda class. This representation has Steinberg factors precisely at the specified finite set. It is not an all-place Steinberg representation.

18.19 An adelic principal-series extension

The local principal series E_p do have compatible distinguished vectors, namely the constant functions $\mathbf{1}_p$. These vectors are fixed by all of G_p. For finite S, write $E_S = \boxtimes_{p\in S} E_p$, inflated to G_f with trivial factors outside S. If $S \subset T$, define

$$E_S \longrightarrow E_T, \qquad x \longmapsto x \otimes \bigotimes_{p\in T\setminus S} \mathbf{1}_p.$$

The superscript res below means restricted tensor product. It does not name an automorphic residual spectrum. These maps are injective and G_f-equivariant. The canonical associativity and symmetry identifications make their composites agree for $S \subset T \subset U$.

Put $E^{\mathrm{res}} = \operatorname{colim}_S E_S$. Each vector lies in some E_S and is smooth at the finitely many primes of S. The full groups outside S fix it. Thus the colimit representation is smooth. Its central character is trivial.

PROPOSITION 18.19.1. Let $X = \prod_p \mathbb{P}^1(\mathbb{Q}_p)$ with its compact product topology. There is a G_f-equivariant isomorphism

$$E^{\mathrm{res}} \simeq C^{\mathrm{lc}}(X, \mathbb{C})$$

for the coordinatewise right action. The exact sequence

$$0 \longrightarrow \mathbb{C} \longrightarrow E^{\mathrm{res}} \longrightarrow Q_{\mathrm{ad}} \longrightarrow 0, \qquad Q_{\mathrm{ad}} = E^{\mathrm{res}}/\mathbb{C}, \tag{18.24}$$

is nonsplit in $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(G_f)$ and in its trivial-central-character category. Both E^{res} and Q_{ad} are admissible: their invariants under every compact open subgroup are finite-dimensional.

Proof. For finite S, products of functions identify E_S with $C^{\mathrm{lc}}(\prod_{p\in S} X_p, \mathbb{C})$. Surjectivity follows by covering clopen subsets of the compact finite product by finitely many clopen rectangles and refining this cover to a finite partition. Evaluations separate every finite-dimensional space of functions. For each space involved, choose a basis and finitely many evaluation points giving an injective matrix. The tensor of these matrices is injective, proving injectivity.

Every locally constant function on X has a finite cover by basic open cylinders on which it is constant. Such a finite cover exists by compactness. The union of the finite coordinate sets defining the cylinders is finite. Two points equal in these coordinates belong to the same cylinders and therefore have equal function values.

The function thus depends on only finitely many coordinates. This proves surjectivity from the colimit, and injectivity follows from the finite-stage statement. The insertion maps become pullback along coordinate projections. Each $g \in G_f$ acts by the coordinate homeomorphisms $x_p \mapsto x_p g_p$, so the isomorphism is equivariant. Smoothness also follows from the finite-coordinate description established above.

A compact open subgroup contains $U_S \times \prod_{p\notin S} K_p$ for some finite S. Here U_S is a product of local compact open subgroups at the places of S. Invariance under the tail K_p forces a finite-coordinate

function to be independent of those tail coordinates, because K_p is transitive on X_p. Its invariants therefore lie in $E_S^{U_S}$.

Each local compact open subgroup has open orbits on the compact space X_p, hence finitely many orbits. It follows that $E_S^{U_S}$ is finite-dimensional. This proves admissibility of E^{res}. Compact-open invariants are exact by the same finite averaging argument, so its quotient Q_{ad} is also admissible.

A splitting of (18.24) would give a G_f-invariant retraction $E^{\mathrm{res}} \to \mathbb{C}$. Its restriction to the embedded $E_{\{p\}}$ would be a G_p-invariant retraction of the constants, contradicting Lemma 18.17.1. The same argument applies when the full center acts trivially. □

The quotient Q_{ad} retains mixed finite-place terms. To describe them, set $F_{-1}E^{\mathrm{res}} = 0$ and, for $m \geq 0$, let $F_m E^{\mathrm{res}}$ be the sum of the images of E_T over finite sets T with $|T| \leq m$. This is an increasing, exhaustive filtration by G_f-subrepresentations, with $F_0 E^{\mathrm{res}} = \mathbb{C}$.

Proposition 18.19.2. For every $m \geq 0$ there is a canonical isomorphism

$$\mathrm{gr}_m^F E^{\mathrm{res}} \simeq \bigoplus_{\substack{T \text{ finite} \\ |T|=m}} \mathrm{St}_T^{(f)},$$

where the empty-set factor is $\mathbb{C}$. The induced exhaustive filtration $Q_{\mathrm{ad},m} = F_m E^{\mathrm{res}}/\mathbb{C}$ of Q_{ad} starts with $Q_{\mathrm{ad},0} = 0$ and has these same associated graded pieces for $m \geq 1$.

Proof. At a finite stage S, use the two-step filtration $\mathbb{C}\mathbf{1}_p \subset E_p$ in every tensor factor. Take a class in $\boxtimes_{p\in T} \mathrm{St}_p$, where $T \subset S$ has size m. Lift its factors to E_p and insert constants elsewhere. This defines a class in the mth associated graded.

Changing a lift adds a tensor from the preceding filtration term, so this map is canonical and equivariant. It is an isomorphism: choose arbitrary vector-space complements to the constants in each E_p and expand the finite tensor product. The summands with precisely m complement factors give the asserted graded piece. The complements prove bijectivity but do not define the map.

The canonical maps are compatible with the constant insertions as S grows. Taking the filtered colimit gives the displayed direct sum, since each vector involves only finitely many places. Quotienting by the constant subrepresentation gives the statement for Q_{ad}. □

In particular there is a nonsplit degree-one extension

$$0 \longrightarrow \mathbb{C} \longrightarrow F_1 E^{\mathrm{res}} \longrightarrow \bigoplus_p \mathrm{St}_{\{p\}}^{(f)} \longrightarrow 0.$$

Pulling it back to any single summand gives (18.21), inflated to G_f. This degree-one construction has a direct sum as its quotient. The full quotient Q_{ad} additionally contains every finite mixed tensor through its filtration. Neither quotient is the all-place tensor $\otimes'_p \mathrm{St}_p$.

Indeed, the local quotient maps $E_p \to \mathrm{St}_p$ send the distinguished constant vectors to zero. Using those zero vectors as insertions makes every finite tensor map zero after a new prime is added. The resulting colimit is zero. Thus the quotient maps cannot turn (18.24) into a nonzero all-place Steinberg extension.

18.20 ARCHIMEDEAN AND AUTOMORPHIC SCOPE

All preceding Ext groups belong to explicitly stated categories of smooth finite-adelic or finite-product representations. Tensoring with the trivial representation of $GL_2(\mathbb{R})$ gives a specified archimedean factor and an action of $GL_2(\mathbb{A})$, without adding another extension class. A nontrivial archimedean extension requires its own smooth topological representation category or Harish–Chandra module category, its central character, and its tensor conventions. An additional degree-one exterior factor contributes an additional degree when its exterior product is defined. It does not erase the finite-place degrees above.

A representation of $GL_2(\mathbb{A})$ is not thereby a realization on $GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})$. Such a realization requires a specified automorphic function space or enhanced category, central quotient and support conditions, and a comparison functor. The symbols $\mathrm{Ext}^1_{[GL_2]}$ alone do not specify that category. The constructions here give genuine local and adelic group representations and their Yoneda extensions. They neither identify a residue with an extension class nor supply an arithmetic or automorphic comparison.

18.21 GALOIS TOPOLOGY AND THE GEOMETRIC RECIPIENT

For a finite field $\mathbb{F}_q$, its absolute Galois group is procyclic, generated topologically by arithmetic Frobenius. For a nonarchimedean local field F, the corresponding exact sequence is

$$1 \longrightarrow I_F \longrightarrow G_F \longrightarrow G_{\mathbb{F}_q} \longrightarrow 1.$$

Its kernel is inertia. The tame quotient of inertia has its prime-to-residue-characteristic Tate twist, whereas wild inertia is a pro-p group. Neither is this Frobenius quotient.

Precomposition with a quotient $G \to Q$ embeds representations of Q among those representations of G on which the kernel acts trivially. It does not descend an arbitrary representation. Similarly, a representation of a product of groups has commuting component images, with continuity for the chosen topologies. Independently chosen local representations need not define such a product representation.

Unramified twists make the distinction visible without wild ramification. Two different unramified characters of W_F have the same trivial inertia restriction and different Frobenius eigenvalues. Thus inertia alone does not determine the full parameter. On a general test scheme, a mapping stack also retains torsors and their descent. A conjugacy set on field-valued points does not define that stack.

Finite cyclic and ordinary loops

Let k be algebraically closed of characteristic zero. For the finite cyclic group C_n,

$$\mathrm{Map}(BC_n, B\mathbb{G}_m) \simeq \coprod_{\zeta \in \mu_n} B\mathbb{G}_m.$$

Indeed, a character of C_n is determined by an nth root of unity. Its automorphism group is $\mathbb{G}_m$. This is distinct from ordinary derived loops

$$\mathcal{L}(B\mathbb{G}_m) = \mathrm{Map}(B\mathbb{Z}, B\mathbb{G}_m) \simeq \mathbb{G}_m \times B\mathbb{G}_m.$$

It is also distinct from an infinitesimal neighborhood of the identity diagonal.

If $n \mid m$, the quotient $C_m \to C_n$ induces

$$\mathrm{Map}(BC_n, X) \longrightarrow \mathrm{Map}(BC_m, X)$$

by precomposition. The arrows reverse those of the groups. A continuous homomorphism from $\widehat{\mathbb{Z}}$ to a discrete group has finite image, since a compact discrete subgroup is finite. A topology on the coefficient group can change that condition. The ambient prestack and topology must therefore be fixed before a profinite loop comparison.

Selmer deformation functors

Fix one finite residual field k, one coefficient ring $W(k)$, a residual representation, determinant convention and a finite ramification set. Let $\mathcal{F}_{\mathrm{glob}}$ and $\mathcal{F}_v$ be the continuous deformation functors on the same category of simplicial Artin coefficient rings. Give every local condition an actual map $\mathcal{L}_v \to \mathcal{F}_v$. Then the Selmer functor is

$$\mathcal{F}_{\mathrm{Sel}} = \mathcal{F}_{\mathrm{glob}} \times^{h}_{\prod_v \mathcal{F}_v} \prod_v \mathcal{L}_v.$$

Its construction and tangent fiber are proved in Theorem 10.7.1. A cochain quotient notation is available when compatible subcomplexes have actually been chosen. Local stacks over unrelated residue-characteristic bases cannot be inserted into this product without coefficient comparisons.

Framing retains cocycles. A determinant identification gives the fiber of the trace map on the full shifted cochain complexes. Fixed determinant value modulo arbitrary strict GL_2 conjugacy has the different gauge convention described above. Automorphisms and obstructions remain in their respective degrees. At coefficient characteristic two, real decomposition groups also require their specified archimedean or modified Tate condition.

Formal pullback notation proves neither representability nor a cotangent-amplitude bound. For example, the dual numbers over a characteristic-zero field have a two-term cotangent complex and a nonzero obstruction tangent at their closed point. Such an obstruction is allowed in a quasi-smooth derived scheme. Likewise, smoothness of X does not make its derived loop space classical: for $X = \mathbb{A}^1_k$,

$$\mathcal{O}(\mathcal{L}X) \simeq k[t] \otimes \Lambda(dt), \qquad |dt| = -1.$$

Cotangent comparisons on finite products use the pullbacks of each factor's cotangent complex over the common base. Changes of charts use the transitivity triangle. An inverse-limit formula or an ind-coherent refinement requires its own continuity theorem.

18.22 Restriction to two places

Unramified matrices describe a local deformation problem. Global restriction imposes further relations between places and can have several lifts over the same local pair. The following example retains absolute irreducibility of the residual representation and fixes its determinant.

Fix distinct finite primes p, q and a coefficient prime $p_0 \neq p, q$. Let k be a finite field of characteristic p_0, and put $W = W(k)$. Choose a finite set S of places of $\mathbb{Q}$ containing p, q, p_0, ∞. Write $G_{\mathbb{Q},S}$ for the Galois group of the maximal extension unramified outside S.

Fix a continuous representation $\bar{\rho} : G_{\mathbb{Q},S} \to GL_2(k)$ which is absolutely irreducible, and let $\bar{D}$ be its determinant polynomial law. Here a determinant of dimension two is a multiplicative homogeneous polynomial law of degree two on the group algebra, as in Definition 18.2.1. Its characteristic coefficients, rather than a trace alone, define the object in all residual characteristics.

Choose decomposition-group maps $G_{\mathbb{Q}_p}, G_{\mathbb{Q}_q} \to G_{\mathbb{Q},S}$. Choose closed local and global deformation conditions preserved by restriction. These may include a fixed determinant character lifting $\det \bar{\rho}$. Let A be a finite local W-algebra with residue field k. Write $\mathcal{D}_{\mathrm{glob}}(A)$ and $\mathcal{D}_v(A)$ for the corresponding continuous determinant lifts, where $v = p, q$. The local residual restrictions need not be absolutely irreducible.

Chenevier's representability theorem gives complete Noetherian local rings R^{Ch}, R^{Ch}_p, R^{Ch}_q for these functors. The precise hypotheses are those of Proposition 18.2.2. Its source is Chenevier, Proposition 3.3 and Example 3.4, p. 42, and Example 3.6 and Proposition 3.7, p. 43. Each closed condition must be

represented by the quotient used here. These are formal deformation rings over one coefficient ring W. An identification with functions on a local or global spectral stack is additional geometric data.

A pair of indistinguishable local restrictions

PROPOSITION 18.22.1 *(nonuniqueness with absolutely irreducible residual representation).* There are distinct continuous rank-two determinant deformations over $\mathbb{Z}/8\mathbb{Z}$ with the same absolutely irreducible reduction and fixed determinant character. Their restrictions at 3 and 5 coincide.

Proof. Let K be the splitting field of $X^3 - X - 1$ over $\mathbb{Q}$. The polynomial has no root modulo 2, hence is irreducible over $\mathbb{Q}$. Its discriminant is -23, so its Galois group is S_3. An integral standard representation of this group is generated by

$$A = \begin{pmatrix} 0 & -1 \\ 1 & -1 \end{pmatrix}, \qquad B = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Direct multiplication gives $A^3 = B^2 = 1$ and $BAB = A^{-1}$. Modulo 2, the two eigenlines of A over $\mathbb{F}_4$ are interchanged by B. Thus this residual representation is absolutely irreducible. Inflate the integral representation to $\rho : G_{\mathbb{Q}} \to GL_2(\mathbb{Z}_2)$.

Let χ be the quadratic character of $L = \mathbb{Q}(\sqrt{241})$. For $v = 3, 5$, the polynomial $X^2 - 241$ has the simple root 1 modulo v. A root u_r modulo v^r has a unique lift modulo v^{r+1} in its residue class. The correction $u_r + cv^r$ solves an equation with invertible coefficient $2u_r$ modulo v. Taking the limit gives a root in $\mathbb{Z}_v$.

Hence $\chi|_{G_{\mathbb{Q}_v}} = 1$ for both places. Set $\rho' = \chi\rho$. Then

$$\bar{\rho}' = \bar{\rho}, \qquad \det \rho' = \chi^2 \det \rho = \det \rho.$$

The restrictions of ρ and ρ' at 3 and 5 agree. Both are unramified outside $S = \{2, 3, 5, 23, 241, \infty\}$.

The unique quadratic subfield of K is $\mathbb{Q}(\sqrt{-23})$, which differs from L. Consequently $K \cap L = \mathbb{Q}$, and the composite extension has Galois group $S_3 \times C_2$. Choose g whose image is $(1, -1)$. Then

$$\det(T - \rho(g)) = T^2 - 2T + 1, \qquad \det(T - \rho'(g)) = T^2 + 2T + 1.$$

The traces are 2 and 6 modulo 8. Thus the two determinant laws modulo 8 lift the same residual law and are distinct. Their local restrictions and fixed determinant character agree, as asserted. □

The example lies in a single finite-ramification deformation problem. A more restrictive arithmetic condition could exclude one lift. Uniqueness on such a condition would require its own proof.

18.23 RESTRICTION, CLOSED IMAGE AND FIBERS

The local product functor is represented by

$$B_{p,q} = R_p^{\mathrm{Ch}} \widehat{\otimes}_W R_q^{\mathrm{Ch}} = \varprojlim_r (R_p^{\mathrm{Ch}}/\mathfrak{m}_p^r) \otimes_W (R_q^{\mathrm{Ch}}/\mathfrak{m}_q^r).$$

The completion is for the sum of the maximal ideals. Restriction is a natural transformation $\mathcal{D}_{\mathrm{glob}} \to \mathcal{D}_p \times \mathcal{D}_q$, so its map on representing rings has the opposite direction.

Proposition 18.23.1 *(the formal restriction diagram).* Restriction induces a continuous local W-algebra homomorphism

$$r^{\sharp}_{p,q} : B_{p,q} \longrightarrow R^{\mathrm{Ch}}, \qquad x \otimes y \longmapsto r^{\sharp}_{p}(x) r^{\sharp}_{q}(y). \tag{18.25}$$

For the map in Equation (18.25), put $J_{p,q} = \ker r^{\sharp}_{p,q}$ and $C_{p,q} = B_{p,q}/J_{p,q}$. Then

$$B_{p,q} \twoheadrightarrow C_{p,q} \hookrightarrow R^{\mathrm{Ch}}, \qquad \operatorname{Spf} R^{\mathrm{Ch}} \longrightarrow \operatorname{Spf} C_{p,q} \hookrightarrow \operatorname{Spf} B_{p,q}.$$

For a continuous local map $b : B_{p,q} \to A$, the fiber over the prescribed local pair is represented over A by $R^{\mathrm{Ch}} \widehat{\otimes}_{B_{p,q},b} A$.

Proof. Restricting the universal determinant gives maps $r^{\sharp}_{v} : R^{\mathrm{Ch}}_{v} \to R^{\mathrm{Ch}}$. Their images commute, and their W-actions agree. The completed tensor-product property gives $r^{\sharp}_{p,q}$ with the displayed formula. The kernel is closed. The quotient is complete and injects into R^{Ch}.

Since the rings are profinite, its image is closed. The formal-spectrum diagram reverses these maps. Let A' be a finite local A-algebra. A map from the completed base change to A' is a map $R^{\mathrm{Ch}} \to A'$ agreeing with the prescribed $B_{p,q}$-action through A. This proves the fiber assertion. □

Definition 18.23.2 *(the closed image of two-prime restriction).* The formal scheme $\operatorname{Spf} C_{p,q}$ is the closed image of restriction inside the local deformation product. A proposed two-prime Selmer algebra $R^{\mathrm{Ch}}_{p,q}$ requires a specified $B_{p,q}$-algebra structure and comparison $R^{\mathrm{Ch}}_{p,q} \to C_{p,q}$ before the two can be identified. The quotient $C_{p,q}$ itself imposes the kernel relations only.

Example 18.23.3 *(a flat closed-image map with a nonliftable point).* Let $B = k[[x]]$ and $R = k[[t]]$, with $x \mapsto t^2$. Every series in t is uniquely $f(t^2) + t\,g(t^2)$. Thus R is free of rank two over B, and the map is injective. Its kernel quotient is B itself.

Nevertheless, the local point $B \to k[\epsilon]/(\epsilon^2)$, $x \mapsto \epsilon$, has no lift to R. A local image of t is $a\epsilon$, whose square is zero. Flatness does not turn the closed image into the image functor on these Artinian points.

Example 18.23.4 *(an ordinary fiber with nontrivial derived structure).* For $B = k[[x]] \to R = k$, $x \mapsto 0$, the fiber over the residue point has ordinary coordinate ring k. The free resolution $[B \xrightarrow{x} B]$, in cohomological degrees -1, 0, gives

$$k \otimes^{\mathbb{L}}_{B} k \simeq k \oplus k[1], \qquad H^{-1}(k \otimes^{\mathbb{L}}_{B} k) = k.$$

Thus the derived fiber retains information lost by the ordinary fiber. The same calculation proves that this map is not flat.

Remark 18.23.5 *(the information retained by restriction).* The kernel quotient records equations satisfied by local pairs. The fibers record their global lifts. Proposition 18.22.1 shows that those lifts need not be unique, so $r^{\sharp}_{p,q}$ need not be surjective. In a derived deformation theory the fiber uses derived completed tensor product. None of these constructions identifies a Nygaard filtration or supplies a comparison with prismatic sheaves.

18.24 The pairwise pullback and its central actions

Definition 18.24.1 *(completed external product and pullback).* Let M_p, M_q be finite modules over the local deformation rings. Their completed external product is the finite $B_{p,q}$-module

$$M_{p,q} = \varprojlim_r (M_p/\mathfrak{m}_p^r M_p) \otimes_W (M_q/\mathfrak{m}_q^r M_q).$$

The module obtained by ordinary restriction pullback is

$$M_{p,q}^{\mathrm{res}} = R^{\mathrm{Ch}} \widehat{\otimes}_{B_{p,q}} M_{p,q} = \varprojlim_r \frac{R^{\mathrm{Ch}} \otimes_{B_{p,q}} M_{p,q}}{\mathfrak{m}_{\mathrm{glob}}^r (R^{\mathrm{Ch}} \otimes_{B_{p,q}} M_{p,q})}. \tag{18.26}$$

The algebraic base change is finite over R^{Ch} and therefore already complete. Equation (18.26) also specifies its topology.

PROPOSITION 18.24.2 *(the action on the formal pullback).* Let Z_p, Z_q be unital W-algebras acting R_p^{Ch}-linearly and R_q^{Ch}-linearly on M_p, M_q, respectively. Each acting endomorphism is continuous for the maximal-ideal topology. Then $M_{p,q}^{\mathrm{res}}$ has a canonical action of $Z_p \otimes_W Z_q$, given by

$$(z_p \otimes z_q)(a \otimes (m_p \otimes m_q)) = a \otimes (z_p m_p \otimes z_q m_q).$$

This action commutes with the R^{Ch}-action.

Proof. Finite presentations of M_p, M_q show that $M_{p,q}$ is finite over $B_{p,q}$. Base change gives a finite module over R^{Ch}. Local linearity makes the displayed action compatible with the balancing relations and with every quotient in the inverse limits. It therefore defines an action on the completed tensors.

The two local actions affect separate factors, so they commute. Multiplication on the first factor commutes with both. No topology on the abstract algebras Z_p, Z_q is needed. □

The associated coherent sheaf on $\mathrm{Spf}\, R^{\mathrm{Ch}}$ is the ordinary pullback of the completed external product. The derived construction replaces the external product and pullback by their derived completed versions. Its boundedness requires additional Tor conditions. The ordinary pullback is exact only on a domain where the required higher Tor groups vanish.

PROPOSITION 18.24.3 *(transport of ordinary central actions).* For a W-linear category $\mathcal{C}$, let $Z(\mathcal{C}) = \mathrm{End}(\mathrm{id}_{\mathcal{C}})$ be its ordinary center. A W-linear equivalence $F : \mathcal{C} \to \mathcal{D}$ induces an isomorphism

$$Z(\mathcal{C}) \xrightarrow{\sim} Z(\mathcal{D}). \tag{18.27}$$

For a fully faithful functor, this statement applies to its essential image. It does not identify the center of a larger target category.

Proof. Choose a quasi-inverse G and the unit and counit isomorphisms. A natural endomorphism z of $\mathrm{id}_{\mathcal{C}}$ defines an endomorphism of $\mathrm{id}_{\mathcal{D}}$ by conjugating FzG with the counit. Naturality gives a central action, and composition and addition are preserved. This defines the map in Equation (18.27). The construction with G is its inverse. Restricting a fully faithful functor to its essential image makes it an equivalence. □

Remark 18.24.4 *(local coefficients and Bernstein blocks).* For smooth representations of $GL_2(\mathbb{Q}_v)$ in characteristic zero with coefficient prime different from v, the Bernstein decomposition has the form

$$\mathrm{Rep}(GL_2(\mathbb{Q}_v)) = \prod_{\mathfrak{s}} \mathrm{Rep}_{\mathfrak{s}}(GL_2(\mathbb{Q}_v)). \tag{18.28}$$

For the blocks in Equation (18.28), the ordinary scalar comparison and its precise domain are proved in Proposition 116.2.2. Its image in the spectral categorical center is the scalar subalgebra of Proposition 116.2.5. Using a Bernstein center as Z_v in the formal pullback requires an action over the chosen coefficient ring and on the actual module M_v. A categorical comparison additionally needs a functor with specified essential image. A local (φ, Γ)-module at residue prime v is not identified here with a deformation over $W(k)$ of coefficient characteristic $p_0 \neq v$.

18.25 Equivariant isomorphisms on formal charts

The module $M^{\mathrm{res}}_{p,q}$ is constructed from local data. Let N be an independently specified global module. The pairwise comparison asks for an isomorphism from the former to the latter which intertwines their central actions. Equal determinant laws alone do not solve this problem.

Example 18.25.1 *(extension data invisible to determinant laws).* Let $R = k[[t]]$ and $M = N = R^2$. Give them actions of $R[z]$ by

$$z|_M = 0, \qquad z|_N = J = \begin{pmatrix} 0 & t \\ 0 & 0 \end{pmatrix}.$$

For every polynomial f, one has $f(J) = f(0)1 + f'(0)J$, so both actions have characteristic polynomial $(X - f(0))^2$ for $f(z)$. The determinant polynomial laws agree after every coefficient extension.

The actions also coincide modulo t. An invertible intertwiner U would satisfy $JU = 0$, contradicting $J \neq 0$. These are reducible algebra representations. They exhibit the loss of extension data for coherent objects. They do not contradict reconstruction of a representation from an absolutely irreducible residual determinant.

Proposition 18.25.2 *(the scheme of equivariant isomorphisms).* Let $(R, \mathfrak{m}, k)$ be a complete Noetherian local ring. Let M, N be free R-modules of rank n with actions of an R-algebra generated by $a_1, \dots, a_s$. Choose bases and let $P_i, Q_i \in \mathrm{Mat}_n(R)$ denote the action matrices on M, N. The functor of equivariant isomorphisms is represented by

$$\mathrm{Isom}(M, N) = \mathrm{Spec}\, \frac{R[u_{ab}, d]}{(d \det(U) - 1,\ (Q_i U - U P_i)_{ab} : i, a, b)}. \tag{18.29}$$

Here $U = (u_{ab})$, with $1 \leq a, b \leq n$ and $1 \leq i \leq s$.

Proof. Over any commutative R-algebra A, a matrix U is invertible exactly when its determinant is a unit. The variable d specifies the unique inverse of that determinant. Intertwining the generators is equivalent to intertwining the whole algebra. Thus maps from the coordinate ring in Equation (18.29) to A are exactly the equivariant isomorphisms $M \otimes_R A \to N \otimes_R A$, naturally in A. □

Proposition 18.25.3 *(successive lifting obstructions).* In the preceding situation, put $I_r = \mathfrak{m}^r/\mathfrak{m}^{r+1}$ for $r \geq 1$. Let U_r be an invertible intertwiner modulo $\mathfrak{m}^r$. Choose a lift $\widetilde{U}$ modulo $\mathfrak{m}^{r+1}$ and set

$$E_i = Q_i \widetilde{U} - \widetilde{U} P_i \in \mathrm{Mat}_n(I_r).$$

Write bars for reduction modulo $\mathfrak{m}$, and define

$$L_r : \mathrm{Mat}_n(I_r) \longrightarrow \mathrm{Mat}_n(I_r)^s, \qquad V \longmapsto (\overline{Q}_i V - V \overline{P}_i)_i.$$

The class $[(E_i)_i] \in \operatorname{coker} L_r$ is independent of the lift. It vanishes precisely when this U_r extends to an invertible intertwiner modulo $\mathfrak{m}^{r+1}$. A compatible sequence of such lifts determines an equivariant isomorphism over R.

Proof. Changing $\widetilde{U}$ by $V \in \mathrm{Mat}_n(I_r)$ changes the defects by $L_r(V)$, since $\mathfrak{m} I_r = 0$. Thus the class is independent of the lift and vanishes exactly when a correction solves every intertwining equation. The determinant of a corrected lift remains invertible modulo the maximal ideal, hence is a unit. Completeness gives the matrix limit of a compatible sequence. The intertwining equations pass to the limit, and its determinant is a unit because its residue is. Conversely an equivariant isomorphism over R gives such a compatible sequence by reduction. □

The obstruction depends on the specified partial lift U_r. Vanishing for a compatible sequence, rather than separate choices at unrelated orders, constructs the limit. For general coherent complexes the comparison uses a derived equivariant Hom complex. The finite free criterion does not assert that the intended arithmetic sheaves satisfy its hypotheses.

18.26 Global actions and geometric comparison

PROPOSITION 18.26.1 *(the action generated by local centers).* Let E be a commutative ring and Z_v commutative unital E-algebras. For finite sets S of places put $A_S = \bigotimes_{v \in S, E} Z_v$, with transition maps inserting units. Set

$$A = \varinjlim_{S \text{ finite}} A_S. \tag{18.30}$$

Pairwise commuting unital actions $\alpha_v : Z_v \to \mathrm{End}_E(M)$ on an E-module induce a unique action

$$\alpha : A \to \mathrm{End}_E(M), \qquad \alpha(\otimes_{v \in S} z_v) = \prod_{v \in S} \alpha_v(z_v).$$

Its image is $A/\ker \alpha$. Natural actions on an E-linear category instead give a map to its ordinary center.

Proof. The product of the commuting actions is multiplicative and E-multilinear on each finite product. The tensor-product property gives an action of A_S. Inserting a unit changes no endomorphism, so these maps are compatible. The colimit in Equation (18.30) therefore gives α. The quotient assertion is the first isomorphism theorem. Products of natural endomorphisms are natural, which proves the categorical assertion. □

PROPOSITION 18.26.2 *(faithfulness and generation for a global scalar center).* Suppose the preceding actions define $\alpha : A \to Z(C)$ on an E-linear category. Then

$$A/\ker \alpha \xrightarrow{\sim} \operatorname{im} \alpha \subseteq Z(C). \tag{18.31}$$

This image is the entire ordinary center exactly when every central endomorphism is generated by the finite local actions. The map from A itself is an isomorphism exactly when it is also faithful. No identification with R^{Ch} is implicit in this statement.

Proof. The quotient isomorphism in Equation (18.31) follows from the preceding proposition. Surjectivity means precisely that every central endomorphism belongs to this image. Injectivity means $\ker \alpha = 0$. Together these are exactly the isomorphism conditions. □

Remark 18.26.3 *(first-order fixed-determinant deformations).* Let $V = k^2$ with action $\bar\rho$, and let $\operatorname{ad}\bar\rho = \operatorname{End}_k(V)$ with conjugation action. A lift over $k[\epsilon]/(\epsilon^2)$ has the form $(1+\epsilon c(g))\bar\rho(g)$. Multiplicativity is the continuous cocycle equation for c. The fixed-determinant condition is $\operatorname{tr} c(g) = 0$.

Strict change of basis changes c by the coboundary of an element of $\operatorname{ad}\bar\rho$. Thus the tangent space before additional local conditions is

$$\frac{Z^1_{\mathrm{cts}}(G_{\mathbb{Q},S}, \operatorname{ad}^0\bar\rho)}{d\ \operatorname{ad}\bar\rho}.$$

The denominator consists of traceless cocycles. When 2 is invertible, scalar subtraction identifies it with $d\ \operatorname{ad}^0\bar\rho$, giving the usual $H^1_{\mathrm{cts}}(G_{\mathbb{Q},S}, \operatorname{ad}^0\bar\rho)$.

At characteristic two this simplification needs justification. Additional deformation conditions restrict this tangent problem. A tangent-space comparison does not identify the complete rings.

18.27 Frobenius coefficients and global reconstruction

Unramified characteristic polynomials provide scalar functions on a Galois deformation space. The full collection determines the complete local ring with its deformation topology. A finite generating subset exists, but its choice depends on the deformation problem.

Let K be a number field, let k be a finite field of characteristic p_0, and put $W = W(k)$. Fix a finite set S containing the infinite places and all places above p_0. Write $G = G_{K,S}$ for the Galois group of the maximal extension of K unramified outside S. Fix a continuous absolutely irreducible representation $\bar\rho : G \to \mathrm{GL}_2(k)$ and a continuous character $\delta : G \to W^\times$ lifting $\det\bar\rho$.

For a finite local W-algebra A with residue field k, a deformation is a continuous lift $\rho : G \to \mathrm{GL}_2(A)$ with determinant δ_A. Two lifts are strictly equivalent if they are conjugate by an element of $1 + M_2(\mathfrak{m}_A)$. Let $R = R^{\delta}_{\bar\rho,S}$ be the complete Noetherian local W-algebra representing these deformation classes. Equivalently, R represents continuous rank-two determinant laws lifting $\det\bar\rho$ with determinant character δ.

The representability and comparison hypotheses are those of Proposition 18.2.2. In particular, Mazur's finiteness condition gives Noetherianity. Let ρ^u be a universal lift, let $T = \operatorname{tr}\rho^u$, and let $\mathfrak{m}$ be the maximal ideal of R. All topologies on R below are $\mathfrak{m}$-adic.

For a finite place $v \notin S$, use arithmetic Frobenius Frob_v, acting on residue fields by the $\#k(v)$-power map. Its conjugacy class in G is well defined. Put

$$t_v = T(\mathrm{Frob}_v), \qquad d_v = \delta(\mathrm{Frob}_v), \qquad P_v(X) = X^2 - t_vX + d_v.$$

These conventions involve no choice of a square root of $\#k(v)$.

The distinction between a representation and its determinant law is already visible over $\mathbb{F}_2[\epsilon]/(\epsilon^2)$. For the cyclic group $C_2 = \langle s\rangle$, the representations

$$\rho_0(s) = I_2, \qquad \rho_1(s) = (1+\epsilon)I_2$$

have the same trace and determinant on every element. Their determinant laws agree, since

$$\det\rho_1(a+bs) = (a+b(1+\epsilon))^2 = (a+b)^2 = \det\rho_0(a+bs)$$

after every commutative coefficient extension. They are not conjugate, since both images of s are scalar and they differ. Thus equality of determinant laws need not determine a representation when the residual representation is reducible.

A framing retains a chosen basis, so framed deformations are lifts without quotienting by strict conjugacy. Over $A = \mathbb{F}_2[\epsilon]/(\epsilon^2)$, consider the constant lift $\sigma_0 : \mathrm{GL}_2(\mathbb{F}_2) \to \mathrm{GL}_2(A)$ of the natural representation. Its reduction is absolutely irreducible: the matrices

$$U = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad V = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

have different unique invariant lines over $\overline{\mathbb{F}}_2$. Put $P = I_2 + \epsilon E_{12}$ and $\sigma_1 = P\sigma_0 P^{-1}$.

Since $\epsilon^2 = 0$ and the characteristic is 2,

$$PUP^{-1} = U, \qquad PVP^{-1} = V + \epsilon(E_{12}V - VE_{12}) = V + \epsilon I_2.$$

Both lifts have determinant 1. Conjugation preserves all traces and determinant laws, but the displayed images of V differ. These are the same unframed deformation and distinct framed deformations.

LEMMA 18.27.1 *(trace determination with absolutely irreducible reduction).* Let A be a commutative local ring with residue field k. Suppose $\rho_1, \rho_2 : G \to \mathrm{GL}_2(A)$ reduce to the same absolutely irreducible representation over k. If $\operatorname{tr}\rho_1(g) = \operatorname{tr}\rho_2(g)$ for every $g \in G$, then ρ_1 and ρ_2 are strictly equivalent. The assertion includes residue characteristic 2.

Proof. The k-linear span of the residual group matrices is $M_2(k)$. Here is a proof in dimension two. Extend scalars to an algebraic closure $\bar{k}$ and let E be the algebra spanned by the group image. Absolute irreducibility says that E acts irreducibly.

It contains a nonscalar matrix, and subtracting an eigenvalue produces a nonzero rank-one matrix $u\varphi$. Irreducibility gives $Eu = \bar{k}^2$ and $\varphi E = (\bar{k}^2)^*$ over the algebraic closure. Indeed, the annihilator of φE is invariant and cannot be the whole space. Thus the matrices $a(u\varphi)b$ span all endomorphisms. Descent of dimension gives the asserted span over k.

Choose $g_1, \dots, g_4 \in G$ whose residual matrices form a basis. For $a = 1, 2$, the matrices $A_{a,i} = \rho_a(g_i)$ form an A-basis of $M_2(A)$, since their coordinate determinant is a unit. The trace pairing is perfect over every commutative ring:

$$\operatorname{tr}(E_{ij}E_{rs}) = \delta_{jr}\delta_{is}.$$

Hence the common Gram matrix $Q_{ij} = \operatorname{tr}\rho_a(g_i g_j)$ is invertible.

The coordinates $c_i(g)$ of $\rho_a(g)$ in this basis satisfy

$$\sum_i c_i(g) Q_{ij} = \operatorname{tr}\rho_a(g g_j).$$

They are therefore independent of a. The A-linear map $\Phi(A_{1,i}) = A_{2,i}$ sends $\rho_1(g)$ to $\rho_2(g)$ for every g. Since products of basis matrices are group matrices, Φ is a unital algebra isomorphism. Its reduction is the identity.

Put $F_{ij} = \Phi(E_{ij})$, $v = F_{11}e_1$, and $w = F_{21}v$. The matrix $P = (v, w)$ is congruent to I_2 modulo $\mathfrak{m}_A$, so it is invertible. The matrix-unit relations give $F_{ij}P = PE_{ij}$. Consequently $\Phi(X) = PXP^{-1}$, which proves strict equivalence. No division by 2 occurs. □

For example, over $\mathbb{F}_2$ the matrices

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad U = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad V = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad UV$$

form a basis. Their trace Gram matrix is

$$\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix},$$

whose determinant is 1, although $\operatorname{tr}(I) = 0$.

Lemma 18.27.2 *(unramified coefficients determine continuous determinants).* Consider two continuous rank-two determinant laws over a complete separated local coefficient ring. They agree if and only if their characteristic polynomials agree at every $v \notin S$. For deformations of $\bar{\rho}$ with fixed determinant δ, equality of Frobenius traces suffices. Their representation classes then agree.

Proof. Chebotarev's theorem implies that the union of the conjugacy classes of Frob_v, for $v \notin S$, is dense in G. Indeed, every conjugacy class in every finite quotient of G occurs at infinitely many such places. The inverse image of any nonempty open subset of a finite quotient therefore meets this union. Trace and determinant are continuous conjugacy-invariant functions. Equality on Frobenius classes consequently implies equality on G.

The passage from group coefficients to polynomial laws is integral. For a rank-two determinant law D with trace T_D and determinant character d, its value after any commutative coefficient extension $A \to C$ is

$$D_C\left(\sum_{i=1}^{r} a_i g_i\right) = \sum_i a_i^2 d(g_i) + \sum_{i<j} a_i a_j d(g_j) T_D(g_i g_j^{-1}).$$

To derive the mixed coefficient, multiply $Ug_i + Vg_j$ on the right by g_j^{-1} and use multiplicativity. The characteristic polynomial of $g_i g_j^{-1}$ gives

$$D(Ug_i + Vg_j) = d(g_i)U^2 + d(g_j)T_D(g_i g_j^{-1})UV + d(g_j)V^2.$$

A homogeneous quadratic polynomial has only diagonal and mixed coefficients, so this determines the displayed formula for every finite sum. Thus equality of (T_D, d) implies equality of the laws. The previous lemma proves the assertion about representation classes. □

Theorem 18.27.3 *(global scalar reconstruction from Frobenius coefficients).* Define the polynomial parameter algebra

$$H^S = W[\mathsf{T}_v, \mathsf{D}_v, \mathsf{D}_v^{-1} : v \notin S]$$

and its fixed-determinant quotient

$$H^{S,\delta} = H^S/(\mathsf{D}_v - d_v : v \notin S) \simeq W[\mathsf{T}_v : v \notin S].$$

The map

$$\eta : H^{S,\delta} \longrightarrow R, \qquad \mathsf{T}_v \longmapsto t_v$$

has $\mathfrak{m}$-adically dense image.

Choose $a_v \in W$ lifting $\operatorname{tr} \bar{\rho}(\mathrm{Frob}_v)$, put $\mathfrak{n} = (p_0, \mathsf{T}_v - a_v : v \notin S)$, and define

$$\widehat{H}^{S,\delta} = \varprojlim_n H^{S,\delta}/\mathfrak{n}^n.$$

The induced continuous homomorphism $\widehat{\eta} : \widehat{H}^{S,\delta} \to R$ is surjective. It gives the topological quotient

$$R \simeq \widehat{H}^{S,\delta}/\ker \widehat{\eta}.$$

Moreover, finitely many places $v_1, \dots, v_d \notin S$ give a continuous surjection

$$W[[X_1, \dots, X_d]] \longrightarrow R, \qquad X_i \longmapsto t_{v_i} - a_{v_i}.$$

The same density conclusion holds after any quotient imposing a closed deformation condition.

Proof. Let B be the closure of $W[t_v : v \notin S]$ in R. It is a closed subring. Chebotarev and continuity show that $T(g) \in B$ for every $g \in G$. The ring B is profinite, with finite quotients $B_n = B/(B \cap \mathfrak{m}^n)$.

It is local with residue field k. Indeed, if $b \in B$ has nonzero residue, choose a unit $u \in W$ with the same residue. Writing $b = u(1 - x)$ with $x \in B \cap \mathfrak{m}$, the convergent series $u^{-1} \sum_{j \geq 0} x^j$ belongs to B and inverts b.

The quadratic formula in the previous proof defines the universal determinant law over B, because all its coefficients belong to B. Its multiplicativity follows as a polynomial identity: the identities hold after the injection $B[\mathbf{X}] \hookrightarrow R[\mathbf{X}]$, and hence already hold over B. This also proves the identities after arbitrary coefficient extensions, without a flatness assumption. Its coefficient functions are continuous for the subspace topology on B, and its determinant character is δ.

The representing property gives compatible maps $f_n : R \to B_n$. Their inverse limit is a continuous map $f : R \to B$. If $i : B \hookrightarrow R$ is the inclusion, then $i \circ f$ induces the universal determinant over each $R/\mathfrak{m}^n$. Uniqueness in the representing property gives $i \circ f = \mathrm{id}_R$. Therefore $B = R$. This argument uses finite local quotients of B and does not assume that B is Noetherian before proving the equality.

Density implies that the classes of $t_v - a_v$ span $\mathfrak{m}/(\mathfrak{m}^2 + p_0 R)$ over k. In detail, approximate any element of $\mathfrak{m}$ modulo $\mathfrak{m}^2 + p_0 R$ by a polynomial in the t_v. Substituting $t_v = a_v + (t_v - a_v)$ leaves only its linear part in this quotient. Noetherianity makes this vector space finite dimensional, so choose finitely many places whose classes form a basis.

Nakayama's lemma gives $\mathfrak{m} = (p_0, t_{v_1} - a_{v_1}, \dots, t_{v_d} - a_{v_d})$. Completeness then gives the displayed power-series surjection: approximate an element successively modulo $\mathfrak{m}^n$, lifting its degree-n correction to $(p_0, X_1, \dots, X_d)^n$. The resulting corrections converge in the power-series ring.

The polynomial map η sends $\mathfrak{n}^n$ into $\mathfrak{m}^n$, so it extends to $\widehat{\eta}$. The preceding finite power-series map factors through $\widehat{H}^{S,\delta}$, proving surjectivity. If F_n is the kernel of the projection $\widehat{H}^{S,\delta} \to H^{S,\delta}/\mathfrak{n}^n$, then $\widehat{\eta}(F_n) = \mathfrak{m}^n$. The inclusion from left to right follows by construction.

The reverse inclusion follows from the finite power-series surjection on the nth powers of the maximal ideals. Thus the quotient topology is exactly the $\mathfrak{m}$-adic topology. Density passes to every quotient of R. □

Remark 18.27.4 *(topology and global relations).* If $A_0 = \eta(H^{S,\delta})$, its completion for the induced filtration $A_0 \cap \mathfrak{m}^n$ is canonically R:

$$\varprojlim_n A_0/(A_0 \cap \mathfrak{m}^n) \simeq R.$$

The kernel of $\widehat{\eta}$ records the global deformation relations. The theorem does not identify it with the closure of the kernel of η. Such an identification requires a separate comparison of completion and quotient. The finite set of generating places depends on the deformation problem. An arbitrarily prescribed pair of places need not generate its ring.

Proposition 18.27.5 *(obstruction to a product of deformation components).* The fixed-residual ring R has no decomposition as a product of two nonzero unital rings. More generally it cannot be a unital restricted product containing the characteristic idempotents of two nonzero factors.

Proof. If $e^2 = e$ in a local ring, one of e and $1 - e$ is a unit. The equation $e(1 - e) = 0$ then gives $e = 1$ or $e = 0$. A product of two nonzero rings contains the nontrivial idempotent $(1, 0)$. The same obstruction applies whenever a restricted product contains these characteristic idempotents. □

The algebra $H^{S,\partial}$ consists of formal characteristic-polynomial parameters. An automorphic action requires a separate module or category and a homomorphism from these parameters to its endomorphisms. An identification of its completed action image with R additionally requires equality of the two kernels. The scalar reconstruction gives no such equality. It also supplies no local type decomposition, flatness assertion, prismatic filtration, untilt descent, or identification with a higher center.

Example 18.27.6 *(a split generic fiber of a local ring).* Put $R = \mathbb{Z}_2[[x]]/(x(x-2))$. It is local with residue field $\mathbb{F}_2$. The relation $x^m = 2^{m-1}x$ for $m \geq 1$ reduces every series uniquely to $a + bx$ with $a, b \in \mathbb{Z}_2$. The reductions converge 2-adically.

Uniqueness follows by evaluating at $x = 0$ and $x = 2$: $a = 0$ and $2b = 0$ imply $a = b = 0$. After inverting 2, these evaluations give

$$R[1/2] \xrightarrow{\sim} \mathbb{Q}_2 \times \mathbb{Q}_2, \qquad a + bx \longmapsto (a, a + 2b). \tag{18.32}$$

The inverse in Equation (18.32) sends (u, v) to $u + (v - u)x/2$. Integrally, the image consists of pairs in $\mathbb{Z}_2^2$ with $v - u \in 2\mathbb{Z}_2$, so $(1, 0)$ is not in the image. The generic-fiber splitting therefore does not split R.

This distinction is necessary before relating a Bernstein component to a formal deformation space. Such a comparison must specify whether it concerns the integral ring, its generic fiber, a quotient, or an action image. A correspondence of closed points establishes none of those ring identifications by itself.

Remark 18.27.7 *(coefficient variants).* The same proof applies over a complete discrete valuation ring $\mathcal{O}$ finite over W. Fix its finite residue field, residual representation and determinant character. Replace p_0 by a uniformizer of $\mathcal{O}$, and assume the corresponding complete Noetherian representing ring exists. For a deformation problem over k itself, omit the uniformizer from the residual ideal. These are statements about the indicated coefficient problems. A comparison between their representing rings requires its own base-change map and proof.

The density argument uses only the representing determinant functor. Absolute irreducibility is used to identify that functor with representation deformations and to obtain strict conjugacy from traces.

The polynomial-law identities are Chenevier, arXiv:0809.0415v2, Example 1.8 and Lemma 1.9, pp. 10–11. Definition–Proposition 2.18 and Theorem 2.22, pp. 32–34, give the Cayley–Hamilton and absolutely irreducible comparisons. Proposition 3.3 through Proposition 3.7, pp. 42–43, supply the deformation-ring assertions. The number-field density theorem is stated in Stevenhagen–Lenstra, *Chebotarev and his density theorem*, Appendix, p. 35. The finite set of generating places in the theorem is not a prescribed pair: the two-prime nonuniqueness example of Proposition 18.22.1 retains its different quantifiers.

The remaining global automorphic comparison

PROPOSITION 18.27.8 *(a specified action quotient and its comparison).* Use the coefficient ring and deformation problem of Theorem 18.27.3. Suppose an automorphic module or category has a complete separated commutative W-algebra A_{act} of scalar actions. Assume there is a continuous surjection

$$\theta : \widehat{H}^{S,\partial} \longrightarrow A_{\mathrm{act}}.$$

Give A_{act} the quotient topology for this map.

If $\ker\theta = \ker\widehat{\eta}$, there is a unique topological W-algebra isomorphism $A_{\mathrm{act}} \simeq R$ intertwining the maps from $\widehat{H}^{S,\partial}$. To identify this algebra with the full ordinary center of the global category, additionally require that its central action be faithful and exhaust that center. An identification of higher centers additionally requires a specified equivalence of their derived algebras, not only this degree-zero isomorphism.

Proof. Both algebras are topological quotients of the same algebra by the same ideal. The identity of the source descends to the claimed isomorphism, with inverse induced in the same way. It is a homeomorphism because both topologies are quotient topologies. Surjectivity of the source map proves uniqueness.

A faithful central action identifies an algebra with its image. Equality with the full center requires that image to be the whole center. The argument has made no assertion about higher cohomology or operations. □

The Frobenius theorem constructs $\widehat{\eta}$ and its scalar quotient. It does not construct θ or compare these kernels. The unframed Galois deformation problem is fixed at one residual representation. An automorphic spherical locus, local Bernstein types and their coefficient changes must be specified independently. Almost-everywhere sphericity does not provide the missing ring maps.

18.28 COHERENT GLUING AND ITS HYPOTHESES

A restriction diagram reconstructs objects only when it retains their overlap and extension maps. Closed and open restrictions already show the issue on the affine line. A formal neighborhood provides a positive coherent gluing theorem.

Closed and open restriction on the affine line

Let k be a field and put $A = k[t]$, $C = k[t, t^{-1}]$. Let $X = \operatorname{Spec} A$, $Z = V(t)$, and $U = D(t)$. Write $\mathrm{mod}_{\mathrm{fg}}(R)$ for the category of finitely generated left modules over a ring R. The intersection $Z \times_X U$ is empty, since its coordinate ring is $(A/(t))[t^{-1}] = 0$. Consequently a fiber product of categories over the category of this intersection is a product.

PROPOSITION 18.28.1. The restriction functor

$$\mathrm{mod}_{\mathrm{fg}}(A) \longrightarrow \mathrm{mod}_{\mathrm{fg}}(k) \times \mathrm{mod}_{\mathrm{fg}}(C), \qquad M \longmapsto (M/tM, M[t^{-1}]),$$

is not full. The corresponding derived restriction functor on perfect complexes is not full either.

Proof. The object A maps to (k, C). Its endomorphism homomorphism is

$$A \longrightarrow k \times C, \qquad f \longmapsto (f(0), f).$$

The endomorphism $(1, 0)$ does not belong to its image. The same calculation applies to degree-zero derived endomorphisms. □

The extension retained by localization

Let $D(A)$ be the stable k-linear ∞-category obtained by inverting quasi-isomorphisms of unbounded cochain complexes of A-modules. Cohomological shifts satisfy $H^n(M[1]) = H^{n+1}(M)$. Let $D_t(A)$ be its full subcategory of complexes whose cohomology modules are elementwise killed by powers of t. Extension of scalars $L = C \otimes^{\mathbf{L}}_A -$ is left adjoint to restriction of scalars $j_* : D(C) \to D(A)$.

Because C is a localization, it is flat and $C \otimes_A C = C$. Thus $Lj_* = \mathrm{id}$ and j_* is fully faithful. Define

$$\Gamma_t M = \mathrm{fib}(M \longrightarrow j_* LM).$$

Localization is exact, so $L\Gamma_t M = 0$.

Exactness of localization on modules identifies $\ker L$ with $D_t(A)$. If $K \in D_t(A)$, adjunction gives $\mathrm{Map}_{D(A)}(K, j_*N) = 0$ for every $N \in D(C)$. Applying mapping spaces to the defining fiber sequence therefore shows that Γ_t is right adjoint to $D_t(A) \hookrightarrow D(A)$.

Define a stable ∞-category $\mathcal{G}$ whose objects are

$$(K, N, \delta), \qquad K \in D_t(A), \quad N \in D(C), \quad \delta : j_*N \longrightarrow K[1].$$

Precisely, $\mathcal{G}$ is the pullback of $\mathrm{Fun}(\Delta^1, D(A)) \to D(A) \times D(A)$ along $(N, K) \mapsto (j_*N, K[1])$. Morphisms include the homotopies in the resulting commutative squares, rather than merely an equality in a homotopy category.

Proposition 18.28.2. There is an equivalence of stable ∞-categories

$$D(A) \simeq \mathcal{G}.$$

It sends M to $(\Gamma_t M, LM, \delta_M)$, where δ_M is the connecting morphism of the localization triangle. Its inverse sends (K, N, δ) to $\mathrm{fib}(\delta)$.

Proof. A triple defines the fiber sequence

$$K \longrightarrow \mathrm{fib}(\delta) \longrightarrow j_*N \xrightarrow{\delta} K[1].$$

Applying L identifies $L\,\mathrm{fib}(\delta)$ with N. Under this identification, the middle map is the unit of $L \dashv j_*$: by adjunction it corresponds to the identity of N. Its fiber is therefore $\Gamma_t\,\mathrm{fib}(\delta) = K$.

These identifications recover the connecting morphism δ. Conversely, the fiber of the connecting map in a localization triangle is its middle term. Fiber constructions are functorial in a stable ∞-category, so these identifications give mutually inverse functors, including their mapping spaces. □

For $M = A$, the complex $\Gamma_t A$ is represented by $[A \to C]$ in degrees 0, 1. Hence $\Gamma_t A \simeq (C/A)[-1]$, and the connecting map is

$$C \longrightarrow C/A.$$

Its fiber is A in degree zero. This nonzero quotient map is the extension datum that reconstructs A.

The two objects C and $\Gamma_t A$ are not perfect over A: their nonzero cohomology modules are not finitely generated. Thus this localization construction takes place in $D(A)$. It does not present perfect complexes as a product of perfect complexes on the two strata. Nor can the supported category be replaced by $D(k)$ under closed pushforward. Indeed, the resolution $0 \to A \xrightarrow{t} A \to k \to 0$ gives $\mathrm{Ext}^1_A(k, k) = k$, whereas $\mathrm{Ext}^1_k(k, k) = 0$.

Coherent gluing across a formal neighborhood

To retain coherent modules, replace the closed point by its formal neighborhood. Put

$$B = k[[t]], \qquad D = k((t)), \qquad C = k[t, t^{-1}].$$

The maps $A \to B$, $A \to C$, $B \to D$, and $C \to D$ are the inclusions. The overlap $\operatorname{Spec} D$ is the punctured formal disk.

It is not the empty intersection $Z \cap U$. The ring B is the coordinate ring of the t-adic formal disk. Here its coherent category means finitely generated B-modules, with their t-adic topology. Tensor products displayed below are ordinary algebraic tensor products unless explicitly derived.

Let $\mathcal{P}$ be the category of triples

$$(P, Q, \eta), \qquad P \in \operatorname{mod}_{\mathrm{fg}}(B), \quad Q \in \operatorname{mod}_{\mathrm{fg}}(C), \quad \eta : D \otimes_B P \xrightarrow{\sim} D \otimes_C Q.$$

Morphisms are compatible pairs of module homomorphisms.

THEOREM 18.28.3. The functor

$$\operatorname{mod}_{\mathrm{fg}}(A) \longrightarrow \mathcal{P}, \qquad M \longmapsto (B \otimes_A M, C \otimes_A M, \mathrm{can})$$

is an equivalence. Its inverse sends a triple to

$$\{(p, q) \in P \oplus Q : \eta(1 \otimes p) = 1 \otimes q\}.$$

Proof. Every Laurent series is the sum of a power series and a Laurent polynomial. Their intersection is $k[t]$. Consequently

$$0 \longrightarrow A \longrightarrow B \oplus C \xrightarrow{(b,c) \mapsto b - c} D \longrightarrow 0$$

is exact. The modules B, C, D are flat over A.

For C, D this follows from localization and torsion-freeness over the principal ideal domain A. A torsion-free module over a principal ideal domain is the filtered union of its finite free submodules. It is therefore flat, which also applies to B. Since D is flat, tensoring the displayed sequence with any A-module M remains exact.

In particular M is the indicated fiber product of its two scalar extensions. A compatible pair of homomorphisms on these extensions sends this fiber product into the corresponding fiber product for the target. The resulting A-linear homomorphism recovers the pair, since the elements $1 \otimes m$ generate both scalar extensions. This proves full faithfulness.

For essential surjectivity, use the structure theorem for finitely generated modules over the principal ideal domains B and C. A torsion summand $B/(t^m)$ descends from $A/(t^m)$, whose scalar extension to C vanishes. A torsion summand of Q has the form $C/(f)$, where $f \in k[t]$ and $f(0) \neq 0$. It descends from $A/(f)$, whose extension to B vanishes because f is a unit in B. Both kinds of torsion disappear over D. After splitting off these summands, P and Q are free of the same rank r.

Choose $Q = C^r$ and view P as a B-lattice $\Lambda \subset D^r$ through η. There is an integer $n \geq 0$ such that

$$t^n B^r \subset \Lambda \subset t^{-n} B^r.$$

Set $M = \Lambda \cap C^r$. Intersecting the bounds with C^r gives

$$t^n A^r \subset M \subset t^{-n} A^r.$$

Thus M is a finite free A-module of rank r, and $C \otimes_A M = C^r$. For $\lambda \in \Lambda$, truncate its Laurent expansion below degree n. The truncation q is a Laurent polynomial, and $\lambda - q \in t^n B^r \subset \Lambda$. Hence $q \in M$ and $\Lambda = M + t^n B^r$.

The map $B \otimes_A M \to \Lambda$ is therefore surjective. It is injective: an A-basis of M becomes a basis of C^r, so its determinant remains nonzero over the field D. This proves $B \otimes_A M = \Lambda$ with the specified overlap map. Adding the torsion summands proves essential surjectivity. Full faithfulness identifies the stated fiber-product construction with a quasi-inverse on all triples. □

For a k-linear category $\mathcal{C}$, write $Z(\mathcal{C}) = \mathrm{End}(\mathrm{id}_{\mathcal{C}})$ for its ordinary center, with multiplication given by composition.

Corollary 18.28.4. Under the preceding equivalence,

$$Z(\mathrm{mod}_{\mathrm{fg}}(A)) \simeq B \times_D C \simeq Z(\mathrm{mod}_{\mathrm{fg}}(B)) \times_{Z(\mathrm{mod}_{\mathrm{fg}}(D))} Z(\mathrm{mod}_{\mathrm{fg}}(C)).$$

The comparison maps on centers are the indicated inclusions of rings.

Proof. For every commutative ring R, a natural endomorphism z of $\mathrm{mod}_{\mathrm{fg}}(R)$ is multiplication by $a = z_R(1) \in R$. Indeed, for each $m \in M$, apply naturality to $R \to M$, $1 \mapsto m$. This yields $z_M(m) = am$. Thus the center is R, compatibly with scalar extension. The exact ring sequence above gives $A = B \times_D C$. □

Effective equivariant descent

Let X be a specified global parameter space in a fixed coefficient theory, and let $U_\bullet \to X$ be an augmented simplicial diagram. Fix the coherent or ind-coherent support subcategories being used. Suppose restriction is an equivalence

$$\mathcal{C}(X) \xrightarrow{\sim} \mathrm{Tot}\, \mathcal{C}(U_\bullet).$$

An object of the totalization includes the objects on the charts, their isomorphisms on overlaps and every higher compatibility.

Applying the inverse equivalence constructs its global object. Full faithfulness identifies the mapping spaces and gives uniqueness as a descent object. Coherence follows from this equivalence. It does not follow from an arbitrary filtered colimit of coherent objects in an ind-category.

For a derived pairwise construction there are two separate Tor conditions if ordinary tensors are to compute it. One condition makes the external product of the two local objects ordinary. The other makes its pullback to the global base ordinary. Perfectness of the local objects and flatness of the pullback do not imply the first condition. For $W = k[[t]]$, both local modules k are perfect over W, but

$$k \otimes^{\mathbb{L}}_W k \simeq k \oplus k[1].$$

An identity pullback is flat and retains this negative-degree term.

Suppose, in addition, a compatible family of algebra actions $A_S \to Z^\circ(\mathcal{C})$ is given for every finite set S of places. The ordinary center here consists of natural endomorphisms of the identity on the homotopy category. Their colimit $A = \mathrm{colim}_S A_S$ acts, because every element and relation comes from a finite stage. An equivalence which intertwines each action intertwines the assembled action by that same property.

For derived actions, the corresponding input consists of maps of the specified derived algebras and coherent comparisons. The identity

$$\mathrm{Map}(\operatorname*{colim}_S A_S, Z) \simeq \lim_S \mathrm{Map}(A_S, Z)$$

assembles these comparisons, including their homotopies. Equal degree-zero actions alone do not supply them. All finite sets enter this indexing system. The poset of pairs alone is not filtered.

Question 18.28.5. For the continuous Selmer deformation problem over one coefficient base, construct the geometric charts, overlap correspondences and effective equivariant descent above. Compare the local spectral objects with their arithmetic coefficient objects, preserving the full local parameters, the specified support and the global actions. If a prismatic refinement is required, construct its filtered objects and cross-prime maps on this same recipient.

The ordinary formal pullback modules and their central actions have already been constructed. This question asks for their geometric identification and descent. An actual Nygaard filtration on a local prism does not, by itself, provide cross-prime maps.

18.29 Centers, categorical traces and character classes

Fix a commutative coefficient ring k. Let C be a stable presentable k-linear monoidal category whose tensor preserves colimits in each variable. Its categorical center and trace are

$$Z_{\mathrm{cat}}(C) = \mathrm{Fun}^{\mathrm{L}}_{C\otimes C^{\mathrm{op}}}(C, C), \qquad \mathrm{Tr}_{\mathrm{cat}}(C) = C \otimes_{C\otimes C^{\mathrm{op}}} C.$$

Here tensors are in k-linear presentable categories, and the functors preserve colimits.

Both expressions are categories. The center is braided and the trace has a circle action. For an associative k-algebra A, the scalar Hochschild complexes instead have the forms

$$C^{\bullet}(A, A) = \mathrm{RHom}_{A\otimes^{\mathbb{L}} A^{\mathrm{op}}}(A, A), \qquad C_{\bullet}(A) = A \otimes^{\mathbb{L}}_{A\otimes^{\mathbb{L}} A^{\mathrm{op}}} A.$$

Their degree-zero center and trace are still different objects. An identity trace of a chosen perfect module is a class in HH_0, not the whole Hochschild complex.

For a perfect derived stack X, Ben-Zvi–Francis–Nadler, Theorem 1.7, prove

$$Z_{\mathrm{cat}}(\mathrm{QCoh}(X)) \simeq \mathrm{QCoh}(\mathcal{L}X) \simeq \mathrm{Tr}_{\mathrm{cat}}(\mathrm{QCoh}(X)).$$

Here perfect means that X has affine diagonal and $\mathrm{QCoh}(X) = \mathrm{Ind}\,\mathrm{Perf}(X)$. For $X = \mathrm{Spec}\,A$, scalar Hochschild chains of $\mathrm{Perf}(A)$ identify with functions on the derived self-intersection $X \times^{\mathbb{L}}_{X\times X} X$. This affine algebra calculation and the categorical theorem occur at different levels.

A commutative algebra can still have nontrivial Hochschild information: $HH_1(k[t]) = k[t]\,dt$. Nor does an E_1-algebra automatically have E_2 operations. These observations rule out deductions of arithmetic trace identities from spherical commutativity alone.

The finite Hecke character theorem

Let G be a complex reductive group, B a Borel subgroup, and N its unipotent radical. Put

$$\mathcal{H}_G = D(B\backslash G/B).$$

Its unipotently monodromic version $\widetilde{\mathcal{H}}_G$ is the full colimit-generated subcategory of $D(N\backslash G/N)$ generated by pullbacks from $\mathcal{H}_G$. Both use convolution.

The horocycle correspondence

$$G/\mathrm{Ad}\,G \xleftarrow{p} G/\mathrm{Ad}\,B \xrightarrow{\delta} B\backslash G/B$$

defines the Harish–Chandra transform $p_* \partial^!$. Let Ch_G be the full subcategory of $D(G/\mathrm{Ad}\, G)$ generated under colimits by its image. Ben-Zvi–Nadler, Theorem 1.8 of *The character theory of a complex group*, prove

$$Z_{\mathrm{cat}}(\mathcal{H}_G) \simeq \mathrm{Ch}_G \simeq \mathrm{Tr}_{\mathrm{cat}}(\mathcal{H}_G),$$

and the same for $\widetilde{\mathcal{H}}_G$. These Hecke categories are semi-rigid and have the specified pivotal and Calabi–Yau structures. Semi-rigid means compactly generated with dualizable compact generators. It does not require a compact unit.

A dualizable Hecke module has a character object in Ch_G. This is a positive categorical character construction. It is not an identification of $HH(D(G/\mathrm{Ad}\, G))$ with functions on an unspecified flat locus. An arithmetic identity trace requires its own source category, chosen object and comparison to the intended arithmetic recipient.

Continuity and arithmetic trace comparisons

There is an elementary continuity model on a small differential graded presentation. In an orthogonal union of small K-flat dg categories, every cyclic composable word stays in one block. The Hochschild complex is therefore the direct sum of the block complexes, compatibly with all faces, degeneracies and the Connes operator. Perfect completion retains finite block support. This proves the corresponding circle-equivariant trace formula on that carrier.

An infinite coordinatewise sum of nonzero unital algebras has no unit, and a categorical product is not that algebraic sum. A multiplicative trace comparison consequently needs its actual monoidal enhancement. For a filtered dg diagram, a Hochschild continuity statement likewise requires its compact or Morita presentation and the specified maps on cyclic bars. Neither a cofiltered limit of geometric spaces nor its functions is exchanged with an arithmetic completed trace by notation.

Question 18.29.1. Construct the arithmetic representation or Hecke category, its chosen object and identity trace, and an operation-preserving map to the specified geometric trace recipient. Compare the coefficient theory, completion, singular support and circle action. If a scalar evaluation is prescribed, prove that the map intertwines it on its stated domain.

18.30 Restricted tensors and local actions

A finite collection of local categories has a tensor product over a common coefficient category. Passing to all places requires maps which insert the omitted factors. These maps must preserve the operations being assembled.

Write $\mathcal{V} = \mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$ for the symmetric monoidal ∞-category of stable presentable categories and colimit-preserving functors. Its tensor represents functors preserving colimits separately in each input. Its unit is Sp, with sphere object $\mathbb{S}$. The same construction can be made in a specified linear version, whose tensor unit is the corresponding module category.

Fix a small coherent one-colored ∞-operad $\mathcal{O}$, for example E_n or E_∞. Let V be a set of places, and let $E \subset V$ be finite. For each v, give C_v an $\mathcal{O}$-algebra structure in $\mathcal{V}$. For $v \notin E$, supply a morphism

$$\eta_v : \mathrm{Sp} \longrightarrow C_v \quad \text{in } \mathrm{Alg}_{\mathcal{O}}(\mathcal{V}), \qquad u_v = \eta_v(\mathbb{S}).$$

The map includes every operation and its coherences. In the unital E_n cases it sends the unit to the unit, so $u_v \simeq \mathbb{1}_{C_v}$.

Let J_E be the filtered poset of finite subsets $S \subset V$ containing E. Define

$$C_S = \bigotimes_{v \in S} C_v, \qquad \iota_{S,S'} = \mathrm{id} \otimes \bigotimes_{v \in S' \setminus S} \eta_v.$$

For a chain $S \subset S' \subset S''$, both composites insert the same maps at the same places. Tensor coherence supplies their identification and all higher compatibilities. Thus these are a diagram of O-algebras.

THEOREM 18.30.1. The underlying restricted tensor

$$C'_V = \operatorname*{colim}_{S \in J_E} C_S \quad \text{in } \mathcal{V}$$

is the underlying object of the colimit in $\mathrm{Alg}_O(\mathcal{V})$. Every finite-stage map is an O-algebra map. Fixing the full diagram and its underlying colimit cocone, the space of lifts to this structured colimit cocone is contractible.

A canonical single-place map $C_v \to C'_V$ is supplied directly when $E \subset \{v\}$. In general, such a map additionally requires pointings $\mathrm{Sp} \to C_w$ for $w \in E \setminus \{v\}$. The theorem makes no full-faithfulness assertion about these maps.

Proof. Tensor product in $\mathcal{V}$ preserves colimits separately. For a filtered diagram and each finite arity, its diagonal indexing functor is cofinal. Hence tensor powers commute with its colimit. The forgetful functor from O-algebras therefore creates filtered colimits, by the operadic colimit theorem of *Higher Algebra*, §3.2.3. Apply it to the displayed diagram. The structure maps of its colimit are morphisms of O-algebras.

An initial object in a category of cocones has a contractible space of choices. A comparison between two structured colimit cocones has the underlying equivalence determined by their fixed colimit cocones. The forgetful functor detects equivalences. Thus the space asserted in the theorem concerns the entire coherent cocone, and is contractible.

If $E \subset \{v\}$, the singleton is an object of J_E. Otherwise the extra maps give

$$C_v \longrightarrow \bigotimes_{w \in E \cup \{v\}} C_w \longrightarrow C'_V.$$

The first arrow inserts the additionally supplied pointings. Its compatibility with larger finite sets follows from tensor coherence. It depends on these choices. □

The need for a unital map is already visible at one place. In $C = D(k) \times D(k)$, with componentwise tensor, the object $u = (k, 0)$ is a compact central idempotent algebra under the unit (k, k). The insertion $D(k) \to C$ with value u does not preserve that unit. One can instead use the monoidal subcategory with unit u, or a separately specified lax or nonunital theory. These change the recipient of the construction.

Nor is a unit insertion generally fully faithful. Extension of scalars $D(k) \to D(k[t])$ sends the unit to the unit, but its map on unit endomorphisms is $k \to k[t]$. Unitality and full faithfulness are different conditions.

Factorization, coefficient change and iteration

For a partition $V = V_1 \sqcup V_2$, finite subsets separate as pairs of finite subsets. Cofinality and separate colimit preservation give

$$C'_V \simeq C'_{V_1} \otimes C'_{V_2},$$

using $E \cap V_i$ in each factor. The same proof handles every finite partition, with its associativity and permutation coherences: all maps are induced by the corresponding finite tensor diagrams.

Suppose colimit-preserving $\mathcal{O}$-algebra maps $F_v : \mathcal{C}_v \to \mathcal{D}_v$ come with coherent identifications $F_v\eta_v \simeq \eta'_v$. Their finite tensor products commute with every insertion. Taking their colimit gives the induced map of restricted tensors. An enlargement of the exceptional finite set restricts to a cofinal subdiagram and leaves the colimit unchanged.

If $B : \mathcal{V} \to \mathcal{W}$ is a symmetric monoidal, colimit-preserving functor between the chosen coefficient categories, then

$$B(\mathcal{C}'_V) \simeq \operatorname*{colim}_{S \in J_E} \bigotimes_{v \in S} B(\mathcal{C}_v).$$

The comparison retains $B(\eta_v)$, including their nullary compatibilities. This is the coefficient-change map. The same argument commutes two filtered systems of finite subsets. It gives iterated restricted tensors whenever the stated pointings define both diagrams and the paired indexing systems are cofinal.

Dunn additivity identifies an E_{m+n}-structure with a compatible E_m-structure in E_n-algebras. When this full structure is supplied at each finite stage and on the insertion maps, the preceding colimit transports it. An E_m-structure by itself supplies no E_{m+n}-structure. A matrix algebra in degree zero is a simple test: an E_2-algebra has commutative degree-zero homology, whereas $\mathrm{Mat}_2(k)$ is noncommutative.

Module categories and compact objects

For E_∞-ring spectra R_v over a common E_∞-ring A, extension of scalars gives the pointings of Mod_A-linear module categories. The universal property of the module-category tensor gives

$$\bigotimes_{v \in S, \mathrm{Mod}_A} \mathrm{Mod}_{R_v} \simeq \mathrm{Mod}_{\otimes_{v \in S, A} R_v}.$$

Here the tensor on rings is the derived spectral tensor over A. The finite comparisons are natural under unit insertion. Module categories preserve this filtered algebra colimit, so

$$\bigotimes_{v \in V}' \mathrm{Mod}_{R_v} \simeq \mathrm{Mod}_{\operatorname{colim}_S \otimes_{v \in S, A} R_v}.$$

This formula does not replace a tensor of rings by their product, or an arithmetic completion by an uncompleted tensor.

For compact generation, suppose every $\mathcal{C}_S$ is compactly generated and each insertion preserves compact objects. Write $\mathcal{C}_S^c$ for its small idempotent-complete stable category of compacts. The colimit is then

$$\mathcal{C}'_V \simeq \mathrm{Ind}\left(\operatorname*{colim}_{S \in J_E} \mathcal{C}_S^c\right),$$

where the inner colimit is taken in small idempotent-complete stable categories. Indeed, Ind-completion identifies that category with compactly generated presentable stable categories and compact-preserving colimit functors.

The universal property on both sides gives the displayed equivalence. A selected spherical generator only produces the sector it generates. Taking $\mathrm{Ind}(\mathcal{C}^c)$ does not remove a continuous spectrum from an already compactly generated category.

Actions at separate places

Let $T_v : C_v \to C_v$ be an exact colimit-preserving endofunctor at one place. The subposet of finite sets containing v is cofinal. On that diagram T_v acts on the v-factor and the identity acts on the other factors. It commutes with every insertion, which occurs away from v. Thus it defines an exact colimit-preserving endofunctor on C'_V.

Finitely many such actions extend on the cofinal diagram containing all their places. The tensor interchange gives their coherent commutation. No monoidal structure on the individual endofunctors is needed. A construction on a diagram which omits an acting place, or a specified simultaneous infinite action, additionally needs compatibility with the relevant pointings. A Hecke correspondence is therefore usable through its actual endofunctor. It need not be a unital monoidal endofunctor.

Finite labeled disks

The finite-set tensor diagram gives a discrete factorization construction: disjoint sets of labels tensor independently. A geometric factorization algebra additionally requires a space and categories on its opens or configurations. It also requires maps at their collisions.

There is also a distinction within a finite disk construction. Putting a fixed algebra $A_S = \bigotimes_{v \in S} A_v$ on each of r disjoint disks gives $A_S^{\otimes r}$. Putting A_v on one disk carrying label v gives one factor per label. Their products need not agree.

For example, for $A_S = k[x]$, two copies give $k[x_1, x_2]$, whereas a single labeled factor gives $k[x]$. A varying-label factorization diagram must retain this assignment and the maps for every labeled embedding. The finite-set colimit theorem alone supplies no arithmetic collision comparison.

18.31 TENSOR SECTORS AND EXTENSION DATA

An orthogonal decomposition into local sectors gives a direct-sum decomposition of their tensor product. Even with two sectors at each of two places, tensor distributivity gives four terms:

$$(\mathcal{A}_0 \oplus \mathcal{A}_1) \otimes (\mathcal{B}_0 \oplus \mathcal{B}_1) \simeq (\mathcal{A}_0 \otimes \mathcal{B}_0) \oplus (\mathcal{A}_0 \otimes \mathcal{B}_1) \oplus (\mathcal{A}_1 \otimes \mathcal{B}_0) \oplus (\mathcal{A}_1 \otimes \mathcal{B}_1).$$

The middle two terms record different sector choices at the two places. A relation between those choices requires additional structure.

Orthogonal decompositions

Let $\mathcal{V}$ be a symmetric monoidal ∞-category with small colimits. Assume its tensor product preserves colimits separately in each variable. Write $\mathbf{1}$ for its tensor unit and $\coprod$ for its categorical coproduct. The following argument applies to the ∞-category of presentable stable ∞-categories and colimit-preserving functors.

Its tensor represents functors preserving colimits separately in each variable. See Lurie, *Higher Algebra* (2017), Remarks 4.8.1.18 and 4.8.1.24, and Proposition 4.8.2.18. For finite families of stable categories, this coproduct is their orthogonal direct sum, denoted $\oplus$.

Indeed, in a finite product $\prod_i C_i$, every object is the finite direct sum of its components. A colimit-preserving functor out of this product is therefore determined by its restrictions to the factors. Conversely, functors $F_i : C_i \to \mathcal{D}$ extend by $(x_i)_i \mapsto \bigoplus_i F_i(x_i)$. This proves the coproduct universal property. Distinct factors have zero mapping spectra.

Proposition 18.31.1 *(Finite sector decomposition).* Let S be a finite set. For each $v \in S$, fix a finite set I_v and a specified equivalence $C_v \simeq \coprod_{r \in I_v} C_{v,r}$ in $\mathcal{V}$. There is an equivalence, induced by the given sector inclusions,

$$\bigotimes_{v \in S} C_v \simeq \coprod_{\alpha \in \prod_{v \in S} I_v} \bigotimes_{v \in S} C_{v,\alpha(v)}.$$

For $S = \varnothing$, both sides are $\mathbf{1}$.

Proof. For one factor the assertion is the specified decomposition. Tensoring that decomposition with another factor preserves its coproduct. Applying the same fact to the new factor gives the Cartesian product of the two index sets. Induction proves the formula. The maps are induced by the sector inclusions, so the equivalence respects maps that preserve the specified decompositions. □

Write $D(k)$ for the stable ∞-category of unbounded cochain complexes of k-vector spaces, with quasi-isomorphisms inverted. For example, in complex-linear presentable stable categories, put $\mathcal{A}_i = \mathcal{B}_j = D(\mathbb{C})$ and tensor over $D(\mathbb{C})$. This category is the tensor unit, so the result is $D(\mathbb{C})^{\oplus 4}$. Keeping only the two equal-index factors gives $D(\mathbb{C})^{\oplus 2}$. These categories are not equivalent.

Their compact objects have Grothendieck groups $\mathbb{Z}^4$ and $\mathbb{Z}^2$, respectively. Here the Grothendieck group imposes the relation $[y] = [x] + [z]$ for each exact triangle $x \to y \to z$. In $\mathrm{Perf}(\mathbb{C})$, splitting a bounded complex into its cohomology identifies this group with $\mathbb{Z}$, by Euler characteristic. Finite products give the stated ranks. An equivalence preserves compact objects and exact triangles, hence would preserve these groups.

The restricted tensor construction also depends on the sector of each insertion. Let V be a small set. For each $v \in V$, fix a finite nonempty set I_v, an element $\mathrm{o}_v \in I_v$, and a specified decomposition of C_v as above. Fix a morphism $e_v : \mathbf{1} \to C_{v,\mathrm{o}_v}$ in $\mathcal{V}$. For finite $S \subset V$, set

$$C_S = \bigotimes_{v \in S} C_v.$$

For $S \subset T$, tensor with the morphisms e_v, followed by sector inclusion, for $v \in T \setminus S$. The monoidal coherence maps give a diagram on the poset of finite subsets of V. Define its restricted product by

$$C^{\mathrm{res}} = \operatorname*{colim}_{S \subset V,\, S \text{ finite}} C_S.$$

This is an algebraic colimit in $\mathcal{V}$. No analytic or topological completion is implicit.

Let I^{fin} consist of functions α with $\alpha(v) \in I_v$ whose support $\mathrm{supp}(\alpha) = \{v : \alpha(v) \neq \mathrm{o}_v\}$ is finite. For such α, define

$$C^{\mathrm{res}}_\alpha = \operatorname*{colim}_{\substack{S \subset V \text{ finite} \\ S \supset \mathrm{supp}(\alpha)}} \bigotimes_{v \in S} C_{v,\alpha(v)},$$

with the same distinguished insertions.

Proposition 18.31.2 *(Restricted sector decomposition).* Under these hypotheses, the sector inclusions induce an equivalence

$$C^{\mathrm{res}} \simeq \coprod_{\alpha \in I^{\mathrm{fin}}} C^{\mathrm{res}}_\alpha.$$

Proof. For each α, extend its displayed diagram to all finite S by assigning the initial object when S does not contain its support. Call the resulting diagram E_α. At a fixed finite S, only functions supported in S contribute noninitial terms. The finite sector decomposition therefore gives $C_S \simeq \coprod_\alpha E_\alpha(S)$.

The insertion lies in sector 0_v, so the transition maps preserve this identification of diagrams. Colimits commute with coproducts. Thus

$$\operatorname{colim}_S C_S \simeq \coprod_\alpha \operatorname{colim}_S E_\alpha(S).$$

The finite sets containing a fixed support form a cofinal subposet: $S \mapsto S \cup \operatorname{supp}(\alpha)$ supplies a finite upper bound compatible with inclusions. Each inner colimit is consequently C_α^{res}. □

A general insertion need not lie in one sector. If it has several components, its transition maps need not preserve the finite-support indexing above. The finite sector formula still holds. The restricted colimit must then retain the actual transition maps between those finite decompositions.

A nonsplit extension

Orthogonal direct sums exclude extensions between distinct factors. The quiver $1 \to 2$ gives a concrete extension that must be retained when orthogonality is absent. Let k be a field, with no restriction on its characteristic. A representation is a linear map $u : A \to B$ of k-vector spaces. A morphism is a pair (f, g) satisfying $gu = u'f$. Kernels and cokernels are computed at the two vertices.

Consider

$$S_1 = (k \to 0), \qquad S_2 = (0 \to k), \qquad P = (k \xrightarrow{1} k).$$

There is an exact sequence of representations

$$0 \longrightarrow S_2 \longrightarrow P \longrightarrow S_1 \longrightarrow 0.$$

It does not split: a morphism $S_1 \to P$ has source component $f : k \to k$ satisfying $f = 0$. It cannot be a section.

Moreover, $\operatorname{Hom}(P, (A \to B)) \cong A$ and $\operatorname{Hom}(S_2, (A \to B)) \cong B$. Both functors are exact, so P and S_2 are projective. The sequence is therefore a projective resolution of S_1. Applying $\operatorname{Hom}(-, S_2)$ gives

$$\operatorname{Hom}(P, S_2) = 0, \qquad \operatorname{Hom}(S_2, S_2) = k, \qquad \operatorname{Ext}^1(S_1, S_2) = k.$$

The displayed sequence represents the image of $1 \in k$ under the connecting isomorphism. Projectivity of S_2 also gives $\operatorname{Ext}^n(S_2, S_1) = 0$ for every $n \geq 0$. Thus one direction is orthogonal, while the opposite direction carries an extension.

Equivalently, these are left modules over

$$T = \left\{ \begin{pmatrix} a & 0 \\ m & b \end{pmatrix} : a, b, m \in k \right\}, \qquad \begin{pmatrix} a & 0 \\ m & b \end{pmatrix} \begin{pmatrix} a' & 0 \\ m' & b' \end{pmatrix} = \begin{pmatrix} aa' & 0 \\ ma' + bm' & bb' \end{pmatrix}.$$

The two diagonal idempotents recover A and B. The lower-left matrix unit acts by $u : A \to B$. Associativity gives exactly the representation relations. Replacing this algebra by $k \times k$ removes its lower-left entry and the extension above.

Stable gluing

To retain extensions in a stable category, the connecting morphism must be part of each object. Let $\mathcal{A}$ and $\mathcal{B}$ be stable ∞-categories and let $F : \mathcal{A} \to \mathcal{B}$ be exact. All mapping objects below are spectra, written $\operatorname{map}_{\mathcal{A}}(-, -)$ and similarly for other categories. The shift $[1]$ denotes suspension. For cochain complexes it has $K[1]^n = K^{n+1}$ and differential $-d_K$.

Define $\mathcal{G}(F)$ to be the pullback

$$\mathcal{G}(F) = (\mathcal{A} \times \mathcal{B}) \underset{\mathcal{B}\times\mathcal{B}}{\times} \mathrm{Fun}(\Delta^1, \mathcal{B}),$$

where the first map is $(a, b) \mapsto (Fa, b)$ and the second records the source and target of an arrow. Thus an object is (a, b, u) with $u : Fa \to b$. A morphism consists of $f : a \to a'$, $g : b \to b'$, and a specified homotopy from $u'Ff$ to gu. The pullback retains all higher coherences.

Proposition 18.31.3 *(Mapping spectra and extensions).* The category $\mathcal{G}(F)$ is stable, with finite limits and colimits computed in the two components. For $x = (a, b, u)$ and $x' = (a', b', u')$,

$$\mathrm{map}_{\mathcal{G}(F)}(x, x') \simeq \mathrm{fib}\Big(\mathrm{map}_{\mathcal{A}}(a, a') \oplus \mathrm{map}_{\mathcal{B}}(b, b') \xrightarrow{d} \mathrm{map}_{\mathcal{B}}(Fa, b')\Big). \tag{18.33}$$

Here $d(f, g) = u'Ff - gu$.

The exact fully faithful functors

$$i(b) = (0, b, 0), \qquad j(a) = (a, 0, 0)$$

satisfy

$$\mathrm{map}(i(b), j(a)) = 0, \qquad \mathrm{map}(j(a), i(b)) \simeq \Omega\,\mathrm{map}_{\mathcal{B}}(Fa, b) \simeq \mathrm{map}_{\mathcal{B}}(Fa[1], b).$$

Every object has a natural exact triangle

$$i(b) \longrightarrow (a, b, u) \longrightarrow j(a) \xrightarrow{\delta_u} i(b)[1].$$

Under the induced equivalence $\mathrm{map}(j(a), i(b)[1]) \simeq \mathrm{map}_{\mathcal{B}}(Fa, b)$, the connecting morphism δ_u corresponds to u. The choice of sign in this last equivalence is fixed by this exact triangle.

Proof. Exactness of F allows componentwise finite limits and colimits to supply the required arrows. The zero components give a zero object. Pushout squares are pullback squares componentwise, proving stability. A map between two arrows is a homotopy-commutative square.

Its mapping space is the homotopy equalizer of the two compositions $u'Ff$ and gu. The same statement after every suspension gives the homotopy equalizer of mapping spectra. In spectra this is the fiber of their difference, which proves (18.33).

For two objects in the image of i, the formula reduces to $\mathrm{map}_{\mathcal{B}}$. For two in the image of j, it reduces to $\mathrm{map}_{\mathcal{A}}$. The two cross formulas follow by substituting the zero components. In particular, the fiber of $0 \to E$ is ΩE, not E.

The cofiber of $i(b) \to (a, b, u)$ is $(a, 0, 0)$ componentwise. Its connecting morphism includes the homotopy encoded by u. The suspension equivalence identifies that homotopy with u and fixes the stated sign convention. □

The triangle splits precisely when δ_u is nullhomotopic, equivalently when u is nullhomotopic. Indeed, a nullhomotopy identifies its fiber with $i(b) \oplus j(a)$. Conversely, a splitting makes the connecting morphism zero in the homotopy category. When $F = 0$, $\mathcal{G}(F) \simeq \mathcal{A} \times \mathcal{B}$.

Taking $\mathcal{A} = \mathcal{B} = D(k)$ and $F = \mathrm{id}$ gives the arrow category of complexes. Here $h\mathcal{G}(F)$ denotes the homotopy category. For $a = b = k$ in degree zero, the second cross formula gives

$$\mathrm{Hom}_{h\mathcal{G}(F)}(j(k), i(k)[1]) \cong k.$$

The object $(k, k, 1)$ gives its nonzero connecting class. This recovers the extension mechanism in the quiver calculation, including its degree.

Reconstruction from a semiorthogonal filtration

The same description applies to a category whose extension structure is already specified. Let C be stable and let $i : \mathcal{B} \to C$ and $j : \mathcal{A} \to C$ be exact fully faithful functors. Assume

$$\mathrm{map}_C(i(b), j(a)) = 0 \quad \text{for all } a \in \mathcal{A},\ b \in \mathcal{B}.$$

Assume every $x \in C$ admits an exact triangle

$$i(b) \longrightarrow x \longrightarrow j(a) \longrightarrow i(b)[1].$$

These hypotheses state the orientation of the semiorthogonal filtration. They are stronger than generation by the two subcategories alone.

Let $\mathcal{E}$ be the full pullback of the arrow category of C whose arrows have source $j(a)$ and target $i(b)[1]$. Its objects are triples (a, b, δ) with $\delta : j(a) \to i(b)[1]$. Then

$$\mathrm{map}_{\mathcal{E}}((a,b,\delta),(a',b',\delta')) \simeq \mathrm{fib}\big(\mathrm{map}_{\mathcal{A}}(a,a') \oplus \mathrm{map}_{\mathcal{B}}(b,b') \longrightarrow \mathrm{map}_C(j(a), i(b')[1])\big),$$

where the map sends (f, g) to $\delta' j(f) - i(g)[1]\delta$.

PROPOSITION 18.31.4 *(Semiorthogonal reconstruction).* Under these hypotheses, the functor

$$\mathcal{E} \longrightarrow C, \qquad (a,b,\delta) \longmapsto \mathrm{fib}(\delta)$$

is an equivalence. Suppose, in addition, that i has an exact left adjoint $L : C \to \mathcal{B}$. Put $F = (Lj)[-1]$. Then $C \simeq \mathcal{G}(F)$, with the given embeddings i, j.

Proof. A connecting arrow has a fiber triangle $i(b) \to \mathrm{fib}(\delta) \to j(a)$. The filtration hypothesis gives essential surjectivity. To prove full faithfulness, consider two such triangles with middle objects x, x'. Applying $\mathrm{map}_C(-, j(a'))$ to the first triangle gives an equivalence

$$\mathrm{map}_C(j(a), j(a')) \xrightarrow{\sim} \mathrm{map}_C(x, j(a')),$$

because the mapping spectrum from $i(b)$ to $j(a')$ is zero. Consequently a map $h : x \to x'$ determines, with contractible choices, a map $j(f) : j(a) \to j(a')$ and a homotopy between $j(f)(x \to j(a))$ and $x \xrightarrow{h} x' \to j(a')$.

Taking fibers gives a map $i(g) : i(b) \to i(b')$. Taking cofibers supplies the compatible square of connecting arrows. Conversely, a square of connecting arrows gives h by taking fibers. The fiber and cofiber universal properties make these constructions inverse on mapping spaces, including all their higher homotopies. Thus the functor is fully faithful.

For the additional assertion, adjunction and exactness give

$$\mathrm{map}_C(j(a), i(b)[1]) \simeq \mathrm{map}_{\mathcal{B}}(Lj(a), b[1]) \simeq \mathrm{map}_{\mathcal{B}}(F(a), b).$$

This natural equivalence identifies objects, squares, and their higher coherences in $\mathcal{E}$ with those in $\mathcal{G}(F)$. □

In particular, a recollement can supply such a filtration without supplying an orthogonal direct sum. Use the convention $i_* : \mathcal{B} \to C$ for the closed embedding and $j_! : \mathcal{A} \to C$ for the open extension

functor. The recollement adjunctions include $i^* \dashv i_* \dashv i^!$ and $j_! \dashv j^* \dashv j_*$. Its defining vanishing $j^* i_* = 0$ gives $\mathrm{map}(j_! a, i_* b) = 0$, and its exact triangle is

$$j_! j^* x \longrightarrow x \longrightarrow i_* i^* x \longrightarrow j_! j^* x[1].$$

The first assertion of the proposition applies with the roles of the closed and open categories interchanged. It retains the connecting arrow $i_* i^* x \to j_! j^* x[1]$. It does not require a left adjoint to $j_!$ or assert one exists.

The semiorthogonal description becomes an orthogonal direct sum if the other cross mapping spectrum also vanishes. Then every connecting spectrum is zero, and $\mathcal{E} \simeq \mathcal{A} \times \mathcal{B}$. Without this vanishing, tensor assembly must retain the gluing functors or connecting spectra and their composition data. The two sector names alone do not determine the category.

For automorphic categories, applying these propositions requires actual local decompositions or semiorthogonal filtrations and specified insertion functors. An identification with a global automorphic category also requires a comparison functor preserving the Hecke actions, parameter constraints, and extension data. Neither tensor distributivity nor semiorthogonal reconstruction constructs that comparison functor.

18.32 Adelic factorization and automorphic realization

The restricted tensor construction has an algebraic representation theorem as a model. For a restricted product of local groups, choose nonzero reference vectors in the almost-everywhere spherical lines of given local representations. The algebraic restricted tensor is the colimit of finite tensors under insertion of these vectors.

Flath's factorization theorem says that every admissible irreducible adelic representation has this form. For a number field, the archimedean factors in its algebraic form are $(\mathfrak{g}, K)$-modules. Cuspidality is not a hypothesis of this factorization theorem. Changing the nonzero vectors in the almost-everywhere spherical lines changes the concrete insertions but not the isomorphism class of the restricted tensor. It does not choose canonical vectors.

The unitary Hilbert restricted tensor is a different completion. Its reference vectors are unit vectors and its inner product is defined first on the algebraic finite tensors. An infinite tensor without these reference choices has not been specified by listing its local factors.

Neither construction places every independent tuple of local representations in automorphic functions. For GL_1, the idele character must be trivial on the diagonal number field's multiplicative group. For GL_n, automorphic realization likewise imposes its global relations, growth and spectral conditions. The local tuples and their tensor are positive constructions before that additional comparison.

The real place

Let $\mathfrak{g}_{\mathbb{C}}$ be the complexified Lie algebra of the real group and let K be a maximal compact subgroup. A Harish–Chandra module has compatible $\mathfrak{g}_{\mathbb{C}}$- and K-actions. Admissibility asks for finite multiplicity of each irreducible K-type. It does not ask for only finitely many types.

The category of admissible modules is not closed under arbitrary direct sums. An infinite sum of trivial representations has an infinite-dimensional trivial K-isotype. Consequently it is not the asserted presentable category merely by being admissible. One algebraic recipient is the Ind-completion of a chosen small bounded derived category of finite-length Harish–Chandra modules. Its analytic realization and comparison with Hilbert representations require their own functors.

A spherical principal series is one object in a family, not the tensor unit of this category. On a cofinal finite-place diagram which always includes infinity, the smallest stage is the specified archimedean category. In a linear tensor theory the genuinely empty tensor is the coefficient module category.

The real Weil group is the nonsplit extension generated by $\mathbb{C}^\times$ and j, with

$$j^2 = -1, \qquad jzj^{-1} = \bar{z}.$$

For a lift zj of the nontrivial Galois element, $(zj)^2 = -|z|^2 \neq 1$, proving that this extension does not split. Using $\mathbb{C}^\times \rtimes C_2$ would change its representation theory.

Strong approximation for SL_2, with its specified omitted places and noncompactness hypotheses, can simplify a group quotient. For GL_2 the determinant still gives the idele-class quotient. Neither group-theoretic statement identifies all independent local representation data with an automorphic category.

Comparisons of enhanced categories

Let $(\mathcal{C}_S)$ and $(\mathcal{D}_S)$ be supplied diagrams of stable presentable categories on finite sets of places. Suppose exact colimit-preserving equivalences $F_S : \mathcal{C}_S \simeq \mathcal{D}_S$ intertwine every insertion, with their higher coherences. Taking the colimit gives

$$\operatorname*{colim}_S \mathcal{C}_S \simeq \operatorname*{colim}_S \mathcal{D}_S.$$

Indeed, their inverse diagrams give an inverse colimit functor, and the coherent units and counits pass to these colimits. This is a comparison of the supplied diagrams. Identifying either colimit with an independently specified geometric or automorphic category is additional data.

For a global functor $F : \mathcal{C}_{\mathrm{arith}} \to \mathcal{D}_{\mathrm{aut}}$, Theorem 18.1.2 gives a sufficient test. Compare the full mapping spectra of compact generators and preserve their compactness. Prove that their images generate the intended target. Natural compatibility with finite-place Hecke, ramified, Whittaker and archimedean operations must also be supplied. A match of central characters does not provide it.

The cuspidal, residual and continuous summands in a Hilbert spectral decomposition have a precise analytic meaning. Hilbert orthogonality does not imply vanishing of cross mapping spectra in an enhanced category. The nonsplit principal-series and adelic extensions above exhibit the data a categorical gluing must retain. Such a gluing uses its actual connecting functor, all mixed finite-place sectors and coherent transitions.

Question 18.32.1. Construct an enhanced global automorphic category and a geometric recipient for the fixed Selmer problem, together with the comparison functor. Identify the local and global generators, their full derived endomorphisms and the essential image. Prove compatibility with finite and archimedean actions, Whittaker realization, coefficient completion and the specified trace or pairing.

The local full embeddings, determinant-ring reconstruction, formal patching and restricted tensor theorems supply parts of this construction. Their hypotheses do not state a necessity theorem for every possible arithmetic realization. A different geometric recipient or a restricted natural domain remains possible when its comparison maps are constructed.

18.33 Formal operators and arithmetic recognition

Formal spectral variables make sense over a common coefficient ring. Their existence is separate from identifying the resulting algebra with arithmetic operators. In particular, Spec $\mathbb{Z}$ is not discrete: its generic

point is dense. The lack of a chosen comparison between different local fields does not prevent the formal expression $u - v$ over $\mathbb{Z}$.

An integral RTT construction

Let R be a commutative ring and set

$$T_{ij}(u) = \delta_{ij} + \sum_{r \geq 1} t_{ij}^{(r)} u^{-r}.$$

Define an R-algebra by the coefficient relations

$$(u - v)[T_{ij}(u), T_{kl}(v)] = T_{kj}(u)T_{il}(v) - T_{kj}(v)T_{il}(u).$$

The denominator has been cleared, so these are integral relations among the formal coefficients. Equivalently, they are RTT with $\mathcal{R}(u - v) = 1 - P/(u - v)$, where P exchanges the two auxiliary factors, in the corresponding rational formal notation.

Proposition 18.33.1. These relations admit the coproduct and counit

$$\Delta T_{ij}(u) = \sum_{a} T_{ia}(u) \otimes T_{aj}(u), \qquad \epsilon(T_{ij}(u)) = \delta_{ij}.$$

The formal matrix inverse defines the antipode. There is an evaluation homomorphism to $U_R(\mathfrak{gl}_n)$ given by $T_{ij}(u) \mapsto \delta_{ij} + E_{ij}u^{-1}$.

Proof. Suppose T and S satisfy RTT and their coefficients commute with one another. Move the R-matrix through T_1T_2, and then through S_1S_2. This proves RTT for their matrix product. The coefficients in the two tensor factors commute, so the intermediate factors can be reordered as required.

This proves that the coproduct preserves the relations. Associativity of matrix multiplication gives coassociativity. The identity matrix gives the counit.

The constant term of T is the identity. Its inverse is therefore defined coefficientwise, with each coefficient a finite sum of products of the generators. Inverting RTT gives the opposite-algebra relation required of an antipode, and matrix inversion gives both antipode identities. Finally, substitute the displayed evaluation. The relation reduces to

$$[E_{ij}, E_{kl}] = \delta_{jk}E_{il} - \delta_{il}E_{kj},$$

which holds in the enveloping algebra over R. □

This is a formal algebraic construction. It neither identifies primes with spectral coordinates nor produces an arithmetic coproduct on an independently specified Hecke category. A proposed shuffle obstruction must likewise specify its kernel and the identity which fails. A name for a zeta-valued kernel is not an obstruction proof.

Bethe algebras in specified representations

A Bethe algebra is a commutative subalgebra of the Yangian. Its image on a chosen representation is a quotient of that subalgebra. It is not thereby a quotient of the entire Yangian.

The discrete Wronski theorem gives a precise positive model. Fix distinct nonzero $q_1, \dots, q_N \in \mathbb{C}$ and nonnegative integers λ_i with $\sum_i \lambda_i = n$. Let

$$f_i(u) = q_i^u(u^{\lambda_i} + p_{i,1}u^{\lambda_i - 1} + \cdots + p_{i,\lambda_i}).$$

The $p_{i,j}$ are coordinates on an affine n-space.

For $\mathrm{Wr}(g_1, \dots, g_N) = \det(g_i(u - j + 1))_{i,j}$, write

$$\mathrm{Wr}(f_1(u-1), \dots, f_N(u-1)) = \prod_i q_i^{u-1} \prod_{i<j} (q_j^{-1} - q_i^{-1}) \left(u^n + \sum_{s=1}^{n} (-1)^s \Sigma_s u^{n-s} \right).$$

The map given by the Σ_s is the discrete Wronski map. Let $O^q_{\lambda,\mathbf{a}}$ be the coordinate ring of its scheme-theoretic fiber at $\mathbf{a} = (a_1, \dots, a_n)$.

Choose $b_1, \dots, b_n \in \mathbb{C}$ with $b_i \neq b_j + 1$ for $i > j$, and put $a_s = e_s(b_1, \dots, b_n)$. For the tensor of vector evaluation modules

$$V(\mathbf{b}) = \mathbb{C}^N(b_1) \otimes \cdots \otimes \mathbb{C}^N(b_n),$$

Mukhin–Tarasov–Varchenko, Theorem 5.2 and Corollary 5.4, identify $V(\mathbf{b})_\lambda$ with the regular module of $O^q_{\lambda,\mathbf{a}}$. This identifies its Bethe action for the diagonal twist q.

The resulting Bethe image is maximal commutative and Frobenius. Their Theorem 6.3 and Corollary 6.4 give the polynomial Wronski version for the untwisted singular weight space. These specified fibers and evaluation modules are the recipients of the theorem.

In contrast, a local spherical Hecke algebra for GL_n is a Laurent symmetric Satake algebra with its chosen normalization. Its determinant generator is invertible. Already for GL_1, valuation translation acts on a bilateral lattice, whereas a unilateral creation operator has no inverse at the vacuum. Arbitrary characters of a tensor of local Satake algebras specify local parameter tuples. Their global automorphic and Galois realizations still require the maps of Question 18.32.1. An oper or critical-center comparison must also specify its actual Lie algebra, representation and spectral curve.

18.34 Scalar invariants from chiral geometry

A numerical invariant can be computed before its proposed geometric realization is constructed. The examples below retain the scalar calculation and identify the additional object it would have to describe.

Example 18.34.1 *(A rational function and its square root).* Define

$$W(c) = \frac{c^2(5c + 22)}{4(45c + 218)}.$$

It has a simple pole at $c = -218/45$, a double zero at $c = 0$, and a simple zero at $c = -22/5$. These statements follow from the numerator and denominator, which have no common root. For $c > 0$, let $\Omega(c)$ be its positive square root.

Then

$$\Omega(c) = \frac{c}{6} - \frac{1}{27} + O(c^{-1}) \qquad (c \longrightarrow +\infty).$$

Indeed,

$$W(c) = \frac{c^2}{36} \left(1 - \frac{4}{9c} + O(c^{-2}) \right),$$

and the positive square-root expansion gives the result. This computation specifies a rational function and a real branch. Identifying either with a Borel invariant requires its defining transform and an equality on the common domain.

There is a separate differential identity. Let $Q(t)$ and $H(t)$ be twice differentiable functions on a domain where t, Q, H are nonzero, and suppose $H^2 = t^4 Q$. Then

$$U = \frac{H'}{H} - \frac{2}{t} = \frac{Q'}{2Q}, \qquad U' + 2U^2 = \frac{Q''}{2Q}.$$

The first equality follows by logarithmic differentiation.

Differentiating $Q'/(2Q)$ proves the second, including the cancellation of $(Q')^2/(2Q^2)$. The identity is valid for any such Q, H. It therefore does not identify a particular chiral operation by itself.

A weighting also changes the scalar coefficients. The two functions

$$S_6(c) = \frac{4(240c + 1031)}{c^3(5c + 22)^2}, \qquad \widehat{S}_6(c) = \frac{80(45c + 193)}{3c^3(5c + 22)^2}$$

satisfy

$$\widehat{S}_6(c) - S_6(c) = \frac{4(180c + 767)}{3c^3(5c + 22)^2}.$$

They cannot be interchanged without a comparison of their weighting conventions. If a formal series $H(t) = \sum_{r \geq 2} S_r t^r$ satisfies $[t^6]H^2 = 0$, its coefficients instead obey the literal equation

$$2S_2S_4 + S_3^2 = 0.$$

The equation $2S_2S_6 + 2S_3S_5 + S_4^2 = 0$ is the coefficient equation in degree eight. Which degree vanishes must be determined from the specified right-hand side of H^2.

Example 18.34.2 *(The Bernoulli numerator* 691*).* Define $B_n \in \mathbb{Q}$ by

$$\frac{x}{e^x - 1} = \sum_{n \geq 0} B_n \frac{x^n}{n!}.$$

Multiplication by $e^x - 1$ gives $B_0 = 1$ and

$$\sum_{j=0}^{m} \binom{m+1}{j} B_j = 0 \qquad (m \geq 1).$$

Successive substitution yields $B_1 = -1/2$, vanishing of the odd values from B_3 through B_{11}, and

n	2	4	6	8	10	12
B_n	1/6	−1/30	1/42	−1/30	5/66	−691/2730.

This is an exact rational calculation.

It specifies neither a two-dimensional Galois representation nor its determinant law. A proposed representation attached to a shadow coefficient must first be constructed, with its coefficient ring and continuous action. Its characteristic polynomials can then be compared by the determinant methods of this chapter.

An automorphic product has a similarly limited numerical test: a seed coefficient $c(0)$ gives the proposed weight $c(0)/2$. An identification with a chiral central invariant also requires the product, its transformation law and the comparison map. A form of half-integral or quarter-integral weight requires its actual multiplier system or covering group. The numerical weight alone chooses none of these structures.

18.35 PHYSICAL REALIZATIONS AND SCALAR TESTS

Gauge-theoretic constructions give further possible recipients for arithmetic data. The Kapustin–Witten construction starts with a smooth geometric curve and a twisted four-dimensional gauge theory. The Costello–Witten–Yamazaki construction uses a topological surface and a complex curve with a chosen meromorphic one-form, together with a partial connection and its boundary conditions. Replacing that curve by an arithmetic compactification requires new geometric and physical data. The absence of those data does not prove nonexistence of every arithmetic bulk theory.

The protected chiral construction of Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees assigns a chiral algebra to the protected sector of a four-dimensional $\mathcal{N} = 2$ superconformal theory. Its normalization has $c_{2d} = -12c_{4d}$ and $k_{2d} = -k_{4d}/2$. A precise finite-current obstruction requires a finite-dimensional weight-one space. Under that hypothesis, there cannot be an infinite linearly independent family of weight-one currents, by dimension alone. This argument does not establish that hypothesis for every possible superconformal theory.

The oscillator commutator and its logarithmic energy are independent normalizations. For example,

$$[a_{p,m}, a_{q,n}] = m\delta_{pq}\delta_{m+n,0}, \qquad E = \sum_p (\log p) N_p$$

retain level one at each prime while weighting the occupation energy by $\log p$. They do not force Chern–Simons levels $1/\log p$. Nor does finite rank of a root lattice bound the number of states or generators in all of its infinite-dimensional representations.

A stronger concrete automorphic model comes from the odd Maaß eigenfunctions on the Dirichlet half-modular domain. The Eisenstein continuum of the full modular quotient does not satisfy that odd boundary condition. For a fixed Hecke eigenstate, assume its normalized parameters are $e^{i\theta_p}, e^{-i\theta_p}$. Then on two charged oscillators at each prime,

$$\operatorname{Tr}\left(e^{i\theta_p(N_{p,1}-N_{p,2})} p^{-s(N_{p,1}+N_{p,2})}\right) = \frac{1}{(1-e^{i\theta_p}p^{-s})(1-e^{-i\theta_p}p^{-s})}.$$

The local identity is an ordinary geometric-series calculation. Under these unit-modulus parameters, the product is absolutely convergent for $\operatorname{Re} s > 1$. Real phases retain the Ramanujan hypothesis. General Satake parameters require the corresponding convergence bound.

In the Hartnoll–Yang model the dilatation wavefunction contains the completed L-function as a factor. Its zeros are wavefunction zeros. They are not, on that account, eigenvalues or a density of states of the closed dilatation operator. A fixed-prime spectral average, a fixed-state prime-distribution statement and a large-prime continuum limit have separate hypotheses. In particular, the formal multiplicity $(p-1)/2$ is not an integer at $p = 2$.

The evaluation map remains part of the comparison

For a finite set of primes, an exterior generator of energy $\log p$ contributes $1 - p^{-s}$ to a supertrace. The natural dual Ext generator instead has energy $-\log p$ and contributes $1 - p^{s}$. Assigning it positive energy is an additional grading. The restricted exterior limits have their different absolute-convergence half-planes, $\operatorname{Re} s > 1$ and $\operatorname{Re} s < -1$. They do not identify unrestricted Ext over an infinite polynomial algebra with that restricted direct limit.

Likewise, a local Whittaker pairing has its full measure and adjoint-L normalization. A common nonzero complex rescaling preserves an equality of sesquilinear pairings, but does not establish positivity. A regularized global product is not an ordinary convergent Euler product at one. The arithmetic comparison must supply the actual maps and their evaluation domains.

Satake estimates also have a precise scope. For a unitary normalized GL_2 parameter with extremal exponent θ_p, the extremal symmetric-m exponent is $m\theta_p$. The general rank-four and rank-five estimates give $5/34$ through the symmetric cube and $3/26$ through the symmetric fourth. Its refined estimate gives $7/64$. Conditional cuspidal automorphy of the Maaß symmetric ninth would give $11/202$ by the general rank-ten bound. Automorphy for an unbounded sequence of these symmetric powers would force $\theta_p = 0$.

These are implications under the indicated automorphy hypotheses. Newton–Thorne's symmetric-power theorem concerns non-CM regular algebraic forms. A holomorphic companion does not multiply a Maaß exponent by its own symmetric-power degree. The identity

$$\Lambda^2 \operatorname{Sym}^3(V) \simeq \left(\operatorname{Sym}^4(V) \otimes \det V\right) \oplus (\det V)^3$$

retains both summands.

It does not supply missing cuspidality or temperedness. In Ramakrishnan's tensor-product criterion, nondihedral twist-related pairs are also noncuspidal. A bound on local Satake exponents still requires an actual comparison estimate before it gives a summable adelic error.

The arithmetic realization problem therefore retains the object, its operators and their full comparison, followed by the scalar evaluation. The finite coefficient, local representation and formal gluing constructions above remain positive at those levels. The automorphic trace, physical bulk and analytic positivity comparisons require their separately stated maps.

Chapter 19

Marked duality and coefficient polarity

Arithmetic duality must transport an operation before it can explain a functional equation. Its first datum is a pairing between specified objects. The pairing determines the direction of a transpose and the tensor product in which evaluation is defined. A topology then decides which transposes remain continuous. These choices already distinguish several dualities on the polynomial oscillator representation.

We begin with finite coefficients, where evaluation is explicit. We then pass to compact modules, marked derived modules and coalgebras. The completed oscillator shows why a continuous coaction can exist without a continuous evaluation on the proposed tensor. Full collision coefficients admit a different duality, whose field realization can be constructed on a marked charged-current domain. The arithmetic question is to compare such operations with theta and Mellin reflection while retaining the vacuum and both polar terms.

19.1 The pairing fixes the dual

Let R be a commutative ring. For a finite projective R-module P, put $P^\vee = \mathrm{Hom}_R(P, R)$. Evaluation is $P^\vee \otimes_R P \to R, f \otimes p \mapsto f(p)$.

A map $a : P \to Q$ has transpose $a^\vee : Q^\vee \to P^\vee, f \mapsto f \circ a$. Thus

$$\langle a(p), f\rangle = \langle p, a^\vee(f)\rangle, \qquad (ba)^\vee = a^\vee b^\vee. \tag{19.1}$$

These formulas determine variance. They do not assert that a given bilinear form identifies P with its dual.

Proposition 19.1.1 *(Finite projective polarity).* Evaluation gives natural isomorphisms

$$P \xrightarrow{\sim} P^{\vee\vee}, \qquad Q^\vee \otimes_R P^\vee \xrightarrow{\sim} (P \otimes_R Q)^\vee.$$

The second isomorphism uses evaluation in the order of the displayed factors. For a ring map $R \to R'$, the natural map

$$P^\vee \otimes_R R' \longrightarrow \mathrm{Hom}_{R'}(P \otimes_R R', R')$$

is an isomorphism. These statements extend to perfect complexes, with derived tensors and the cohomological Koszul signs.

Proof. For $P = R^n$ the evaluation matrix in a basis and its dual is the identity. The tensor assertion and coefficient comparison are the corresponding identities for finite matrices. A finite projective module is a direct summand of a finite free module, so the identities restrict to it.

Apply the same argument to bounded complexes of finite projectives. For a degree-j functional the dual differential is $d(f) = (-1)^{j+1} f\, d_P$. This makes evaluation a chain map. Finite cones and direct summands preserve all three comparisons. □

If C is a finite projective coalgebra, its coproduct transposes to an associative multiplication on $C^\vee$. The coalgebra counit transposes to the algebra unit. Conversely, an algebra multiplication transposes to a coproduct on its finite projective dual. Each identity is obtained by applying the same duality to its defining diagram. This is coefficient transposition. The cobar algebra of C instead uses tensor words in its shifted coaugmentation quotient and a differential determined by the reduced coproduct.

An integral divided-power example

Consider $R[x]$ with x primitive: $\Delta x = x \otimes 1 + 1 \otimes x$. Give x weight one, and write f_n for the coefficient functional on x^n. The *restricted graded dual* is $\bigoplus_{n \geq 0} R f_n$, the direct sum of the dual weight spaces.

Transposing the coproduct gives

$$f_a f_b = \binom{a+b}{a} f_{a+b}, \qquad f_1^n = n! f_n, \qquad f_0 = 1.$$

Indeed the coefficient of $x^a \otimes x^b$ in $\Delta(x^{a+b})$ is the binomial coefficient. The identity

$$\binom{a+b}{a}\binom{a+b+c}{a+b} = \frac{(a+b+c)!}{a!b!c!} = \binom{b+c}{b}\binom{a+b+c}{a}$$

proves associativity over the integers, and hence over every R. It involves no division in R.

Over a field of characteristic zero the substitution $f_n \mapsto y^n/n!$ identifies this algebra with a polynomial algebra. Over $\mathbb{F}_p$, however, $f_1^p = 0$ while $f_p \neq 0$. The integral dual therefore retains divided powers. For several primitive variables the formula is the product of the corresponding binomial coefficients. The energy grading of the oscillator makes each weight finite, so the same calculation applies weight by weight.

The full linear dual of $\bigoplus_n R x^n$ is instead $\prod_n R f_n$. Its multiplication still has finite sums in each output weight. Whether its evaluation extends to a tensor completion is a separate question, considered in Section 19.6.

19.2 Compact coefficients and their discrete duals

For a locally compact Hausdorff abelian group G, its Pontryagin dual is $G^* = \mathrm{Hom}_{\mathrm{cts}}(G, \mathbb{R}/\mathbb{Z})$, with the compact-open topology. The classical duality theorem says that evaluation $G \to G^{**}$ is a topological isomorphism. It exchanges compact and discrete groups. See Roeder, *Category theory applied to Pontryagin duality*, Theorems 2, 4 and 5. The specialization needed for Iwasawa coefficients has an elementary proof through finite groups.

Fix a prime p and put $D_p = \mathbb{Q}_p/\mathbb{Z}_p$, with the discrete topology. A *profinite $\mathbb{Z}_p$-module* is an inverse limit of finite p-primary modules with its inverse-limit topology. For such an M, and for a discrete p-primary torsion module N, define

$$M^\vee = \mathrm{Hom}_{\mathrm{cts}}(M, D_p), \qquad N^\vee = \mathrm{Hom}_{\mathbb{Z}_p}(N, D_p).$$

The first dual is discrete. Give the second the inverse-limit topology obtained by restricting characters to finite submodules of N. Every finitely generated submodule of N is finite.

THEOREM 19.2.1 *(Compact and discrete coefficient duality).* These duals are exact contravariant inverse equivalences between profinite $\mathbb{Z}_p$-modules and discrete p-primary torsion modules. Their double-dual comparisons are evaluation maps.

Proof. For $\mathbb{Z}/p^n$, a character is determined by the image of 1, an element of $D_p[p^n]$. The pairing of these two cyclic groups is perfect. Finite direct sums prove the assertion for every finite p-group.

A continuous character on M has an open kernel, so it factors through a finite quotient. Consequently

$$M^\vee = \varinjlim_{U} (M/U)^\vee, \qquad N^\vee = \varprojlim_{N_0 \subset N} N_0^\vee,$$

where U runs through open submodules and N_0 through finite submodules. Taking a second dual and using the finite evaluation identities recovers M with its topology and N with its discrete topology. The comparisons are natural.

To prove exactness, let $L \subset M$ be a closed submodule and let $\chi : L \to D_p$ be continuous. Choose an open submodule U of M such that $L \cap U \subset \ker \chi$. The character of $L/(L \cap U) \subset M/U$ extends to M/U, since D_p is divisible and hence injective as a $\mathbb{Z}$-module. Pulling back gives a continuous extension to M. The kernel of restriction is exactly the dual of M/L. Double duality gives exactness on the discrete side as well. □

The same D_p describes circle characters of a profinite p-group. Choose an arc around zero in $\mathbb{R}/\mathbb{Z}$ containing no nonzero subgroup. The inverse image of this arc contains an open subgroup U.

Its image must be zero. Every character therefore factors through a finite p-group and has p-primary torsion image. Here D_p is identified with the p-power torsion subgroup of the circle. It is given its discrete topology in the preceding duality.

The dual tensor and the Iwasawa algebra

For profinite modules define

$$M \mathbin{\widehat{\otimes}}_{\mathbb{Z}_p} N = \varprojlim_{U,V} (M/U) \otimes_{\mathbb{Z}_p} (N/V).$$

For discrete p-primary modules use the transported product

$$A \odot B = (A^\vee \mathbin{\widehat{\otimes}}_{\mathbb{Z}_p} B^\vee)^\vee. \tag{19.2}$$

Its unit is D_p, since $D_p^\vee = \mathbb{Z}_p$. Associativity and symmetry are transported through the natural double-dual maps. Thus a compact unital algebra Λ has a dual coalgebra $C = \Lambda^\vee$ for $\odot$, with $\Delta : C \to C \odot C$ and counit $C \to D_p$.

Dualizing an action $M \mathbin{\widehat{\otimes}} \Lambda \to M$ gives a coaction $M^\vee \to M^\vee \odot C$. Its associativity diagram becomes the coassociativity diagram. Dualizing again recovers the action. Hence continuous compact right Λ-modules and discrete right C-comodules for $\odot$ are exactly anti-equivalent. Exactness extends this comparison to bounded derived categories, with the dual differential used above.

The transported tensor is essential. Ordinary tensor gives $D_p \otimes_{\mathbb{Z}_p} D_p = 0$: if $p^n a = 0$, write $b = p^n c$ and compute $a \otimes b = p^n a \otimes c = 0$. Moreover $\operatorname{Hom}_{\mathbb{Z}_p}(D_p, \mathbb{Z}_p) = 0$. Thus D_p cannot be a nonzero ordinary counital $\mathbb{Z}_p$-coalgebra. Its counit for $\odot$ takes values in the correct unit D_p.

Let G be a profinite group and put

$$\Lambda(G) = \mathbb{Z}_p[[G]] = \varprojlim_{U,n} (\mathbb{Z}/p^n)[G/U],$$

where U is open and normal. The finite coefficient pairing identifies the dual of $(\mathbb{Z}/p^n)[G/U]$ with the functions $G/U \to D_p[p^n]$. Therefore

$$\Lambda(G)^\vee = C_{\mathrm{lc}}(G, D_p).$$

Every locally constant function on the compact group has finite image and factors through some finite quotient. Its values are killed by a common power of p. This proves surjectivity of the displayed identification as well as injectivity.

For left translation on $\Lambda(G)$, choose the contragredient left action on its dual. It is $(g \cdot f)(h) = f(g^{-1}h)$. This follows by evaluating a character on the group-ring basis element $[h]$. The full local abelian Galois group can be used for G, but it is not the chosen procyclic group whose Iwasawa algebra is $\mathbb{Z}_p[[T]]$.

There is also a natural identity

$$(M/pM)^\vee = M^\vee[p].$$

Indeed a character vanishes on pM exactly when multiplication by p kills it. This is an identity of ordinary modules. Derived reduction retains additional Tor groups.

Matlis duality and the coefficient object

For a complete Noetherian local ring $(R, \mathfrak{m}, k)$, let E_R be an injective hull of k. Thus E_R is injective and contains k as an essential submodule: every nonzero submodule meets k. Define the *Matlis dual* by $D_R(M) = \mathrm{Hom}_R(M, E_R)$. Its coefficient object is E_R, rather than R.

THEOREM 19.2.2 *(Matlis duality).* The functor D_R is an exact anti-equivalence between finite R-modules and Artinian R-modules. Evaluation identifies either kind of module with its double dual.

Proof. The injectivity of E_R makes D_R exact. The structural facts are that E_R is Artinian, that $\mathrm{End}_R(E_R) = R$, and that every Artinian M has a finite copresentation $0 \to M \to E_R^a \to E_R^b$. They are proved in the Stacks Project, Tags 08Z6–08Z8. A finite module has a presentation $R^b \to R^a \to M \to 0$.

Dualizing twice and using $D_R(R) = E_R$, $D_R(E_R) = R$ proves biduality by kernels and cokernels. The same argument applied to the copresentation proves biduality on the Artinian side. Naturality of evaluation proves that the two functors are inverse. See also Tag 08Z9. □

Completeness enters the identity for $\mathrm{End}_R(E_R)$. Without it that endomorphism ring is $\widehat{R}$. Indeed $E_R = \bigcup_n E_R[\mathfrak{m}^n]$, and endomorphisms restrict to the finite-length duality on each quotient. Their inverse limit is $\varprojlim_n R/\mathfrak{m}^n$. For $R = \mathbb{Z}_p$, the injective hull is D_p, so Matlis duality agrees with the preceding pairing on finite $\mathbb{Z}_p$-modules. Its stated domain is smaller: $\bigoplus_{n\geq 0} \mathbb{F}_p$ is discrete p-primary torsion but is not Artinian.

Replacing E_R by R can lose the entire module. For example, $\mathrm{Hom}_{\mathbb{Z}_p}(\mathbb{F}_p, \mathbb{Z}_p) = 0$, whereas $D_{\mathbb{Z}_p}(\mathbb{F}_p) \cong \mathbb{F}_p$. A claim of biduality must therefore specify its dualizing object and its module class.

19.3 MARKED MODULES AND BALANCED INTERFACES

The dual of a module can retain a chosen boundary object rather than a scalar coefficient ring. The domain of biduality is then determined by the objects generated from that boundary.

Let A be a dg algebra and P a right A-module. Choose a derived model for

$$E_P = \mathrm{RHom}_A(P, P),$$

with multiplication given by composition. Then P is an (E_P, A)-bimodule. Write $\mathrm{thick}_A(P)$ for the smallest full stable subcategory of $D(A)$ containing P and closed under direct summands. Its objects

are obtained by finitely many shifts, cones and summands. A left E_P-module is *perfect* when it lies in $\mathrm{thick}_{E_P}(E_P)$.

Proposition 19.3.1 *(Duality generated by a marked module).* The functors

$$F_P = \mathrm{RHom}_A(-, P), \qquad G_P = \mathrm{RHom}_{E_P}(-, P)$$

give inverse anti-equivalences $\mathrm{thick}_A(P)^{\mathrm{op}} \simeq \mathrm{Perf}(E_P)$. The first Hom has a left E_P-action by post-composition. The second has a right A-action through P.

Proof. Both functors are exact and preserve finite direct summands. They send P to the regular module E_P and E_P to P. The evaluation maps from an object to its double Hom are equivalences on these generators. The class where either evaluation is an equivalence is closed under shifts, cones and summands. Hence both evaluations are equivalences on the stated categories. The evaluation identities give the inverse functors on mapping complexes and their compositions. □

Now let S be a Noetherian ring of finite global dimension and let A be an ordinary augmented S-algebra, finite over S. Assume that its augmentation ideal I is nilpotent. A complex of right A-modules is *coefficient-perfect* when its restriction to S is perfect. Put $E = \mathrm{RHom}_A(S, S)$.

Theorem 19.3.2 *(The coefficient-perfect domain).* Coefficient-perfect A-modules form $\mathrm{thick}_A(S)$. The functor $F_A(M) = \mathrm{RHom}_A(M, S)$ therefore gives an anti-equivalence from this category to perfect left E-modules. It sends S to E and A to the augmentation module S of E.

Proof. The object S is coefficient-perfect, and this property is preserved by finite cones and summands. This proves one inclusion. Conversely, a coefficient-perfect complex has bounded, finite S-module cohomology. A finite Postnikov filtration reduces the claim to each cohomology module M. Filter M by the powers of I.

Since I is nilpotent, there are finitely many quotients, each a finite S-module with A-action through the augmentation. Every such quotient has a finite projective S-resolution, so belongs to $\mathrm{thick}_A(S)$. Finite extensions prove the other inclusion. Apply Proposition 19.3.1 with $P = S$. The boundary values follow from the two displayed derived Hom complexes. □

Let $C = \mathrm{thick}_A(S)$. Its pro-category retains an inverse system as an object, including its transition maps. The extension of the preceding duality is

$$\mathrm{Pro}(C)^{\mathrm{op}} \simeq \mathrm{Ind}(\mathrm{Perf}(E)) \simeq D(E), \qquad \{M_i\} \longmapsto \varinjlim_i \mathrm{RHom}_A(M_i, S).$$

The direct limit is taken over the opposite of the cofiltered index category.

To see the first equivalence, apply the small anti-equivalence to the formula for maps of pro-objects, $\varprojlim_j \varinjlim_i \mathrm{Map}(M_i, N_j)$. The resulting formula is precisely that for the corresponding ind-objects, with the arguments reversed. The second equivalence uses the regular module E as a compact generator of $D(E)$. Taking the inverse limit of $\{M_i\}$ inside $D(A)$ before dualizing is a different operation.

Two tests for the domain

For $A = k[\epsilon]/(\epsilon^2)$, with k a field, the augmentation has the free resolution

$$\cdots \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \longrightarrow k.$$

The kernel and image of each multiplication map are both $k\epsilon$, which proves exactness. Applying $\mathrm{Hom}_A(-, k)$ gives zero differentials and one copy of k in every nonnegative degree.

The periodic extension class generates their Yoneda products: splicing its first n steps gives the nonzero class in degree n. Consequently

$$E \simeq k\langle t\rangle, \qquad |t| = 1, \qquad t^2 \neq 0.$$

To obtain the dg model, lift the degree-one class to the endomorphism complex of the resolution. Its components are alternating scalar identities, so it anticommutes with the differential.

Its powers represent the nonzero extension classes just computed. The resulting map from the free associative dg algebra $k\langle t\rangle$ is a quasi-isomorphism. This algebra is not required to be graded commutative. The nonzero Ext groups in arbitrarily high degrees show that k is coefficient-perfect and is not perfect over A.

The same small duality sends $\mathrm{Perf}(A)$ to $\mathrm{thick}_E(k)$. Its ind-extension generates $\mathrm{Loc}_E(k)$, the full stable subcategory closed under colimits and generated by k. Inverting t annihilates k, and hence this whole localizing subcategory, but does not annihilate E. Thus the algebra-perfect and coefficient-perfect extensions differ. In this example k is perfect over E, as the two-cell resolution given by multiplication by t shows.

Nilpotence of the augmentation ideal also matters. Take $A = k[x]$ and $E = \Lambda_k(\eta)$, with $|\eta| = 1$ and zero differential. The augmentation $E \to k$ has a semifree resolution with generators e_n, $n \geq 0$, of degree zero and

$$de_0 = 0, \qquad de_n = e_{n-1}\eta \quad (n \geq 1).$$

Every element is a finite sum of generators with coefficients in E.

All positive-degree cycles are boundaries, and its degree-zero cohomology is generated by e_0. Applying $\mathrm{Hom}_E(-, k)$ gives $\prod_{n\geq 0} k$ in degree zero. The endomorphism $e_n \mapsto e_{n-1}$, with $e_{-1} = 0$, identifies composition with multiplication of formal power series. Hence

$$\mathrm{RHom}_A(A, k) = k, \qquad \mathrm{RHom}_E(k, k) = k[[x]].$$

Each formal series acts by a finite sum on every e_n. The second dual has completed $k[x]$. It has not returned the polynomial algebra. Retaining the tower $\{A/(x^n)\}_n$ records the missing topology.

The identity interface

Choose right modules P_A, P_B, P_C over dg algebras A, B, C, and let $E_A = \mathrm{RHom}_A(P_A, P_A)$, with analogous notation for B, C. An (A, B)-bimodule K acts on right modules by $M \mapsto M \otimes^{\mathbb{L}}_A K$. Assume

$$P_A \otimes^{\mathbb{L}}_A K \in \mathrm{thick}_B(P_B), \qquad P_B \otimes^{\mathbb{L}}_B H \in \mathrm{thick}_C(P_C)$$

for a second bimodule ${}_BH_C$. Define the transformed interfaces

$${}_{E_B}L_{K\,E_A} = \mathrm{RHom}_B(P_A \otimes^{\mathbb{L}}_A K, P_B), \qquad {}_{E_C}L_{H\,E_B} = \mathrm{RHom}_C(P_B \otimes^{\mathbb{L}}_B H, P_C).$$

Their left actions are postcomposition and their right actions are precomposition. These choices fix the order of the product.

Proposition 19.3.3 *(Composition of marked interfaces).* Composition induces a natural equivalence

$$L_H \otimes^{\mathbb{L}}_{E_B} L_K \xrightarrow{\sim} L_{K \otimes^{\mathbb{L}}_B H}, \qquad g \otimes f \longmapsto g \circ (f \otimes 1_H).$$

It respects iterated composition. The identity A-bimodule is sent to the regular E_A-bimodule.

Proof. The formula is balanced because acting on g by precomposition has the same effect as acting on f by postcomposition. Put $Q = P_A \otimes^{\mathbb{L}}_A K$. Both sides are exact contravariant functors of $Q \in \operatorname{thick}_B(P_B)$. At $Q = P_B$, the map is the unit isomorphism for tensor over E_B.

It is therefore an equivalence on the thick closure. For three interfaces, both parenthesizations compose the same three maps. The derived associativity constraints give the same comparison. For $K = A$, the definition gives $L_A = \mathrm{RHom}_A(P_A, P_A) = E_A$ with its two regular actions. □

The augmentation boundary and the identity interface have different roles. The first becomes a regular dual module in Theorem 19.3.2. The second becomes the unit bimodule for balanced composition. Replacing that bimodule by its augmentation would change the composition law. A field realization must preserve the chosen boundary action as well as these units.

19.4 Comodules, contramodules and the direction of a map

A coalgebra has a second correspondence that is covariant in its module argument. Let C be a counital coalgebra over a field k. A left comodule has a coaction $M \to C \otimes_k M$.

A *left contramodule* has instead a map

$$\pi : \mathrm{Hom}_k(C, P) \longrightarrow P.$$

It satisfies the unit identity induced by the counit of C and the associativity identity obtained from $\mathrm{Hom}_k(C, \mathrm{Hom}_k(C, P))$. The two maps in that identity are composition with π and precomposition with the coproduct, using tensor–Hom adjunction. For an infinite coalgebra this retains operations on all linear maps from C, not only finite linear combinations.

For a right comodule N and a left contramodule P, their *contratensor product* $N \odot_C P$ is the cokernel of

$$N \otimes_k \mathrm{Hom}_k(C, P) \rightrightarrows N \otimes_k P.$$

One map is $n \otimes f \mapsto n \otimes \pi(f)$. The other is $n \otimes f \mapsto \sum n_{(0)} \otimes f(n_{(1)})$, where $\delta n = \sum n_{(0)} \otimes n_{(1)}$. The sums here are finite on each comodule element. The subscript C distinguishes this quotient from the transported tensor $\odot$ of (19.2).

The regular coalgebra is a bicomodule. It defines functors

$$\Phi_C(P) = C \odot_C P, \qquad \Psi_C(M) = \mathrm{Hom}_C(C, M), \qquad \Phi_C \dashv \Psi_C. \tag{19.3}$$

The Hom consists of colinear maps.

The left coaction on $\Phi_C(P)$ comes from the first factor of the coproduct. The right coaction on C induces the contramodule operation on $\Psi_C(M)$. In ungraded notation it sends $F : C \to \mathrm{Hom}_C(C, M)$ to $c \mapsto \sum F(c_{(2)})(c_{(1)})$. Tensor–Hom adjunction identifies the two balancing conditions and proves the adjunction in (19.3).

For a dg coalgebra, use the same constructions in complexes with Koszul signs. In the homotopy category of dg comodules, take the thick subcategory generated by total complexes of exact triples and closed under direct sums. The quotient is the *coderived category*.

The objects in this subcategory are called coacyclic. The *contraderived category* uses exact triples of contramodules and closure under products. Its corresponding objects are contraacyclic. These are the acyclic classes relevant to the unbounded correspondence.

THEOREM 19.4.1 *(The field-coefficient correspondence).* For a dg coalgebra over a field, the derived functors of (19.3) give inverse covariant equivalences

$$\mathbb{L}\Phi_C : D^{\mathrm{ctr}}(C\text{-contra}) \rightleftarrows D^{\mathrm{co}}(C\text{-comod}) : \mathbb{R}\Psi_C.$$

Proof. The coderived category is modeled by dg comodules that are injective after forgetting the differential. The contraderived category is modeled by contramodules that are projective after forgetting the differential. These resolution statements are Positselski, *Two kinds of derived categories*, Theorem 4.4. They concern the graded comodule and contramodule categories.

For a graded vector space V, the functors send the free contramodule $\mathrm{Hom}_k(C, V)$ to the cofree comodule $C \otimes_k V$, and conversely. The comparisons follow from evaluation, coproduct and counit. Graded projectives are summands of free contramodules, and graded injectives are summands of cofree comodules. Thus the comparisons extend to these two classes, commute with their differentials and give inverse functors on the two homotopy models. This is the correspondence theorem of that source, Section 5.2. □

For $C = k$, the functor Ψ_C is the identity on complexes. It is not vector-space dualization. Even for a finite coalgebra, colinear Hom cannot be replaced by all linear maps.

Let $C = k1 \oplus kc$, with c primitive. A colinear endomorphism has the form

$$f(1) = a1, \qquad f(c) = b1 + ac.$$

Indeed the coaction identity first forces the displayed value on 1 and then the coefficient of c. Thus $\dim_k \mathrm{Hom}_C(C, C) = 2$, whereas $\dim_k \mathrm{Hom}_k(C, C) = 4$.

The injective condition also retains the coaction. The inclusion $k1 \subset C$ has no comodule retraction. If $r(1) = 1$, the colinearity equation on c would read $1 \otimes r(c) = 1 \otimes r(c) + c \otimes 1$. Thus the trivial comodule k is not injective, although its underlying vector space is injective. Underlying coefficient injectivity alone cannot justify the resolutions in the theorem.

Bar and cobar supply additional algebra comparisons

Let A be an augmented dg algebra over k, and let BA be its normalized bar coalgebra. In this subsection use left A-modules. Write $\tau : BA \to A$ for the canonical degree-one twisting cochain.

Its identity is

$$d_A\tau + \tau d_{BA} + \mu_A(\tau \otimes \tau)\Delta = 0,$$

where the tensor of maps includes its Koszul sign. For a module M, the twisted tensor $BA \otimes_\tau M$ has the ordinary tensor differential plus the term applying the coproduct, τ and the module action. The identity above makes its differential square to zero. Twisted Hom is defined by the adjoint formula.

The resulting equivalences are

$$D(A\text{-mod}) \simeq D^{\mathrm{co}}(BA\text{-comod}), \qquad D(A\text{-mod}) \simeq D^{\mathrm{ctr}}(BA\text{-contra}). \tag{19.4}$$

They are Positselski's Theorem 6.3. One composite is the reduced bar resolution of M. Its augmentation is a quasi-isomorphism.

For the other composite, filtration by the number of bar entries reduces the unit comparison to the cofree coalgebra resolution. The corresponding Hom argument uses products and the contraderived acyclic class. Section 6.4 gives the analogous statement for a conilpotent dg coalgebra C and $A = \Omega C$. The normalized algebra bars and their signs were constructed in Chapter 3.

The two equivalences in (19.4) intertwine the comodule–contramodule correspondence. On a twisted cofree object this is the explicit identity

$$\Psi_C(C \otimes_\tau M) \cong \mathrm{Hom}_\tau(C, M).$$

Thus coefficient transposition, bar–cobar comparison and comodule–contramodule correspondence have specified connecting maps. They remain different functors. Replacing the field by $\mathbb{Z}_p[[T]]$ requires an exact structure and resolution hypotheses over that ring.

Changing the coalgebra

Let $f : C \to D$ be a coalgebra map. Corestriction sends a left C-comodule to a left D-comodule by

$$M \xrightarrow{\partial_M} C \otimes M \xrightarrow{f \otimes \mathrm{I}} D \otimes M.$$

It has the same underlying vector space. A C-contramodule likewise becomes a D-contramodule by

$$\mathrm{Hom}_k(D, P) \xrightarrow{\mathrm{Hom}(f,P)} \mathrm{Hom}_k(C, P) \xrightarrow{\pi} P.$$

Both functors go from C to D. Applying the word "opposite" to f does not produce a linear map $D \to C$.

The reverse comodule functor uses cotensor. Give C its (C, D)-bicomodule structure through f. For a left D-comodule N, set

$$f^! N = C \,\square_D\, N = \ker\big(C \otimes N \rightrightarrows C \otimes D \otimes N\big).$$

The maps use the right D-coaction on C and the left D-coaction on N.

It is right adjoint to corestriction. For example, the adjoint of $u : M \to N$ is $m \mapsto \sum m_{(-1)} \otimes u(m_{(0)})$. The inverse adjunction map applies the counit of C. These formulas prove the adjunction identities.

On contramodules the reverse functor is $f_! Q = \mathrm{Cohom}_D(C, Q)$. For a left D-comodule L, define $\mathrm{Cohom}_D(L, Q)$ as the cokernel of two maps

$$\mathrm{Hom}_k(D \otimes L, Q) \rightrightarrows \mathrm{Hom}_k(L, Q).$$

One precomposes with the coaction of L. The other uses

$$\mathrm{Hom}_k(D \otimes L, Q) \cong \mathrm{Hom}_k(L, \mathrm{Hom}_k(D, Q))$$

and then the contraaction of Q. For $L = C$, the right C-coaction induces the left C-contramodule structure on the quotient. This is left adjoint to the contramodule corestriction.

Proposition 19.4.2 *(Naturality with derived adjoints).* For dg coalgebras over a field there is a natural comparison

$$\mathbb{R}\Psi_C \, \mathbb{R}f^! \simeq \mathbb{L}f_! \, \mathbb{R}\Psi_D : D^{\mathrm{co}}(D\text{-comod}) \longrightarrow D^{\mathrm{ctr}}(C\text{-contra}).$$

Here the derived functors use the graded injective and projective models of Theorem 19.4.1.

Proof. For a graded-injective D-comodule N, the comparison is induced by

$$\mathrm{Hom}_C(C, C \,\square_D\, N) \cong \mathrm{Hom}_D(C, N) \cong \mathrm{Cohom}_D(C, \mathrm{Hom}_D(D, N)).$$

The first isomorphism is the cotensor adjunction. For a cofree $N = D \otimes V$, the second is the evaluation identification with $\mathrm{Hom}_k(C, V)$.

It extends to injective summands. The cotensor functor preserves graded injectives, and its cohomomorphism counterpart preserves graded projectives. Thus the isomorphisms commute with differentials and pass to the two homotopy models. This is the naturality comparison of Positselski, Section 5.4. □

There is a related comparison when algebra maps and coalgebra maps preserve a specified acyclic twisting cochain. If $\tau : C \to A$, $\sigma : D \to B$, $g : A \to B$ and $f : C \to D$ satisfy $\sigma f = g\tau$, then extension over g corresponds, under the twisted tensor equivalences, to corestriction over f. Restriction over g corresponds to derived cotensor. The chain identities follow by substituting $\sigma f = g\tau$ in the twisted differentials. See Positselski, Section 6.9. The equation is an additional compatibility of actual maps.

Example 19.4.3 *(A linear splitting does not reverse a coaction).* Let D have basis $1, c, d$ and coproduct

$$\Delta c = 1 \otimes c + c \otimes 1, \qquad \Delta d = 1 \otimes d + c \otimes c + d \otimes 1.$$

The counit kills c, d. Coassociativity follows by expanding these formulas, or by dualizing multiplication in $k[x]/(x^3)$. The subspace $C = k1 \oplus kc$ is a subcoalgebra.

The linear retraction $r : D \to C$ fixing $1, c$ and killing d preserves the counit, but

$$\Delta_C r(d) = 0, \qquad (r \otimes r)\Delta_D d = c \otimes c \neq 0.$$

It is not a coalgebra map. Applying $1 \otimes r$ to the right regular coaction of D gives a map $\delta : D \to D \otimes C$ whose coassociativity defect on d is

$$(\delta \otimes 1)\delta(d) - (1 \otimes \Delta_C)\delta(d) = 1 \otimes c \otimes c.$$

Thus even a counital splitting of underlying modules does not give the reverse corestriction functor.

For a finite projective coalgebra map, the algebra transpose $f^\vee : D^\vee \to C^\vee$ does exist. Ordinary restriction of modules along it goes from $C^\vee$-modules to $D^\vee$-modules. Extension in the other direction changes the underlying module. The evaluation identity (19.1) remains valid without implying any of the incorrect reverse functors.

19.5 Completion and detection of a comparison

Integral duality requires control of the entire coefficient tower. Let R be a commutative Noetherian ring and $I \subset R$ an ideal. The derived I-adic completion of $M \in D(R)$ is

$$\mathbb{L}\Lambda_I M = \mathrm{Rlim}_n(M \otimes^{\mathbb{L}}_R R/I^n). \tag{19.5}$$

A complex is *derived I-complete* when its natural map to (19.5) is an equivalence. For Noetherian R this is the reflection into the complexes satisfying $\mathrm{RHom}_R(R[1/f], M) = 0$ for every $f \in I$. The equivalence of these definitions is the Noetherian derived-completion theorem, Stacks Project, Tag 0922.

Write $K_n = M \otimes^{\mathbb{L}}_R R/I^n$. The inverse-limit term is visible in the exact sequence

$$0 \longrightarrow \varprojlim_n {}^1H^{j-1}(K_n) \longrightarrow H^j(\mathbb{L}\Lambda_I M) \longrightarrow \varprojlim_n H^j(K_n) \longrightarrow 0.$$

Indeed the derived limit is the fiber of $1 - s : \prod_n K_n \to \prod_n K_n$, where s applies the transition to the next coordinate. Products of modules are exact. The long exact cohomology sequence therefore identifies the two outer terms with the cokernel and kernel of $1 - s$.

The first derived limit vanishes for a surjective cohomology tower, since $(1 - s)x = y$ can then be solved recursively. It also vanishes under the Mittag–Leffler condition: for each fixed index the images of all sufficiently late transition maps agree. This is weaker than surjectivity of each transition.

The reduction tower of $M = [\mathbb{Z}_p \xrightarrow{p} \mathbb{Z}_p]$, in degrees zero and one, gives an example:

$$H^0(M \otimes^{\mathbb{L}}_{\mathbb{Z}_p} \mathbb{Z}/p^n) = p^{n-1}\mathbb{Z}_p/p^n \cong \mathbb{F}_p.$$

Every transition on this group is zero. Its eventual image is zero, so it is Mittag–Leffler but is not a surjective tower. Each term of the complex is flat over $\mathbb{Z}_p$.

Ordinary quotients can lose all the cohomology in the answer. For $D_p = \mathbb{Q}_p/\mathbb{Z}_p$, one has $D_p/p^n D_p = 0$, but the two-term resolution of $\mathbb{Z}/p^n$ gives

$$D_p \otimes^{\mathbb{L}}_{\mathbb{Z}_p} \mathbb{Z}/p^n \simeq D_p[p^n][1], \qquad \mathbb{L}\Lambda_{(p)} D_p \simeq \mathbb{Z}_p[1].$$

The transition on the kernels is multiplication by p. Writing a kernel element as a/p^n identifies it with the reduction $\mathbb{Z}/p^{n+1} \to \mathbb{Z}/p^n$. This tower is surjective, with inverse limit $\mathbb{Z}_p$. Our shift convention places the displayed cohomology in degree -1.

For finite cohomology modules there is a useful simplification. If every $H^j(M)$ is finite over R, then

$$H^j(\mathbb{L}\Lambda_I M) \cong \varprojlim_n H^j(M)/I^n H^j(M).$$

This is Stacks Project, Tag 0A06.

The Noetherian Artin–Rees theorem makes completion exact on finite modules. Finite free resolutions and truncations give the assertion for complexes. In particular finite cohomology over $\mathbb{Z}_p[[T]]$ is already p-adically complete. This does not justify replacing the derived tensor in (19.5) by every chosen termwise quotient.

The unit and counit must be the maps tested

Proposition 19.5.1 *(Conservativity of reduction).* Let $u : M \to N$ be a map of derived I-complete complexes. If $u \otimes^{\mathbb{L}}_R R/I$ is an equivalence, then u is an equivalence.

Proof. The cone K is derived complete, since derived completion is exact. The hypothesis says $K \otimes^{\mathbb{L}}_R R/I = 0$. It follows that $K \otimes^{\mathbb{L}}_R V = 0$ for every R/I-module V, by associativity of derived tensor. The finite filtration of R/I^n by powers of I has such successive quotients. Induction therefore gives $K \otimes^{\mathbb{L}}_R R/I^n = 0$ for every n. Taking the derived limit and using completeness gives $K = 0$. □

Suppose now that an integral adjunction $F \dashv G$ is defined between stable coefficient categories. Suppose both categories have exact reduction functors, conservative on the complete objects under consideration. Assume F, G preserve these objects and that their reductions form an adjunction $\bar{F} \dashv \bar{G}$.

The comparison must identify the reductions of the actual unit and counit with the unit and counit of $\bar{F} \dashv \bar{G}$.

Under these hypotheses, if the reduced adjunction is an equivalence, then the original adjunction is an equivalence on that complete domain. Its unit and counit have zero reduced cones, so conservativity makes both maps equivalences. For coderived or contraderived recipients, this argument requires an internal detection statement for those cones. An underlying ordinary derived complex suffices only when the forgetful comparison detects them.

A compatible tower gives another positive construction. Let $C_n \simeq \mathcal{D}_n$ be equivalences of categories, equipped with coherent comparisons to their transition functors. They form an equivalence of diagrams, so induce

$$\varprojlim_n C_n \simeq \varprojlim_n \mathcal{D}_n.$$

The limits retain their descent data and mapping spaces. Equivalences chosen independently at each level do not yet give the required equivalence of diagrams.

Limits of reduction

Conservativity detects equivalences of supplied maps. It is not faithfulness: multiplication by p on $\mathbb{Z}_p$ is nonzero and reduces to zero. Nor does reduction make a lift unique. For $R = \mathbb{Z}_p[[T]]$, the modules

$$M_0 = R/(T), \qquad M_1 = R/(T - p)$$

have the same reduction modulo p. They are not isomorphic as R-modules, since their annihilator ideals differ. Even a fixed lift has distinct automorphisms 1 and $1 + p$ with the same reduction.

There is a second distinction between scalar and power-series coefficients. The module $R/(T)$ is free over $\mathbb{Z}_p$, but the free R-resolution $[R \xrightarrow{T} R]$ gives

$$\operatorname{Tor}_1^R(R/(T), R/(T)) = R/(T).$$

It is not flat over R. Its Iwasawa invariant μ is zero, because T becomes invertible at the height-one prime (p). Thus $\mu = 0$ supplies neither flatness nor the required base-change comparison.

The coefficient ring $\Lambda = \mathbb{Z}_p[[T]]$ is regular local of dimension two. The parameters p, T form a regular sequence, and their Koszul complex resolves the residue field in length two. A minimal free resolution of a finite module has zero differentials after reduction to the residue field. Its terms then compute Tor. Computing Tor instead with the Koszul resolution shows that every term above degree two is zero, by Nakayama's lemma.

Finite Λ-modules therefore have projective dimension at most two. In particular this holds for Λ/J for every ideal J, since Λ is Noetherian. Dimension shifting and Baer's injectivity criterion then bound the injective dimension of every Λ-module by two. These bounds can support resolution arguments, but the exact comodule and contramodule structures must still be specified. In particular the module condition $\mu = 0$ and coalgebra conilpotence are independent, as the two explicit coalgebras in Proposition 10.10.2 show.

For an abelian number field, form the Iwasawa module from the p-primary class groups of its cyclotomic tower. Ferrero–Washington proves that its μ invariant vanishes. Transferring this invariant to another arithmetic object requires a comparison of the specified coefficient modules, for example a pseudo-isomorphism. Neither the oscillator basis nor the coproduct alone provides that comparison.

19.6 Completed coordinate coactions and Fock fields

The transpose of a coaction can have infinitely many output coordinates even when each input state is a polynomial. This does not prevent a continuous coordinate coaction. It does force a choice of recipient.

Let k be a discrete field of characteristic zero and let H be a Hopf algebra with bijective antipode s. Suppose a right comodule is an increasing union of finite subcomodules, $M = \bigcup_N M_N$. Define

$$D_M = \varprojlim_N M_N^*, \qquad \mathscr{T}_r(M) = \varprojlim_N (M_N^* \otimes_k H^{\otimes r}).$$

The finite-stage spaces are discrete. An element of $\mathscr{T}_r(M)$ is equivalently a linear map $M \to H^{\otimes r}$, with the topology of restriction to finite stages. In particular the target of a completed coaction is $\mathscr{T}_1(M)$. It need not be $D_M \otimes_k H$.

Use the following tensor convention on right comodules:

$$\delta(m \otimes n) = m_{(0)} \otimes n_{(0)} \otimes n_{(1)} m_{(1)}. \tag{19.6}$$

The order of the two Hopf-algebra coefficients is part of the convention. Associativity of H makes this a monoidal tensor.

Proposition 19.6.1 *(The continuous coordinate coaction).* There is a natural continuous map

$$\widehat{\delta}_M : D_M \longrightarrow \mathscr{T}_1(M), \qquad (\widehat{\delta}_M f)(m) = \sum f(m_{(0)}) \mathsf{s}^{-1}(m_{(1)}). \tag{19.7}$$

It is counital and coassociative in the corresponding coordinate recipients. It gives a natural tensor comparison

$$D_{M \otimes N} \cong D_N \widehat{\otimes} D_M := \varprojlim_{a,b} (N_b^* \otimes M_a^*),$$

where both sides retain their inverse systems of comodules.

Proof. In a basis e_j of M_N, write $\delta e_j = \sum_i e_i \otimes u_{ij}$. The coaction identity is $\Delta u_{ij} = \sum_l u_{il} \otimes u_{lj}$. The proposed dual coaction sends e^i to $\sum_j e^j \otimes \mathsf{s}^{-1}(u_{ij})$. Since the antipode reverses coproduct,

$$\Delta \mathsf{s}^{-1}(u_{ij}) = \sum_l \mathsf{s}^{-1}(u_{lj}) \otimes \mathsf{s}^{-1}(u_{il}).$$

This is precisely coassociativity of the dual formula. The counit identity follows from the identity coefficient matrix. Restriction to a smaller subcomodule commutes with the formula, so it defines the inverse-limit map. Each finite projection uses only $f|_{M_N}$, which proves continuity.

At a finite pair of stages, $g \otimes f$ corresponds to the functional $m \otimes n \mapsto f(m)g(n)$. Its Hopf coefficient is compatible because

$$\mathsf{s}^{-1}(n_{(1)} m_{(1)}) = \mathsf{s}^{-1}(m_{(1)}) \mathsf{s}^{-1}(n_{(1)}).$$

This is the coefficient of $g \otimes f$ under (19.6). Passing through the restriction maps gives the tensor comparison. A map of the exhaustive filtered unions takes each finite-dimensional stage into a finite stage, so its transpose is continuous and all comparisons are natural. □

The reversal is visible in the four-dimensional Hopf algebra generated by g, x, with

$$g^2 = 1, \quad x^2 = 0, \quad gx = -xg, \qquad \Delta g = g \otimes g, \quad \Delta x = 1 \otimes x + x \otimes g.$$

Its inverse antipode has $\mathsf{s}^{-1}(x) = -gx$. Consequently $\mathsf{s}^{-1}(xg) = -x$, while $\mathsf{s}^{-1}(x)\mathsf{s}^{-1}(g) = x$. Keeping the original tensor order changes this coefficient by $2x$.

The full binomial coaction

Take $F_K = k[x_1, x_2, \ldots]$, with $K \neq 0$, and give x_n energy n. Let $H = k[b_2, b_3, \ldots]$ with every b_j primitive, and set

$$\delta_K(x_n) = x_n \otimes 1 - nK\, 1 \otimes b_{n+1}.$$

Extending as an algebra map gives a right coaction. The subspace of energy at most N is finite-dimensional and stable under it.

Let f_α extract the coefficient of $x^\alpha = \prod_j x_j^{\alpha_j}$, where α has finite support. Applying (19.7) to the binomial expansion gives

$$\widehat{\delta}_K(f_\alpha) = \sum_{\beta \geq \alpha} \binom{\beta}{\alpha} f_\beta \otimes \prod_{j \geq 1} (jK b_{j+1})^{\beta_j - \alpha_j}, \qquad \binom{\beta}{\alpha} = \prod_j \binom{\beta_j}{\alpha_j}.$$

Each finite-energy projection has finitely many terms. For the vacuum functional, $(\widehat{\delta}_K f_0)(x_1^n) = (Kb_2)^n$. The arbitrarily high powers show why the algebraic restricted-dual tensor is too small for this formula.

The construction also works over a formal coefficient tower. Suppose that H_d and $M_{N,d}$ are compatible Hopf algebras and finite free subcomodules over $k[\hbar]/(\hbar^d)$, with bijective antipodes. The same finite matrix proof gives a coaction with target

$$\varprojlim_{N,d} \left(M_{N,d}^\vee \otimes_{k[\hbar]/(\hbar^d)} H_d \right).$$

For example, a translation derivation satisfying $Tb_n = nb_{n+1}$ gives primitive tails

$$\beta_{K,n} = \frac{b_n - e^{K\hbar T} b_n}{\hbar} = -\sum_{r \geq 1} \frac{K^r \hbar^{r-1}}{r!} T^r b_n.$$

This quotient is defined by the series and does not invert $\hbar$. On the polynomial Hopf algebra with primitive b_n, these tails define $\delta_K(x_n) = x_n \otimes 1 + 1 \otimes \beta_{K,n}$. At each precision only finitely many terms of each tail remain. The limit recovers a continuous coordinate coaction on $\prod_\alpha k[[\hbar]] f_\alpha$.

Evaluation imposes another topology

Let $M = \bigoplus_{n \geq 0} M[n]$, with each $M[n]$ finite, and let $D^{\mathrm{res}} = \bigoplus_n M[n]^*$. Consider the matrix completion

$$\mathscr{E}(M) = \prod_{p,q \geq 0} M[p] \otimes M[q]^*, \tag{19.8}$$

with discrete finite blocks. The finite sums of the identity tensors on $M[0], \ldots, M[N]$ converge to an element of $\mathscr{E}(M)$ with identity diagonal blocks and zero off-diagonal blocks. This is the formal diagonal coevaluation.

PROPOSITION 19.6.2 *(Failure of continuous contraction).* If infinitely many $M[n]$ are nonzero, ordinary evaluation on $M \otimes D^{\mathrm{res}}$ has no continuous extension to (19.8).

Proof. Choose distinct $n_j \to \infty$, vectors $e_j \in M[n_j]$ and functionals f_j with $f_j(e_j) = 1$. The tensors $e_j \otimes f_j$ converge to zero in the product topology, since every fixed finite collection of blocks is eventually zero. Their evaluations are all 1, which does not converge to zero in k. This contradicts continuity. □

The argument persists over $k[[\hbar]]$ with the product of the $\hbar$-adic block topologies: the constant scalar 1 still does not approach zero. Exchanging the two tensor orders is a homeomorphism of the underlying matrix products, so it does not repair continuity. No assertion about that flip as a comodule map is needed.

Weighting the coevaluation by q^n gives a different map. Its zigzag on $M[n]$ is q^n id rather than id. Such a weighted sewing operator can be useful, but it is not the coevaluation of ordinary duality. The coordinate coaction above and the diagonal coevaluation therefore do not make this matrix completion into a rigid tensor category.

The inverse coordinate and the central level

On F_K use the Heisenberg modes $J_{-n} = x_n$, $J_n = nK\partial_{x_n}$ for $n > 0$, and $J_0 = 0$. Then $[J_m, J_n] = mK\delta_{m+n,0}$. For an operator A, its transpose is $(A^t f)(v) = f(Av)$. At the same coordinate the evaluation-compatible Lie action is $-J_m^t$. It has level $-K$. It is not lower truncated on the restricted dual: the positive modes send f_0 to $-nKf_{e_n}$ for every $n > 0$.

In the inverse coordinate $w = z^{-1}$, the weight-one contragredient instead has

$$J^\infty(w) = -w^{-2}J(w^{-1})^t, \qquad J_m^\infty = -J_{-m}^t. \tag{19.9}$$

This is the primary-current specialization of Huang, *Introduction to vertex operator algebras, III*, equation (1.26). Its properties here can be checked directly.

Proposition 19.6.3 *(Restricted contragredient Fock module).* The current (19.9) is lower truncated on $F_K^{\mathrm{res}} = \bigoplus_n F_K[n]^*$. It has level K and is isomorphic to F_K by

$$x^\alpha \longmapsto \left(\prod_j (-jK)^{\alpha_j}\alpha_j!\right) f_\alpha. \tag{19.10}$$

On the full product $\prod_n F_K[n]^*$ the same current need not be lower truncated.

Proof. For $n > 0$ its modes are

$$J_n^\infty f_\alpha = -f_{\alpha-e_n}, \qquad J_{-n}^\infty f_\alpha = -(\alpha_n + 1)nKf_{\alpha+e_n}.$$

The first expression is zero when $\alpha_n = 0$. Positive modes lower dual energy, so sufficiently large ones kill every vector in the direct sum. These formulas also prove (19.10), whose coefficients are nonzero because k has characteristic zero and $K \neq 0$. Transposition reverses commutators, giving

$$[J_m^\infty, J_n^\infty] = -[J_{-m}, J_{-n}]^t = mK\delta_{m+n,0}.$$

Normal ordering and differentiation then identify all the Heisenberg module fields.

For the full product, take the functional f with $f(x_n) = 1$ for every $n > 0$ and zero on the other monomials. Its vacuum component is $(J^\infty(w)f)(1) = -\sum_{n\geq 1} w^{-n-1}$. It has no lower Laurent bound, proving the last assertion. □

The inverse coordinate restores truncation on the restricted dual and restores the original level. For a tensor that adds levels and has scalar unit of level zero, it is therefore not an inverse-level dual when $K \neq 0$. The field-module isomorphism does not assert compatibility with the completed coordinate coaction. Finding a category in which the desired evaluation, coaction and field maps coexist remains a further construction. The two explicit failures above concern their stated recipients.

19.7 FULL COLLISION COEFFICIENTS

A singular field needs a coefficient category that retains all its translates. Suppose $Y(a,z)b$ has a nonzero pole over a field of characteristic zero. A relation $p(T)a = 0$ would give $p(\partial_z)Y(a,z)b = 0$. If the lowest Laurent term is vz^{-q} and p has leading term ct^d, the coefficient of z^{-q-d} is

$$c(-q)(-q-1)\cdots(-q-d+1)v \neq 0.$$

No lower derivative contributes there. Thus the translates $T^n a$ are linearly independent.

On $X = \mathbb{A}^1_k$, the right differential-module action is

$$(f\,dz \otimes a)\partial_z = -f'\,dz \otimes a - f\,dz \otimes Ta. \tag{19.11}$$

The translation orbit therefore gives a free rank-one $\mathcal{D}_X$-submodule of $\omega_X \otimes V$. It is perfect over $\mathcal{D}_X$, although it is not holonomic: its characteristic variety is the full cotangent bundle. Holonomicity, perfectness and dualizability for a collision tensor are different conditions.

At finite formal precision a nonzero pole can have a torsion coefficient. Over $k[\hbar]/(\hbar^2)$ the state $\hbar J$ can have a nonzero pole and is still killed by $\hbar$. For a scalar-extended family, freeness of the translation orbit over the parameter ring follows if the pole remains nonzero modulo $\hbar$. A least-order coefficient of any proposed relation then contradicts the argument over k.

The retained perfect diagram

Let U be a smooth affine chart of dimension d, and set $\mathcal{D} = \Gamma(U, \mathcal{D}_U)$. A perfect right $\mathcal{D}$-complex is a summand of a finite complex of finite free right modules. A coordinate volume form converts left modules to right modules by $f^t = f$, $\partial_i^t = -\partial_i$ and $(ab)^t = b^t a^t$. Define

$$P^\dagger = \big(\mathrm{RHom}_{\mathcal{D}}(P, \mathcal{D})\big)^t[d].$$

The canonical line gives the same conversion without a chosen volume form. Finite projective evaluation proves $(P^\dagger)^\dagger \simeq P$. The two shifts cancel because duality reverses shifts. The same finite calculation commutes with restriction to an open chart and with external products. Dimensions add in the latter comparison.

Every derived $\mathcal{D}$-module has a filtered presentation $M \simeq \varinjlim_\alpha P_\alpha$ by perfect objects. The presentation is in the derived category, and need not be a union of submodules. Define its full coefficient dual and the inverse construction by

$$M^\sharp = \{P_\alpha^\dagger\}_\alpha, \qquad \mathbb{S}\{Q_\beta\} = \varinjlim_\beta Q_\beta^\dagger. \tag{19.12}$$

The braces retain the pro-object. The fact used here is that the derived module category is the ind-completion of its perfect objects, since the regular module is a compact generator.

PROPOSITION 19.7.1 *(Full coefficient polarity).* The functors in (19.12) give a presentation-independent anti-equivalence

$$D(\mathcal{D}\text{-right})^{\mathrm{op}} \simeq \mathrm{Pro}(\mathrm{Perf}_{\mathrm{r}}(\mathcal{D})).$$

Proof. For $M = \varinjlim_\alpha P_\alpha$ and $N = \varinjlim_\beta Q_\beta$, the mapping formula is

$$\begin{aligned}\mathrm{Map}_{\mathrm{Pro}}(N^\sharp, M^\sharp) &\simeq \varprojlim_\alpha \varinjlim_\beta \mathrm{Map}(Q_\beta^\dagger, P_\alpha^\dagger)\\ &\simeq \varprojlim_\alpha \varinjlim_\beta \mathrm{Map}(P_\alpha, Q_\beta) \simeq \mathrm{Map}(M, N).\end{aligned}$$

The last equivalence uses compactness of P_α. The formula respects composition. Applying it to any pro-perfect diagram identifies that diagram with the dual of its image under $\mathbb{S}$. It proves both inverse comparisons and independence of the presentation. □

The pro-object contains more information than its ordinary inverse limit. For the Weyl algebra $D = k\langle u, \partial\rangle/([\partial, u] - 1)$, the right-module localization has presentation

$$D[u^{-1}] = \varinjlim(D \xrightarrow{L_u} D \xrightarrow{L_u} \cdots), \qquad a \text{ at stage } n \longmapsto u^{-n}a.$$

Its coefficient dual is the tower of $D[1]$ with transitions L_u. No transition to a fixed stage is zero, so this pro-object is nonzero. Its underived inverse limit is zero: each coordinate of a compatible sequence lies in $\bigcap_n u^n D = 0$, as follows from polynomial coefficients in Weyl normal form. No vanishing of a derived inverse limit is asserted.

The vacuum has another finite resolution, $[D \xrightarrow{L_\partial} D] \to \omega_X$. It gives $\omega_X^\dagger \simeq \omega_X$, whereas $D^\dagger = D[1]$. Thus the full dual retains both the vacuum and the free translation orbit with their respective shifts.

Transporting the collision tensor

Use the ordered collision schemes $\mathscr{R}_I$ and their exceptional collision pullbacks. A coefficient system assigns a right differential complex to each scheme, together with coherent comparisons along these pullbacks. Let C denote this category. Define $C^\sharp$ by applying Proposition 19.7.1 on affine charts and gluing. Opposite categories preserve limits, so the affine comparisons give $C^{\mathrm{op}} \simeq C^\sharp$ on the descent categories.

For any geometric functor F, its transported functor is $F^\sharp = \sharp F \mathbb{S}$. In particular collision pullback becomes $\delta^\dagger = \sharp \delta^! \mathbb{S}$, and open direct image becomes $j_{!,\mathrm{pro}} = \sharp j_* \mathbb{S}$. The latter is a functor to pro-perfect coefficients. It is not an assertion that ordinary $j_!$ exists on every large differential-module coefficient in this form.

For an ordered decomposition $I = G \sqcup H$, let $U_{G|H}$ be the open where the two groups of points are disjoint, and let $j_{G|H}$ be its inclusion. Internal collisions within a group remain allowed. The atlas convolution $\star$ sums the corresponding open direct images over all ordered decompositions. Its transported tensor is

$$(E \star_\sharp F)_I = \bigoplus_{I=G\sqcup H} j_{G|H,!,\mathrm{pro}}\,(E_G \boxtimes^\sharp F_H)\Big|_{U_{G|H}}. \tag{19.13}$$

Here the external product uses the two-index perfect diagrams. The sum is finite. Equivalently, $E \star_\sharp F = (\mathbb{S}E \star \mathbb{S}F)^\sharp$. Associativity and every collision comparison are transported through the same coefficient duality.

The tensor unit K has coefficient k at empty support and zero at nonempty support. Thus $K^\sharp = K$. The word-cut tensor, whose decompositions are consecutive prefixes and suffixes, is a separate construction. In the atlas tensor, $13 \mid 2$ and $2 \mid 13$ are present. Transposition retains these components and all normal derivatives rather than replacing a full collision by an ordered word.

For finite lists there is consequently an equivalence of operation spaces

$$\mathrm{Map}_{C}\left(\bigstar_{i} X_i, \bigstar_{j} Y_j\right) \simeq \mathrm{Map}_{C^\sharp}\left(\bigstar_{j}^{\sharp} Y_j^{\sharp}, \bigstar_{i}^{\sharp} X_i^{\sharp}\right).$$

It follows directly from the mapping equivalence and (19.13). It reverses composition and retains identities, homotopies and their coherences.

Associative algebras in the two polarities

An augmented coefficient algebra is called connected here when its empty coefficient is k. Its augmentation ideal then has zero empty coefficient. On a configuration I, a tensor word in that ideal has at most $|I|$ nonempty factors. This support bound is the finiteness condition for normalized bar and cobar, independently of the dimension of any individual coefficient.

THEOREM 19.7.2 *(Associative coefficient duality).* On the connected augmented domains for the full atlas tensor, normalized bar and full coefficient duality give an anti-equivalence

$$\mathrm{Alg}^{\mathrm{aug,conn}}_{E_1}(C, \star)^{\mathrm{op}} \simeq \mathrm{Alg}^{\mathrm{aug,conn}}_{E_1}(C^\sharp, \star_\sharp).$$

Its functor is $\mathcal{K}(A) = (B_\star A)^\sharp$, and its inverse is $E \mapsto \mathbb{S}B_{\star_\sharp}E$.

Proof. The bar coproduct transposes to the multiplication of $\mathcal{K}(A)$ through (19.13). The bar counit becomes its unit, and its coaugmentation becomes its augmentation. For a connected coalgebra C, dualizing the normalized bar of $C^\sharp$ gives $\mathbb{S}B_{\star_\sharp}(C^\sharp) \simeq \Omega_\star C$. Suspensions reverse, multiplication transposes to the coproduct, and outer deconcatenation becomes concatenation.

The bar–cobar comparison is finite on every I. Filter a composite by its original positive-support entries. For more than one entry, each gap is either an outer cut or an inner product gap. On the associated graded these two choices form a two-term identity complex.

Contract the first gap, with the tensor sign. The single-entry comparison is the identity, and the finite filtration proves the unit and counit equivalences. This is the finite-support bar–cobar argument of Chapter 3 applied to all ordered decompositions. Its triangles, together with coefficient biduality, give the two inverse functors. □

For a formal family the same proof applies at every $R_m = k[\hbar]/(\hbar^m)$ using relative differential operators $\mathcal{D}_U \otimes_k R_m$. Finite perfect duality does not require R_m to be regular. Keep the coefficient-reduction functors and their transported pro-diagrams. No exchange of a pro-limit, an adic limit and a Laurent expansion is used.

This theorem constructs a second associative coefficient algebra with an inverse comparison. The Lie–commutative chiral correspondence concerns other algebra objects and does not supply this associative comparison. A realization of its output by fields must additionally identify the field products, exchange, tensor and local vacuum. The next construction supplies such a realization with explicit markings.

19.8 A field realization with a bar contact marking

The field data must be strong enough to recover the input algebra from its dual. For charged currents the relevant data are a quadratic current core, its translation and jet derivations, and the contact operations retained in the bar. We work over $k = \mathbb{C}$ at the fixed precision $R_2 = k[\hbar]/(\hbar^2)$. The parameter has degree, charge and weight zero. Position on the affine line is denoted by z and field separation by u.

Charged jets and their fields

Let E be a bounded finite-dimensional complex in nonpositive cohomological degrees. Give $e_n = e \otimes t^n$ charge one and weight $n+1$. On $\mathrm{Sym}_k(E \otimes k[t])$ define even derivations

$$T e_n = (n+1)e_{n+1}, \qquad \partial_i e_n = e_{n-i+1} \quad (i \geq 1), \qquad e_j = 0 \ (j < 0). \tag{19.14}$$

They kill the unit, commute with the differential and satisfy $[\partial_i, \partial_j] = 0$ and $[\partial_i, T] = (i-1)\partial_{i-1}$, with $\partial_0 = 0$. The derivation ∂_1 measures charge.

A *charged jet algebra* is a quotient of this dg algebra by an ideal homogeneous in charge and weight and stable under the displayed derivations. Require its charge-zero part to be k. Each weight piece is then a bounded finite-dimensional complex. The quotient presentation is not an extra marking.

The charge-one generators are recovered intrinsically. On A_1 put $D = \partial_2$. Then $[D, T] = 1$ and D is locally nilpotent. The formulas

$$\pi = \sum_{j \geq 0} \frac{(-1)^j}{j!} T^j D^j, \qquad a = \sum_{n \geq 0} \frac{T^n}{n!} \pi(D^n a)$$

give $A_1 = E_A \otimes k[t]$, where $E_A = \ker(D|_{A_1})$.

Both sums are finite on every input. Commuting D through T^j cancels adjacent terms and proves $D\pi = 0$. The binomial identity proves the second formula. Successive powers of D prove its uniqueness. Thus E_A and the kernel of $\mathrm{Sym}(E_A \otimes k[t]) \to A$ are recovered from A and its jet actions.

After scalar extension to R_2, define

$$\begin{aligned} C_1(u) &= \sum_{p,q \geq 0} (-1)^{p+1} \binom{p+q}{p} u^{-p-q-1} \partial_{p+1} \otimes \partial_{q+1}, \\ E(u) &= 1 - \hbar C_1(u), \qquad Y_A(a,u)b = \mu_A(e^{uT} \otimes 1)E(u)(a \otimes b), \\ \mathcal{S}_A(u) &= 1 + 2\hbar C_1(u). \end{aligned} \tag{19.15}$$

On fixed algebraic inputs the contraction is finite. Taylor translation contributes nonnegative powers, so the field output still has a finite lower Laurent bound. The symbol $\mathcal{S}_A$ denotes unpermuted exchange.

An input morphism is an R_2-linear unital dg algebra map preserving charge and commuting with T and every ∂_i. In particular it preserves multiplication, $f\mu_A = \mu_{A'}(f \otimes f)$. These equations imply that it preserves the fields and exchange in (19.15). The weak equivalences are state quasi-isomorphisms.

The first interacting one-seed quotient is

$$A_0 = k[e_0, e_1, \ldots]/I^3 = k \oplus V \oplus Q, \qquad I = (e_0, e_1, \ldots), \quad Q = \mathrm{Sym}^2 V. \tag{19.16}$$

Its differential is zero. The field of e_0 satisfies

$$Y_{A_0}(e_0, u)e_0 = (1 + \hbar/u) \sum_{n \geq 0} e_n e_0 u^n.$$

Its $\hbar u^{-1}$ coefficient is $e_0^2 \neq 0$. The quotient by I^2 would kill this interaction.

The marked current core

Put $\mathfrak{g} = \mathfrak{sl}_2(k)$, with $[h, e] = 2e$, $[h, f] = -2f$ and $[e, f] = h$. An independent current core consists of a discrete nonpositive complex L with bounded finite-dimensional nonnegative weight pieces and

completed generators $W = (L[1])^\vee$. Here the dual of a discrete space is its full degreewise dual with product topology. The dual of a completed space is its continuous degreewise dual. Thus $W^\vee[-1] = L$.

The finite-weight generator space is $W_{\mathrm{pol}} = \bigoplus_q (L_q[1])^*$. Its polynomial core is $\mathrm{Sym}(W_{\mathrm{pol}})$, and its completion is the product of the weight pieces in each cohomological degree. Require a continuous square-zero derivation whose values on generators have linear and quadratic parts. If $|v_i| = a_i$, $d_L v_i = \sum_k D_i^k v_k$ and $[v_i, v_j] = \sum_k f_{ij}^k v_k$, our sign convention is

$$dc^k = \sum_i (-1)^{a_i} D_i^k c^i - \frac{1}{2} \sum_{i,j} (-1)^{a_i(1-a_j)} f_{ij}^k c^i c^j.$$

The linear, quadratic and cubic components of $d^2 = 0$ give the differential, derivation and Jacobi identities on L.

Mark a scalar-current map dual to a dg Lie map $j : \mathfrak{g} \to L$, and require translation to kill $j(\mathfrak{g})$. For $x \cdot v = [j(x), v]$, require

$$\mathfrak{g} \otimes \mathrm{Hom}_{\mathfrak{g}}(\mathfrak{g}, L) \xrightarrow{\sim} L. \tag{19.17}$$

Charge, translation and all jet actions are retained. The recovered multiplicity space must satisfy the charged jet conditions above. This is a condition on the supplied core and its operations.

For a charged jet algebra A, the forward core is constructed from

$$L_A = \mathfrak{g} \otimes A, \quad [x \otimes a, y \otimes b] = [x, y] \otimes ab, \quad d_{L_A} = 1 \otimes d_A, \quad j_A(x) = x \otimes 1.$$

Its translation and jets are $1 \otimes T$ and $1 \otimes \partial_i$. The corresponding derivations on the dual generators are their negative transposes, denoted T_B, D_i.

Let $C^{(n)}$ be charge n of the polynomial core, and set

$$\begin{aligned} \Lambda_n &= k[x_1, \dots, x_n]^{S_n}, & d_n &= \prod_{i<j} (x_i - x_j)^2, \\ B^{\mathrm{mer}} &= \bigoplus_{n \geq 0} C^{(n)} \otimes_{\Lambda_n} \Lambda_n[d_n^{-1}]. \end{aligned} \tag{19.18}$$

Here $d_0 = d_1 = 1$. The variables x_i are constituent dual-jet variables, not positions on the affine line. Their power sums act by $p_m \mapsto -D_{m+1}$, including $p_0 = n$. This symmetric-ring action is determined by the marked jets.

Multilinear polarization explains the action and the localization. At charge n, distribute the n labeled constituents among current generators. Their jet indices give monomials in $x_1, \dots, x_n$.

Take symmetric invariants with cohomological Koszul signs. Multiplication uses the normalized projector $(n!)^{-1} \sum_{\sigma \in S_n} \sigma$. The pairing of x^j with et^j is one, and repeated even constituents contribute their factorials. There is no additional binomial factor.

For a free jet algebra this identifies the charge piece with $(K_n \otimes k[x_1, \dots, x_n])^{S_n}$, where K_n records the finite current and constituent data. For a jet quotient its dual core is a submodule of this free polarized module. Multiplication by d_n is therefore injective. The current differential changes only how the same constituents are grouped. It leaves their variables fixed. It is Λ_n-linear and extends to (19.18).

For two groups of charges p, q, the joint recipient also inverts every cross difference $x_a - y_b$. For field parameters it inverts their translated differences as well. At the fixed precision only finitely many denominator factors occur in any element. Put $w(u) = 1 - \hbar/u$ and define

$$\begin{aligned} \Omega_{p,q}(v) &= \prod_{a,b} w(v + x_a - y_b), & \mu_w &= \mu_0 \Omega_{p,q}(0), \\ Y_B(b, v)c &= \mu_w(e^{vT_B} b \otimes c). \end{aligned} \tag{19.19}$$

The map μ_0 is ordinary current multiplication extended to this joint localization. The native vacuum is the empty symmetric monomial.

A current morphism is an R_2-linear unital dg algebra map of the polynomial cores, linear on the marked generator spaces. It preserves the scalar-current map and charge, commutes with T_B and every D_i, and extends continuously to the completed cores. Its extension to the localizations is then unique. These conditions preserve the product, fields, exchange and vacuum in (19.19). The polynomial core is retained as a marking. It need not be a subalgebra for the deformed product μ_w.

The objects on both sides are scalar extensions from k to R_2. Their morphisms need not be extended from k. After extension, generator duals are R_2-linear with the same topologies. The Frobenius pairing $(a, b) \mapsto [\hbar](ab)$ identifies these dual calculations with exact k-linear duality.

PROPOSITION 19.8.1 *(The two field structures).* The input and current fields just defined satisfy the differential, vacuum, translation, associativity and exchange identities on their stated recipients. Their exchanges are unitary and satisfy Yang–Baxter and the field hexagon.

Proof. The commuting jet derivations give $[T \otimes 1, C_1(u)] = -\partial_u C_1(u)$ and $[T \otimes 1 + 1 \otimes T, C_1(u)] = 0$. Each derivation kills the vacuum. The product rule splits a contraction against a product into its two contractions. Thus either association of three fields uses the same three pair factors, after translation of their separations. The reversed ratio of the two input factors is $\mathcal{S}_A$.

On the current side, normalized symmetrization absorbs each intermediate projector. Both associations have the factor $\Omega_{p,q}(0)\Omega_{p,r}(0)\Omega_{q,r}(0)$. The differential leaves constituent variables fixed, and total translation kills differences. Hence both are derivations of the deformed product.

Empty groups give the two vacuum identities. The exchange is $\Omega_{q,p}(-v)^{21}/\Omega_{p,q}(v)$. Reversing twice gives its inverse. Commuting pair factors give Yang–Baxter, and partitioning their pair sets gives the hexagon. Stability under the jet derivations carries the input identities through the quotient ideals. □

Formal equivalences and the contact coalgebra

The completed core has a specified notion of weak equivalence. Let S be a finite-dimensional nonpositive augmented commutative dg k-algebra with nilpotent augmentation ideal $\mathfrak{m}_S$. Put

$$\Omega_n = k[t_0, \dots, t_n, dt_0, \dots, dt_n]/(\textstyle\sum t_i - 1, \sum dt_i), \qquad d(t_i) = dt_i,$$

where $|t_i| = 0$ and $|dt_i| = 1$. For the completed untwisted core $\widehat{C}_B$ with positive symmetric-degree ideal I_B, consider the simplicial set $X_B(S)$. Its n-simplices are continuous unital R_2-linear dg algebra maps satisfying

$$\begin{aligned} \phi &: \widehat{C}_B \longrightarrow R_2 \otimes S \otimes \Omega_n, \\ \phi(I_B) &\subset R_2 \otimes \mathfrak{m}_S \otimes \Omega_n. \end{aligned} \tag{19.20}$$

In particular $\phi(ab) = \phi(a)\phi(b)$. The target is discrete. These test maps need not preserve the generator splitting or the jet markings. A current morphism $B \to B'$ is a *formal core equivalence* if precomposition gives a weak equivalence $X_{B'}(S) \to X_B(S)$ for every S. This defines the weak equivalences on the current side.

The generator images identify (19.20) with the Maurer–Cartan simplicial set of $(\mathfrak{g} \otimes A_{R_2}) \otimes \mathfrak{m}_S$: the chain-map equation is $d\alpha + \frac{1}{2}[\alpha, \alpha] = 0$. Nilpotence makes all products finite. Continuity gives finite weight support at each simplex. The nilpotent Maurer–Cartan invariance theorem sends a state quasi-isomorphism to an equivalence of these tests. See Getzler, *Lie theory for nilpotent L_∞-algebras*, Theorem 4.8.

Conversely, the test $S = k[\varepsilon]/(\varepsilon^2)$ has, at the zero point,

$$\pi_n X_B(S) = H^{1-n}(\mathfrak{g} \otimes A_{R_2})\varepsilon \quad (n \geq 1), \qquad \pi_0 X_B(S) = *.$$

The bracket is zero in this test, and the polynomial de Rham complex computes the shifted linear complex. Every state degree occurs because the states are nonpositive. Thus a formal core equivalence detects the recovered state quasi-isomorphism. This uses the marked core and does not replace it by ordinary cohomology of the unmarked meromorphic algebra.

Now form the full contact coalgebra C_A of the input fields. Its singleton is $(\omega_X \otimes A_{R_2})[1]$ with right action (19.11). For every ordered partition retain its open and closed direct images and all normal derivatives. A merger uses the principal part of the field, together with exchange to bring nonconsecutive blocks together.

In particular it retains

$$r_A(u^m; a, b) = \mathrm{pp}(u^m Y_A(a, u)b) \qquad (m \in \mathbb{Z}).$$

Here pp takes the strictly negative Laurent part. Fields have expansion $Y_A(a, u)b = \sum_n (a_{(n)}b)u^{-n-1}$, so

$$a_{(n)}b = [u^{-1}]r_A(u^n; a, b).$$

Negative multipliers recover the regular modes as well. The coefficient differential and all its coherences come from the full contact construction, not from the extraction of a single residue.

Define $U_*(A) = \Omega_\star C_A$. If tc is the degree-one desuspension of a reduced coalgebra element, its cobar differential is

$$d(tc) = -t(d_C c) + \sum_{\overline{\Delta}c = c' \otimes c''} (-1)^{|c'|+1}(tc')(tc''). \tag{19.21}$$

Every ordered-subset coproduct is included. The empty word is the unit of $U_*(A)$.

PROPOSITION 19.8.2 *(The bar contact marking).* The identity at empty support and the reduced map

$$\eta_A(c) = \sum_{r \geq 1} (s\tau)^{\star r} \overline{\Delta}^{(r-1)} c, \qquad \tau(c) = tc, \quad |s| = -1,$$

give a natural equivalence $C_A \to B_\star U_*(A)$ preserving the entire contact diagram.

Proof. Use bar signs $b_1(sa) = -s(da)$ and $b_2(sa, sb) = (-1)^{|a|}s(ab)$. In (19.21), a split has sign $(-1)^{|c'|+1}$. It cancels the bar multiplication joining the corresponding adjacent factors. Internal differentials have the suspension sign in b_1. Coassociativity identifies the iterated cuts, proving the chain and coalgebra identities.

Use the finite gap filtration of Theorem 19.7.2. A single original entry gives the identity. A longer word has a contractible first gap. On I the filtration ends at $|I|$, proving equivalence. Every map is a composite of the full coefficient maps, so it retains collisions, spectators and normal derivatives. Naturality gives compatibility with input morphisms. □

Write $\mathcal{N}_*^{\mathrm{bc}}$ for the input category with this bar contact marking, and $\mathcal{N}_\sharp^{\mathrm{cj}}$ for the marked current category just defined. The bar marking realizes the field operations inside $B_\star U_* A$. It is not an identification with bare multiplication on a singleton of the cobar algebra.

For $J = C_k$, the state unit and augmentation give $v_A : J \to C_A$ and $a_A : C_A \to J$, with $a_A v_A = 1$. The bar pointing is $\eta_A v_A : J \to B_\star U_* A$. It is distinct from the empty-support tensor unit K.

Native multiplication and every collision

The current product has a tensor comparison determined by its own pair multipliers. In the ambient current category, the tensor of the cores of A and A' is the core of $A \times A'$. Its localization includes the cross differences between the two groups.

Let $F_{B,C} = \Omega_{B,C}(0)$ and let τ be the Koszul permutation. The deformed crossing and product on this joint tensor are

$$\sigma_w = \tau(F^{21}_{C,B})^{-1} F_{B,C}, \qquad \mu_{B\otimes_w C} = (\mu_B \otimes \mu_C)(1 \otimes \sigma_w \otimes 1).$$

Removing the native cross multiplier has tensor comparison $U_2 = F^{-1}_{B,C}$. For three groups, both tensor comparisons contain the same three commuting cross factors.

This proves their associativity. An empty group gives the unit. The charge-zero-k slice is not closed under this tensor, since $(A \times A')_0 = k \times k$. All tensor assertions here use the ambient category.

Let C°_A denote the contact coalgebra for the regular fields $\mu_A(e^{uT} \otimes 1)$, and write $C^w_A = C_A$ for the deformed one. On an ordered configuration multiply all pair operators $E(u)$ from (19.15). Call this operator E_A.

Translation covariance makes it horizontal, so it extends to closed direct images and all normal derivatives. The product rule at a merger gives, before taking principal parts,

$$\mu_{ab} e^{uT_a} E_{ac}(z_b + u - z_c) E_{bc}(z_b - z_c) = E_{(ab)c}(z_b - z_c)\mu_{ab} e^{uT_a}.$$

The internal factor $E_{ab}(u)$ is precisely the input contraction. This proves compatibility with adjacent mergers and their Laurent multipliers.

For a nonconsecutive merger, exchange supplies the passage through the intervening block. For 13, put $u = z_1 - z_3$, $t = z_2 - z_3$ and $X_{12}(u - t) = E_{12}(u - t)E_{21}(t - u)^{-1}$. The corresponding equality is

$$r^\circ_{13} E_{12}(u - t)E_{13}(u)E_{23}(t) = E_{2,(13)}(t)\,\mathrm{pp}_{u=0}\,\mu_{13} e^{uT_1} E_{13}(u) X_{12}(u - t).$$

It remains valid after every Laurent multiplier. Commuting the pair factors proves the higher collision comparisons. Thus $E_A : C^w_A \to C^\circ_A$ is an isomorphism of full coefficient complexes.

For a cut $G \sqcup H$, let $W_{G,H}$ be the product of the inverse input contractions between the two groups. Cancellation of the internal pair factors gives

$$(E_G \boxtimes E_H)\Delta^w_{G,H} E_A^{-1} = W_{G,H}\Delta^\circ_{G,H}. \tag{19.22}$$

Every ordered-subset cut occurs. For three groups, both composites contain $W_{G,H}W_{G,J}W_{H,J}$. These are identities of the full diagrams, including spectators and normal derivatives.

Recover the state algebra A_B from a current core and put $G(B) = (C^\circ_{A_B})^\sharp$. This constructs the ordinary contact system before coefficient duality is applied. Colored partitions identify the contact system of $A \times A'$ with the two-color coefficient tensor.

Dualizing this comparison and the native map U_2 gives J°. Define its deformed tensor comparison by $J^w = J^\circ(W_{G,H})^\sharp$ on each cut component. The pair factor is forced by expanding the native multiplier $w(v + x_a - y_b)$ in the constituent jets. Its first-order expansion is the negative transpose of $C_1(v)$, so it is the same $W_{G,H}$ as in (19.22).

Consequently actual native multiplication has the comparison

$$G(\mu_w)J^w = (\Delta^\circ_{G,H})^\sharp (W_{G,H})^\sharp. \tag{19.23}$$

Indeed removing the cross multiplier turns native multiplication into ordinary core multiplication. The latter transposes the diagonal $A \to A \times A$, whose colored-partition map is the cut coproduct. Restoring the native multiplier gives the right side of (19.23). Equation (19.22) now shows that $E_A^\sharp$ identifies this realized algebra with $(C_A^w)^\sharp$. Denote the resulting operation-preserving realization by $U_\sharp$.

THEOREM 19.8.3 *(Bar-marked charged-current duality).* At precision R_2 there is an anti-equivalence

$$D : (\mathcal{N}_*^{\mathrm{bc}})^{\mathrm{op}} \xrightarrow{\sim} \mathcal{N}_\sharp^{\mathrm{cj}}, \qquad D(A) = B_A^{\mathrm{mer}}.$$

Its inverse recovers the R_2-algebra

$$R(B) = \mathrm{Hom}_{\mathfrak{g}_{R_2}}(\mathfrak{g}_{R_2}, W_B^\vee[-1]).$$

There is a natural coefficient equivalence

$$\mathcal{K}(U_* A) = (B_\star \Omega_\star C_A)^\sharp \xrightarrow{\eta_A^\sharp} C_A^\sharp \xrightarrow{\sim} U_\sharp D(A). \tag{19.24}$$

It preserves the full operations and both native vacuum identities. It takes the bar pointing to its outgoing transpose to $J^\sharp$. The comparison remains an anti-equivalence after the declared weak equivalences are inverted, including their mapping spaces.

Proof. The adjoint representation of $\mathfrak{sl}_2$ has

$$\mathrm{End}_{\mathfrak{g}}(\mathfrak{g}) = k, \qquad \mathrm{Hom}_{\mathfrak{g}}(\mathfrak{g} \otimes \mathfrak{g}, \mathfrak{g}) = k[\,,\,].$$

Its exterior square is the adjoint representation. Its symmetric square is the sum of the five-dimensional irreducible and the invariant line.

Thus (19.17) forces the recovered bracket to be $[x, y] \otimes m(a, b)$. Graded antisymmetry makes m graded commutative. Jacobi on $e \otimes a, e \otimes b, f \otimes c$ gives $a(bc) = (-1)^{|a||b|} b(ac)$, and hence

$$(ab)c = (-1)^{(|a|+|b|)|c|} c(ab) = (-1)^{|b||c|} a(cb) = a(bc).$$

The scalar current supplies the unit.

Equivariance makes the differential, translation and each marked jet derivation equal to $1 \otimes d_A, 1 \otimes T$ and $1 \otimes \partial_t$. The Lie derivation identities become the product derivation identities. A transposed core morphism is $1 \otimes f$. Its bracket equation is exactly multiplicativity of f. Its other equations give the stated input morphism conditions. This recovers objects and maps.

The inverse comparisons are $a \mapsto (x \mapsto x \otimes a)$ and inverse dual evaluation of $\mathfrak{g} \otimes R(B) \to L_B$. They extend uniquely through the completed core and its localization. They commute with the symmetric-ring actions and pair multipliers, so preserve the actual native fields and products. Their triangles hold on generators and therefore on the complete presentations.

The formal-test calculation identifies the two classes of weak equivalences. The exact R_2-dual is justified by its Frobenius pairing. Thus the inverse functors descend to the localized categories. The universal property of localization retains the inverse comparisons and all mapping spaces.

Finally (19.23) and the bar marking give (19.24). The three-group factor identity proves coherence with the tensor comparisons. The ambient field unit, obtained from the zero state algebra, is R_2 and realizes to K. Its unit map supplies the native vacuum.

The scalar-current object B_k instead realizes to $J^\sharp$. The map to that object is $v_A^\sharp$, and $v_A^\sharp \eta_A^\sharp = (\eta_A v_A)^\sharp$. The augmentation supplies its section. This proves the pointing and both vacuum assertions. □

The theorem uses the bar contact marking, all jet actions and the split quadratic current core. An arbitrary enhancement with the same unmarked coefficient algebra is a larger recognition problem. Even inside the stated categories, coefficient framings and coefficient arrows contain information that an unframed state isomorphism forgets.

19.9 The cubic enhancement space and its arrows

An enhancement of a coefficient algebra P is a native object A together with an equivalence $U(A) \simeq P$. Work in the categories localized at their declared weak equivalences. The space of enhancements is the homotopy fiber, over P, of the map between the maximal subgroupoids of the native and coefficient categories.

Take A_0 from (19.16), and put $C_0 = C_{A_0}$, $P_0 = \Omega_\star C_0$ and $E_0 = C_0^\sharp$. We write coefficient maps in coalgebra coordinates on C_0. Bar–cobar identifies them with maps of P_0. Transposition identifies them, with composition reversed, with maps of E_0. A scalar-pointed map commutes with both maps induced by $k \to A_0 \to k$.

All coefficient endomorphisms

Let $\mathfrak{m} = V \oplus Q$. For $v \in A_0[z]$ and $p \in k[z]$, define

$$J_n(v) = \frac{(\partial_z + T)^n}{n!} v, \qquad S_p(e_n) = J_n(pe_0) = \sum_{j=0}^{n} \frac{p^{(j)}(z)}{j!} e_{n-j}.$$

Extend S_p multiplicatively, fixing $k[z]$. Horizontality of a singleton map $F(z)$ means $[\partial_z + T, F] = 0$. Its field equation is

$$F(y)Y(a,u)b = Y(F(y+u)a,u)F(y)b. \tag{19.25}$$

The shifted position of the first input is essential.

For this full contact system, a coefficient map is determined by its singleton. The residue-lattice description proves this. On n positions the contact complex is a module in degree $-n$. It embeds in the open direct image from the fully distinct locus.

The module is the intersection of the pair residue kernels. Cuts determine a map on that locus. The embedding then determines its extension. Maps between equally shifted modules have no negative Ext groups, so their mapping spaces are discrete. Limits over the collision diagram retain this discreteness.

For completeness, concentration of the contact complex follows by induction on the number of positions. Off the small diagonal it splits into two smaller groups. The remaining cokernel is a principal-part residue on the small diagonal. Insert the vacuum in one colliding input to lift each principal part.

Its other residues vanish by the residue-kernel condition. This proves surjectivity and concentration. The finite complex of flat coefficients remains exact under coefficient extension. This also justifies its use over R_2.

Naturality of every Laurent-multiplied binary boundary gives (19.25). Both cut orders retain unmultiplied exchange. Conversely a horizontal singleton satisfying these field and exchange equations is placed at each block. The field equation intertwines adjacent residues, exchange intertwines nonconsecutive passages, and horizontality retains normal derivatives. It therefore extends to the full coefficient map.

Theorem 19.9.1 *(Coefficient endomorphisms of the cubic system).* Every scalar-pointed coefficient endomorphism is uniquely $F_{p,v}$, with $p \in k[z]$ and $v \in \mathfrak{m}[z]$, where

$$F_{p,v}(1) = 1, \qquad F_{p,v}(e_n) = J_n(pe_0) + \hbar J_n(v), \tag{19.26}$$

extended multiplicatively. Composition is

$$(p, v) \circ (q, w) = (pq, qv + S_p(w)). \tag{19.27}$$

Proof. Reduce F modulo $\hbar$. The constant field coefficient makes F_0 an augmented algebra map. Let $f = F_0(e_0)$. If its largest jet index is $N > 0$, then $\partial_{N+1} f = e_0 \partial f / \partial e_N \neq 0$. In charge at most two, multiplication by e_0 does not kill this nonzero derivative.

The exchange equation on $e_0 \otimes e_0$ is

$$C_1(u)(f(y+u) \otimes f(y)) = -u^{-1} f(y+u) \otimes f(y).$$

The left side has nonzero coefficient

$$[u^{-2N-1}] = (-1)^{N+1} \binom{2N}{N} \partial_{N+1} f(y) \otimes \partial_{N+1} f(y).$$

The two tensor factors are free over $k[y]$. The right side has at most a simple pole, a contradiction. Hence $N = 0$.

Write $f = pe_0 + be_0^2$. The simple-pole equation is $\partial_1 f \otimes \partial_1 f = f \otimes f$. Its bidegree $(2, 2)$ coefficient gives $4b^2 = b^2$, hence $b = 0$. Horizontality then forces $F_0 = S_p$. The displayed formula for S_p shows that it commutes with every jet derivation and satisfies the field equation.

Write $F = S_p + \hbar G$. A first-order correction and a quantum contraction together have order $\hbar^2$, so the remaining equation is classical. It says $G(1) = 0$ and $G(ab) = G(a)S_p(b) + S_p(a)G(b)$.

Horizontality determines $G(e_n) = J_n(v)$ from $v = G(e_0) \in \mathfrak{m}[z]$. Such a derivation preserves I^3, since each generator image has positive charge. The singleton criterion proves existence and uniqueness of the full map. Evaluating a composite on e_0 gives (19.27). □

For example $S_z(e_n) = ze_n + e_{n-1}$, where $e_{-1} = 0$. The term e_0 in $S_z(e_1)$ is forced by horizontality. This map commutes with all jets but is not a constant native state map.

If only the empty unit and counit are fixed, there is also a map Z vanishing on every nonempty coefficient. Every other map is locally unital and has (19.26), with $v \in A_0[z]$ permitted when $p = 0$. Indeed the field equation makes $F(1)$ an idempotent, hence zero or one. A zero value forces the map to vanish on nonempty support.

For value one and $p \neq 0$, a scalar part v_{sc} would give $3\hbar p^2 v_{sc} e_0^2$ in the cubic relation, so it must vanish. For $p = 0$, products of two positive generator images already vanish, and impose no such condition. Composition still has the displayed formula, and Z is absorbing. In particular $F_{0,v} F_{0,w} = F_{0,w_{sc}}$. The scalar-pointed local projection $F_{0,0}$ preserves the local vacuum and differs from Z.

The entire enhancement fiber

An invertible coefficient map has $p = a \in k^\times$. In the coordinates $F_{a,av}$ its group is

$$\Gamma = \mathfrak{m}[z] \rtimes k^\times, \qquad (v, a)(w, b) = (v + \vartheta_a w, ab), \quad \vartheta_a(w_V + w_Q) = w_V + a w_Q. \tag{19.28}$$

The native endomorphisms are exactly $s_\lambda(e_n) = \lambda e_n$, $\lambda \in R_2$. Charge and $\ker(\delta_2|_V) = ke_0$ determine the seed image, and translation and multiplication determine the map. The native automorphism image is therefore $H = \{(be_0, a) : b \in k,\ a \in k^\times\}$.

Theorem 19.9.2 *(Cubic enhancement fibers).* Within the two stated native categories, every enhancement of P_0, respectively E_0, is equivalent to A_0, respectively $D(A_0)$, with a coefficient framing. Its enhancement space is

$$\mathrm{Enh}_*(P_0) \simeq \mathrm{Enh}_\sharp(E_0) \simeq (\Gamma/H)_{\mathrm{disc}} \simeq (\mathfrak{m}[z]/ke_0)_{\mathrm{disc}}. \tag{19.29}$$

The quotient Γ/H is a right-coset set.

Proof. Bar–cobar turns an enhancement into $C_A \simeq C_0$. Singleton cohomology and faithful scalar extension by $k[z]$ and R_2 force $H^i(A) = 0$ for $i \neq 0$. The map $A \to H^0(A)$ is a charged jet quasi-isomorphism: its boundary ideal is stable under all markings. We may therefore work with a degree-zero algebra.

The residue-lattice criterion gives an invertible horizontal polynomial singleton. Modulo $\hbar$, its constant field coefficient is an algebra isomorphism over $k[z]$. Evaluation at $z = 0$ gives $A \cong A_0$ as ordinary algebras.

If $d = \dim E_A$, its map on augmentation indecomposables identifies $\mathcal{D}_X^d$ with $\mathcal{D}_X$. These are the free Weyl modules generated by the seeds. For the Bernstein filtration, $\dim_k F_m\mathcal{D}_X = (m+1)(m+2)/2$. An isomorphism and its inverse have bounded filtration displacement, so comparison of the leading quadratic growth gives $d = 1$.

The ordinary algebra isomorphism transports $\mathfrak{m}^3 = 0$ and the isomorphism $\mathrm{Sym}^2(\mathfrak{m}/\mathfrak{m}^2) \to \mathfrak{m}^2$. Generation in charge one therefore leaves no quadratic relation and kills every cubic product. The one-dimensional seed gives precisely the ideal I^3. Thus A is a charged jet copy of A_0.

Maps between degree-zero objects in this localized nonpositive dg category are their ordinary discrete sets. Indeed H^0 is left adjoint to the inclusion of degree-zero objects. It preserves weak equivalences and has identity counit there. Coefficient maps are discrete by the lattice criterion.

The enhancement fiber is consequently the right action groupoid $\Gamma//H$. This action is free, so the groupoid is equivalent to the discrete coset set. Right multiplication by (be_0, c) sends (v, a) to $(v + be_0, ac)$, giving the last identification in (19.29). The native duality proves the same assertion on the opposite side. □

The set in (19.29) is not a quotient group. For $a \neq 1$,

$$(e_0^2, 1)(0, a)(e_0^2, 1)^{-1} = ((1-a)e_0^2, a) \notin H.$$

The transitive action groupoid of Γ on its coset set is BH. It differs from the enhancement fiber, whose action by H on Γ is free.

Relative arrows and a higher-precision defect

For a realization $U : \mathcal{N} \to \mathcal{A}$ and a coefficient chain $a_0 \to \cdots \to a_n$, take the homotopy fiber of

$$\mathrm{Fun}([n], \mathcal{N})^{\simeq} \longrightarrow \mathrm{Fun}([n], \mathcal{A})^{\simeq}$$

over that chain. The superscript means the maximal subgroupoid. This *relative chain space* retains the enhancements at all vertices and their compatible native arrows. The case $n = 0$ is the enhancement space above.

PROPOSITION 19.9.3 *(Lifting coefficient arrows).* For fixed frames g_s, $g_t \in \Gamma$, a coefficient map F has a native lift exactly when

$$F = g_t s_\lambda g_s^{-1} \qquad \text{for some } \lambda \in R_2.$$

The lifting space is empty or a point. Allowing both frames to vary, $F_{p,v}$ lifts somewhere precisely when $p \in k^\times$, or $p = 0$ and $v \in k e_0$. The map Z never lifts.

Proof. Theorem 19.9.2 supplies all objects, and the maps s_λ are all their native endomorphisms. Distinct λ have distinct singleton values, which proves the fixed-frame assertion. If λ has nonzero reduction it is a unit, and changing one frame produces every coefficient automorphism.

For $\lambda = \hbar b$, let a_s, a_t be the classical scalings of the two frames. The composition law gives

$$g_t s_{\hbar b} g_s^{-1} = s_{\hbar b a_t/a_s}.$$

Every first-order correction in a frame acquires a second factor of $\hbar$ and vanishes. Only the constant e_0 direction can therefore lift in this case. Nonconstant p and the map Z meet neither possibility. □

For a chain (F_i), all lifts are consequently described by $F_i = g_i s_{\lambda_i} g_{i-1}^{-1}$, modulo changes at each vertex

$$g_i \mapsto g_i h_i^{-1}, \qquad s_{\lambda_i} \mapsto h_i s_{\lambda_i} h_{i-1}^{-1}, \qquad h_i \in H.$$

The action on the frames is free. This gives a discrete relative chain space.

Faces compose the adjacent scalars and degeneracies insert 1. The anti-equivalences and (19.24) identify it with the relative chain space over $\mathcal{K}(a_n) \to \cdots \to \mathcal{K}(a_0)$. Indeed a frame g becomes $(g^{-1})^\sharp$, and

$$(g_s^{-1})^\sharp s_\lambda^\sharp g_t^\sharp = (g_t s_\lambda g_s^{-1})^\sharp.$$

This identity retains empty lifting spaces as well as the nonempty ones.

For instance S_z has no lift under any reframing. Neither does F_{0,e_1}, whose singleton satisfies

$$F_{0,e_1}(e_n) = \hbar(n+1)e_{n+1}, \qquad [\partial_2, F_{0,e_1}](e_0) = \hbar e_0.$$

The latter preserves the coefficient field diagram but not the marked native jet action. Its relative space is empty on both sides of the duality.

The fixed first-order precision is also substantive. Define a horizontal derivation on A_0 by

$$D(e_n) = \sum_{i+j=n} e_i e_j.$$

The formula satisfies $[D, T] = 0$, as follows by differentiating the two factors and collecting their coefficients. The map $1 + \hbar D$ is a coefficient automorphism over R_2.

PROPOSITION 19.9.4 *(A frame obstructed at the next precision).* Keep the exchange kernel $w(u) = 1 - \hbar/u$. The frame $1 + \hbar D$ has no extension over $R_3 = k[\hbar]/(\hbar^3)$ preserving exchange, even with an arbitrary position-dependent second-order correction.

Proof. Write a proposed extension as $1 + \hbar D + \hbar^2 K$. Exchange has expansion $1 + 2\hbar C_1 + \hbar^2 \mathcal{S}_2$. Its order-two intertwining defect is forced to be $2[C_1, D \otimes 1 + 1 \otimes D]$. Both the new correction K and $\mathcal{S}_2$ commute with the identity at this order.

On $e_0 \otimes e_0$ the defect is

$$-\frac{2}{u}(e_0^2 \otimes e_0 + e_0 \otimes e_0^2) \neq 0.$$

The terms have separate bidegrees $(2,1)$ and $(1,2)$. Multiplying the two tensor factors would kill both by $I^3 = 0$, but exchange acts before that multiplication. No second-order correction can remove the displayed defect. □

This is an obstruction to extending the specified frame with the fixed exchange kernel. The native duality and the exhaustive fiber calculation remain assertions at R_2. A compatible tower requires its own objects, surviving frames and comparison maps at every precision. More general native enhancements also require a separate recognition theorem or an obstruction on their declared domain.

19.10 Fields can forget a jet marking

The constituent identities in the charged-current presentation contain more information than the commutation relations of its jet derivations. We now vary those identities while retaining the entire rational field. This gives a larger marked category in which the standard recognition statement fails, together with a duality on an explicit family inside that category.

Continue over $R_2 = \mathbb{C}[\hbar]/(\hbar^2)$. Use the cubic algebra $A = R_2 \oplus V_{R_2} \oplus \operatorname{Sym}^2 V_{R_2}$ of (19.16), with $V = \bigoplus_{n\geq 0} \mathbb{C}e_n$. The differential is zero, e_n has charge one and weight $n+1$, and $\hbar$ has weight zero.

Keep T and the standard δ_i of (19.14), and set $N = \delta_1$. On charge one,

$$\delta_{m+1} = \delta_2^m.$$

This identity concerns compositions on V. It does not identify δ_{m+1} with a power of a derivation on the whole algebra.

Definition 19.10.1 *(Filtered jet marking).* A *filtered jet marking* on a nonpositive commutative dg state algebra consists of degree-zero chain derivations T, J_i satisfying

$$J_1 = N, \qquad [J_i, J_j] = 0, \qquad [J_i, T] = (i-1)J_{i-1}, \qquad J_0 = 0.$$

They annihilate the unit and preserve charge. Each J_i is bounded for the weight filtration.

Only finitely many act nontrivially on each state. The rational fields and exchange are (19.15) with δ_i replaced by J_i. Morphisms are constant R_2-linear dg algebra maps preserving charge, translation, every J_i, the fields and exchange. Weak equivalences are the state quasi-isomorphisms among these maps.

In particular $[d, J_i] = 0$ is required. Exact operator weight $1 - i$ and the constituent identities on charge one are additional conditions. The following family satisfies neither additional condition when its parameter is nonzero.

Proposition 19.10.2 *(Equal fields with distinct markings).* For $\kappa \in \mathbb{C}$, put

$$J_1^\kappa = N, \qquad J_2^\kappa = \delta_2, \qquad J_i^\kappa = \delta_i + \hbar\kappa \binom{i-1}{2} \delta_{i-2} \quad (i \geq 3).$$

These are filtered jet markings on A. Write A^κ for the resulting marked algebra. Their rational fields, exchange and full collision coefficients are identical. Distinct parameters remain inequivalent after inverting marked state quasi-isomorphisms. For $\kappa \neq 0$ they are not equivalent there to a standard charged-jet quotient.

Proof. The operators are linear combinations of commuting derivations. Translation covariance follows from

$$\binom{i-1}{2}(i-3) = (i-1)\binom{i-2}{2}$$

for $i \geq 4$. The added term at $i = 3$ is $\hbar\kappa N$, which commutes with T. On e_n both terms vanish for $i > n+3$. The derivation rule proves finite support on every state. Their two weight shifts are $1-i$ and $3-i$.

The contraction in (19.15) has an external factor $\hbar$. Each change of a marked operator has another factor $\hbar$. Thus $\hbar C_1^{J^\kappa} = \hbar C_1^{\delta}$ over the common base R_2. The fields agree before principal parts are taken. Every iterate, normal derivative, spectator and collision comparison therefore agrees.

On the charge-one complex define

$$\Xi_2 = J_3 - J_2^2.$$

It acts on cohomology because the markings are chain maps. In this family

$$\Xi_2^\kappa = \hbar\kappa\, 1_{V_{R_2}}.$$

An invertible intertwiner between parameters κ, λ would imply $\hbar(\kappa-\lambda)1_{V_{R_2}} = 0$. Freeness forces $\kappa = \lambda$. The same reasoning applies to every zigzag, since its cohomology maps are invertible intertwiners. A standard charged-jet quotient has $\Xi_2 = 0$, which gives the last assertion. □

The smallest calculation is $J_2 e_0 = 0$ and $J_3^1 e_0 = \hbar e_0$. The interaction is also nonzero:

$$[\hbar u^{-1}]Y(e_0, u)e_0 = e_0^2.$$

The quotient by the square of the augmentation ideal would retain a marking defect but kill this product. Nor can the infinite jet orbit be replaced by a nonzero finite-dimensional charge-one space in characteristic zero: $[J_2, T] = 1$ would contradict the trace of a commutator.

The chain condition detects the distinction

If the marking need not commute with the differential, a contractible extension can erase the preceding distinction. Let $\widetilde{A}$ be the graded commutative algebra on species e_n, v_n, u_n, truncated at total charge three. Give e_n, v_n degree zero and u_n degree -1, with $du_n = v_n$ and $de_n = dv_n = 0$. All species have weight $n+1$. Use standard shifts and translation on each.

On their linear span set $Me_n = 0$, $Mv_n = e_n + v_n$, $Mu_n = u_n$. Set $\widetilde{J_1} = N$ and $\widetilde{J_2} = \partial_2$. For $i \geq 3$ define on generators

$$\widetilde{J_i}x_n = x_{n-i+1} + \hbar\binom{i-1}{2}Mx_{n-i+3},$$

then extend as derivations. The shifts commute with M, so these derivations commute and obey the same translation identity. Their fields are still the standard dg fields: a correction to a marking acquires a second $\hbar$ in the contraction.

There are marked dg algebra maps

$$A^0 \xrightarrow{i_0} \widetilde{A} \xleftarrow{i_1} A^1, \qquad i_0(e_n) = e_n, \quad i_1(e_n) = e_n + v_n.$$

To verify their quasi-isomorphism property, let p kill u_n, v_n and fix e_n. Let K be the degree--1 derivation $K(v_n) = u_n$, $K(e_n) = K(u_n) = 0$. Then $dK + Kd$ counts the factors from the two contractible species.

On a monomial containing $r > 0$ such factors put $H = K/r$, and put $H = 0$ on pure e-monomials. Here r is one or two. Consequently

$$dH + Hd = 1 - i_0 p.$$

This proves that i_0, p are quasi-isomorphisms. Since $pi_1 = 1$, so is i_1.

The marking nevertheless fails the chain condition:

$$[d, \widetilde{J_3}]u_0 = \hbar v_0 - \hbar(e_0 + v_0) = -\hbar e_0.$$

The cohomologous representatives e_0 and $e_0 + v_0$ have images differing by a nonzero cohomology class. Thus $\widetilde{J_3}$ does not induce a cohomology operator. This span is excluded precisely by the chain condition in Definition 19.10.1.

All markings with fixed first jets

Theorem 19.10.3 *(Polynomial classification on the cubic carrier).* Fix A, T, N and $J_2 = \delta_2$. Every filtered jet marking reducing to δ_i modulo $\hbar$ has the unique form

$$\begin{aligned} J^c_{m+1} &= \delta_{m+1} + \hbar \sum_{r=2}^{m} \binom{m}{r} c_r \delta_{m-r+1}, \\ c(t) &= \sum_{r \geq 2} c_r \frac{t^r}{r!} \in t^2\mathbb{C}[t]. \end{aligned} \tag{19.30}$$

All these markings have the same fields. Distinct polynomials give distinct marked equivalence classes, including under chain-compatible nonpositive dg zigzags. Exact operator weight $-m$ for J_{m+1} forces $c = 0$.

Proof. Write $D = \delta_2$. Commutation with D puts $J_{m+1}e_0$ in $\ker(D|_V) = R_2 e_0$, say $a_m e_0$. The first two markings give $a_0 = 1$, $a_1 = 0$. Reduction gives $a_m = \hbar c_m$ for $m \geq 2$. Finite support on e_0 makes (c_m) finitely supported.

Translation covariance is the recursion

$$(n+1)J_{m+1}e_{n+1} = TJ_{m+1}e_n + mJ_m e_n.$$

Starting at e_0, induction gives

$$J_{m+1}e_n = \sum_{q=0}^{\min(m,n)} \binom{m}{q} a_{m-q} e_{n-q}.$$

The induction uses $(n-q+1)\binom{m}{q} + m\binom{m-1}{q-1} = (n+1)\binom{m}{q}$. Substitute the a_m to obtain (19.30). The derivation property determines the operator on all products.

Conversely the displayed operators commute. The identity $\binom{m}{r}(m-r) = m\binom{m-1}{r}$ proves translation covariance. If $c_r = 0$ for $r > R$, then $J_{m+1}e_n = 0$ for $m > n + R$. The same external-$\hbar$ calculation as before proves equality of fields.

A marked equivalence induces an invertible cohomology map commuting with D, T. It acts on the D-kernel by a unit $a \in R_2^\times$. Intertwining $J_{m+1}e_0$ gives $\hbar(c_m - c'_m)a = 0$, hence $c_m = c'_m$. Finally an operator of weight $-m$ sends e_0 to weight $1 - m$. There is no such charge-one state for $m \geq 2$, forcing every c_m to vanish. □

This classifies markings on the fixed cubic carrier, with the specified first jets and reduction. It does not classify all algebras realizing its coefficient diagram. Write A^c for the algebra with polynomial marking c.

Compensated moments and the current partner

The current partner retains the marked operators without treating them as constituent power sums. Use the polynomial Chevalley core of $\mathfrak{sl}_2 \otimes A$ from Section 19.8. Its negative transposes are

$$T_B = -(1 \otimes T)^\vee, \qquad D_i^c = -(1 \otimes J_i^c)^\vee.$$

On total charge n, let $p_m = \sum_{a=1}^n x_a^m$, with $p_0 = n$. Constituent polarization gives

$$P_m^c = -D_{m+1}^c = p_m + \hbar \sum_{r=2}^{m} \binom{m}{r} c_r\, p_{m-r},$$

$$\widehat{P}_m = P_m^c - \hbar \sum_{r=2}^{m} \binom{m}{r} c_r\, P_{m-r}^c = p_m.$$

The second equality uses $\hbar^2 = 0$. It supplies the ordinary action of $\Lambda_n = \mathbb{C}[x_1, \dots, x_n]^{S_n}$.

Define B^c by localizing the charge-n core at $d_n = \prod_{a<b}(x_a - x_b)^2$ using this compensated action, with $d_0 = d_1 = 1$. Use the same cross differences and their declared translates for multiple inputs. Define the product and fields by the pair multiplier

$$\Omega_{p,q}(v) = \prod_{a=1}^{p} \prod_{b=1}^{q} \left(1 - \frac{\hbar}{v + x_a - y_b}\right), \qquad \mu_w = \mu_0 \Omega_{p,q}(0).$$

They are independent of c. Each D_i^c is a finite linear combination of standard current derivations, so it extends through these localizations and remains a derivation of μ_w. The three-input multiplier is again $\Omega_{p,q}\Omega_{p,r}\Omega_{q,r}$. Thus the differential, associativity, exchange and vacuum identities hold on the same recipients.

A *compensated current presentation* retains the split core, scalar current, charge, translation, D_i^c, compensated spectral action and rational recipients. Its maps preserve these structures and are linear on core generators. It has the formal-core weak equivalences defined in Section 19.8. Standardization replaces D_{m+1}^c by $\widehat{D}_{m+1} = -\widehat{P}_m$. It leaves the underlying map, core, differential, fields and recipients fixed. Every specified morphism preserves $\widehat{P}_m$, so standardization is a functor to the standard current category.

Apply $U_\sharp$ to this standardized presentation, using the algebra structure induced by its native product and tensor comparison. This defines $U_\sharp$ on the displayed compensated category. Standardization is not claimed to be an equivalence of marked fields or to make this category closed under tensor products.

Let C_0 be their common full coefficient coalgebra and $P_0 = \Omega_\star C_0$. The bar marking and the native product comparison give a natural equivalence

$$(B_\star P_0)^\sharp \xrightarrow{\gamma^\sharp} C_0^\sharp \xrightarrow{\theta_c} U_\sharp(B^c). \tag{19.31}$$

Here θ_c is the inverse of the standard current comparison after standardization. It preserves all collisions, cuts, normal derivatives, spectators and local pointings. The bar pointing remains the composite $J \to C_0 \to B_\star P_0$, separate from the empty-support unit.

Raw moments would give the wrong localization. In the one-parameter family and charge one,

$$P_2^\kappa - (P_1^\kappa)^2 = \hbar\kappa\, 1, \qquad D_3^\kappa + (D_2^\kappa)^2 = -\hbar\kappa\, 1.$$

Since $p_2 = p_1^2$ in $\Lambda_1 = \mathbb{C}[x]$, the raw assignment $p_m \mapsto P_m^\kappa$ does not define an action when $\kappa \neq 0$. Compensation repairs this equation while retaining the marked operator invariant.

Proposition 19.10.4 *(All arrows in the displayed family).* The native maps $A^c \to A^d$ are exactly

$$s_\alpha(1) = 1, \quad s_\alpha(e_n) = \alpha e_n, \quad s_\alpha(e_i e_j) = \alpha^2 e_i e_j,$$
$$\hbar\alpha(c_r - d_r) = 0 \quad (r \geq 2),$$

with $\alpha \in R_2$. Current pullback gives an anti-equivalence between the displayed state and compensated current categories. It commutes with (19.31).

Proof. Charge and D preservation put the image of e_0 in $R_2 e_0$. Translation determines every e_n, and multiplication determines the quadratic states. Intertwining J_{r+1} on e_0 gives the condition on α. Formula (19.30) makes it sufficient on all generators, and product defects acquire further powers of α.

For the reverse construction, scalar-current equivariance makes a transposed linear core map $1 \otimes f$. The quadratic Chevalley equation says $f(ab) = f(a)f(b)$. The scalar-current condition gives the unit. Translation and the marked derivations recover the remaining input equations. This recognition calculation does not use the higher constituent identities.

Pullback by s_α scales charge n by α^n. It commutes with the compensated spectral action and extends through the same localizations. If $c \neq d$, the condition forces $\alpha \in \hbar\mathbb{C}$.

Charge-one images then have a factor $\hbar$, and all images of charge at least two vanish. The residual marked differences therefore vanish on the image, without inverting a zero divisor. The native unit and counit are inverse evaluation on the adjoint-isotypic core, as in Theorem 19.8.3. Their triangles and the standardized comparison prove the assertions. □

For equal parameters every α occurs. For unequal parameters exactly $\alpha \in \hbar\mathbb{C}$ occurs. Two arrows between unequal parameters compose to s_0, the scalar projection followed by its section. This map preserves the native unit. Isomorphisms require equal parameters and $\alpha \in R_2^\times$.

The coefficient frame group Γ and subgroup H of (19.28) are unchanged. Thus the framed subspace supported on these displayed classes is

$$\coprod_{c(t) \in t^2\mathbb{C}[t]} (\Gamma/H)_{\mathrm{disc}}.$$

For frames g_s, g_t, a coefficient arrow F has a native lift between parameters c, d exactly when

$$F = g_t s_\alpha g_s^{-1}, \qquad \hbar\alpha(c_r - d_r) = 0 \quad (r \geq 2).$$

Its relative space is then a point and is otherwise empty. The proof of Proposition 19.9.3 applies in each component: chain compatibility makes cohomology preserve all markings, and the frame action is free. Duality sends g to $(g^{-1})^\sharp$ and reverses arrows. Faces compose the scalars and degeneracies insert their identities.

These cosets are sets over the fixed ring R_2, not a quotient group or an exhaustion of arbitrary unmarked native fields. Recovering a current core and its constituent moments from intrinsic field axioms remains a different recognition problem.

19.11 Curvature is a separate comparison

Coefficient transposition and a contragredient module have specified outputs. Neither identifies two curved field algebras. That comparison must include changes of state. A translation class of curvature can remain invariant under all such changes.

Let K be a Noetherian domain containing a characteristic-zero field. A curved vertex superalgebra here has a degree-one derivation d and a degree-two state w with

$$d^2 = w_{(0)}, \qquad dw \in TB.$$

Complete its PBW state space coefficientwise in an independent degree-zero parameter: $\widehat{B} = B_K[[\varepsilon]]$.

Each coefficient is a finite sum of states. Field identities hold at every finite ε-precision. This completion contains $e^{\varepsilon T}a$. It does not contain an arbitrary derivative series in the coefficient of ε^0.

For $\xi \in \widehat{B}^1$, the changed differential and curvature are

$$d^\xi = d + \xi_{(0)}, \qquad w^\xi = w + d\xi + \tfrac{1}{2}\xi_{(0)}\xi.$$

A comparison is a continuous unital graded field isomorphism preserving T and all modes. It intertwines the changed differentials and carries one changed curvature to the other modulo actual translation. There is no weight-preservation requirement.

These changes are well defined at the chosen completion. Operations are finite Cauchy sums at each precision, and

$$T\widehat{B} = (TB_K)[[\varepsilon]], \qquad \widehat{B}/T\widehat{B} = (B_K/TB_K)[[\varepsilon]].$$

Indeed one may choose a translation primitive separately in each coefficient. The zero-mode identities give $(d^\xi)^2 = (w^\xi)_{(0)}$. In the Lie superalgebra $\widehat{B}/T\widehat{B}$, odd Jacobi then gives $d^\xi w^\xi = 0$. Thus its lift is an actual translation.

A detector on a commutative quotient

Consider

$$C_K = \Lambda_K(\theta, T\theta, T^2\theta, \ldots), \qquad |\theta| = 1, \qquad \partial\theta = \theta T\theta.$$

Its fields are $Y(a,u)b = (e^{uT}a)b$. All nonnegative modes vanish. The odd Leibniz rule gives $\partial^2\theta = 0$, so $\partial^2 = 0$. Represent a degree-two monomial $(T^i\theta)(T^j\theta)$, $i < j$, by the antisymmetric polynomial $X^iY^j - X^jY^i$. Translation becomes multiplication by $X + Y$.

Evaluation at $Y = -X$ has kernel exactly $(X + Y)$ times the antisymmetric polynomials. Division by the monic polynomial $X + Y$ preserves antisymmetry of the quotient. Consequently

$$\ell_3([p]) = -\tfrac{1}{2}[X^3]\,p(X,-X)$$

is well defined on C_K^2/TC_K^2. Its values include

$$\ell_3([\theta T^3\theta]) = 1, \qquad \ell_3([T\theta T^2\theta]) = -1, \qquad \ell_3([\theta T\theta]) = 0.$$

The first two are compatible with $T(\theta T^2\theta) = T\theta T^2\theta + \theta T^3\theta$. Extend the detector coefficientwise to the ε-completion.

LEMMA 19.11.1 *(Automorphisms of the quotient).* Every continuous graded $K[[\varepsilon]]$-linear differential field automorphism of $C_K[[\varepsilon]]$ is $\theta \mapsto e^{sT}\theta$ for $s \in \varepsilon K[[\varepsilon]]$. It induces the identity modulo actual translation.

Proof. The image of θ is $P(T)\theta$, where $P \in K[T][[\varepsilon]]$ is a unit. Commutation with ∂ gives

$$P(X)P(Y)(Y - X) = P(X + Y)(Y - X).$$

Cancel $Y - X$ in the domain. Invertibility gives $P(0) = 1$. Differentiation at $Y = 0$ yields $P'(X) = sP(X)$, so $P(X) = e^{sX}$.

Its coefficient at ε^0 must be polynomial in X. Characteristic zero and the domain condition force s to have zero constant coefficient. Conversely such an exponential and its inverse are defined in the specified completion. For any completed state a,

$$(e^{sT} - 1)a = T\left(\sum_{n\geq 1} \frac{s^n}{n!} T^{n-1} a\right).$$

The displayed primitive converges ε-adically. □

Theorem 19.11.2 *(An invariant of changed curvature).* Suppose a family of curved field algebras has closed graded field ideals I preserved by every graded field isomorphism between its members. Assume $dI \subset I$ and identify their completed quotients with $(C_K[[\varepsilon]], \delta)$. If

$$\pi(w) = \frac{c}{24}\theta T^3 \theta,$$

then $24\ell_3([\pi(w^{\xi})]) = c$ for every change of state. Every comparison above preserves c.

Proof. Write $\pi(\xi) = a(T, \varepsilon)\theta$. Zero modes vanish in the quotient, so the changed differential remains δ there. The curvature class is

$$[\pi(w^{\xi})] = \frac{c}{24}[\theta T^3 \theta] + a(0, \varepsilon)[\theta T \theta].$$

Every positive power of T in $\delta\pi(\xi)$ is an actual translation. The detector kills the second summand. A comparison descends to a differential automorphism of the quotient. The lemma makes its action on translation classes the identity, proving invariance. □

This obstruction is conditional on the intrinsic quotient and the specified completion. A reflection $c \mapsto c'$ can be implemented by such a comparison only when $c = c'$. Enlarging the algebra or changing the recipient may change the problem. An uncurving of a larger algebra therefore requires an additional comparison with the original one.

19.12 The arithmetic evaluation

An arithmetic application needs a map from its categorical pairing to an analytic pairing. We first specify the analytic reflection and its normalization. The remaining question can then be stated as a comparison of actual maps.

Half densities and Mellin reflection

On $\mathbb{R}_{>0}$ use Haar measure dt/t. Define

$$\mathcal{H} = L^2(\mathbb{R}_{>0}, t^{1/2}\, dt/t), \qquad (\mathcal{J}f)(t) = t^{-1/2} f(t^{-1}).$$

The map

$$W : \mathcal{H} \longrightarrow L^2(\mathbb{R}, dx), \qquad (Wf)(x) = e^{x/4} f(e^x)$$

is unitary by the substitution $t = e^x$.

The factor $e^{x/4}$ is the square root of the density relating the two measures. Direct calculation gives $W\mathcal{J}W^{-1}h(x) = h(-x)$. Thus

$$\mathcal{J}^2 = 1, \qquad \mathcal{J}^\dagger = \mathcal{J}.$$

The adjoint here belongs to the displayed Hilbert pairing.

For $f \in C_c^\infty(\mathbb{R}_{>0})$ define

$$(\mathcal{M}f)(s) = \int_0^\infty f(t)t^{s/2}\frac{dt}{t}.$$

This is entire. Substitution $t = u^{-1}$ proves

$$\mathcal{M}(\mathcal{J}f)(s) = (\mathcal{M}f)(1-s). \tag{19.32}$$

Complex conjugation satisfies $\mathcal{M}(\overline{f})(s) = \overline{\mathcal{M}f(\overline{s})}$. More explicitly,

$$\mathcal{M}f(1/2 + i\tau) = \int_{\mathbb{R}} (Wf)(x)e^{i\tau x/2}\,dx.$$

These formulas fix both the reflection and its adjoint. Using unweighted inversion on the same Mellin convention would give $s \mapsto -s$ instead.

The Gaussian and both boundary poles

Fix the Fourier convention $\widehat{f}(y) = \int_{\mathbb{R}} f(x)e^{-2\pi ixy}\,dx$. For $f_t(x) = e^{-\pi tx^2}$,

$$\widehat{f_t}(y) = t^{-1/2}e^{-\pi y^2/t}.$$

For completeness, integration by parts at $t = 1$ gives $\widehat{f_1}'(y) = -2\pi y\widehat{f_1}(y)$. The Gaussian integral is one, as follows by squaring it and using polar coordinates. The differential equation gives the formula at $t = 1$, and scaling proves it for every $t > 0$.

Periodize f_t over $\mathbb{Z}$. The series and all derivatives converge uniformly on compact sets. Its Fourier coefficient at m is $\widehat{f_t}(m)$. Both Fourier series converge absolutely, so evaluation at zero gives the theta identity

$$\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t} = t^{-1/2}\theta(t^{-1}).$$

This is a lattice theta series. The oscillator character $\prod_{n\geq 1}(1-q^n)^{-1}$ is a different series: its coefficient at q is one, whereas that of $\sum_{n\in\mathbb{Z}} q^{n^2}$ is two.

PROPOSITION 19.12.1 *(Completed Mellin evaluation).* For $\operatorname{Re} s > 1$,

$$\Lambda_\zeta(s) := \pi^{-s/2}\Gamma(s/2)\zeta(s) = \frac{1}{2}\int_0^\infty (\theta(t)-1)t^{s/2}\frac{dt}{t}.$$

Its meromorphic continuation is

$$\begin{aligned}\Lambda_\zeta(s) = &-\frac{1}{s} - \frac{1}{1-s}\\ &+ \frac{1}{2}\int_1^\infty (\theta(t)-1)\left(t^{s/2} + t^{(1-s)/2}\right)\frac{dt}{t}.\end{aligned}$$

It has residues -1 and 1 at zero and one, respectively, and $\Lambda_\zeta(s) = \Lambda_\zeta(1-s)$.

Proof. Termwise integration is absolutely convergent for $\operatorname{Re} s > 1$. Substitution $u = \pi n^2 t$ in each positive-integer term gives $\pi^{-s/2}\Gamma(s/2)n^{-s}$. The two signs of n cancel the factor $1/2$.

Split the integral at one. On $(0,1)$ use

$$\theta(t) - 1 = t^{-1/2}(\theta(t^{-1}) - 1) + t^{-1/2} - 1.$$

Inverting t in the first summand gives the integral with exponent $(1-s)/2$ over $(1,\infty)$. The last two terms integrate to $1/(s-1) - 1/s$. The remaining integral is entire: the theta tail decays exponentially, uniformly against every power and every power of $\log t$ on compact s-sets. The formula proves the residues and reflection. □

The theta tail is outside $\mathcal{H}$: near zero it has leading term $t^{-1/2}$. Its Mellin evaluation therefore uses the displayed subtraction and continuation. It cannot be obtained by applying an everywhere-defined Hilbert pairing to that state.

On boundary monomials, $\mathcal{J}1 = t^{-1/2}$ and $\mathcal{J}(t^{-1/2}) = 1$. Their integrals over $(0,1)$ produce the two polar terms. An arithmetic comparison must retain these boundary contributions as well as its native vacuum. No identification of that vacuum with either boundary monomial has been assumed.

The entire normalization $\xi(s) = s(s-1)\Lambda_\zeta(s)/2$ removes the poles and is still reflection invariant. Multiplication by this polynomial is not a construction of the missing arithmetic evaluation. Likewise Euler inversion to $1/\zeta(s)$ changes the scalar function without constructing the involution in (19.32).

Detecting a central defect

Let V be a complex vector space, $J : V \to V$ an involution, and $E : V \to \mathscr{M}(\mathbb{C})$ a linear map to meromorphic functions. Fix $v, w \in V$ and scalars $\kappa, \kappa^!$. The following criterion keeps the categorical construction separate from its consequence.

Proposition 19.12.2 *(Detection of a specified central defect).* Suppose

$$v - Jv = (\kappa + \kappa^!)w, \qquad E(v)(s) = \Lambda_\zeta(s), \qquad E(Jv)(s) = \Lambda_\zeta(1-s),$$

and $E(w)$ is not identically zero. Then $\kappa + \kappa^! = 0$ if and only if $\Lambda_\zeta(s) = \Lambda_\zeta(1-s)$. The same equivalence holds for the entire normalization ξ.

Proof. Apply E to the defect equation:

$$\Lambda_\zeta(s) - \Lambda_\zeta(1-s) = (\kappa + \kappa^!)E(w)(s).$$

A scalar multiple of a nonzero meromorphic function vanishes exactly when the scalar does. The polynomial $s(s-1)/2$ is nonzero and reflection invariant, which proves the assertion for ξ. □

For the forward implication, equivariance $E(Jx)(s) = E(x)(1-s)$ and the defect equation suffice. For the converse, detection of the stated defect is necessary. For example, on $\mathbb{C}^2$ let $J(x,y) = (y,x)$ and $E(x,y) = x + y$. The evaluations of $v = (1,0)$ and Jv agree, but $v - Jv = (1,-1) \neq 0$ lies in $\ker E$. Full injectivity of E is unnecessary. Nonvanishing on the specified defect line is the relevant hypothesis.

The scalar reflection has been proved independently above. Consequently this proposition tests a proposed arithmetic construction: if its defect and evaluation identities hold, its level sum must vanish. An equivalence of categories without those identities gives no value for that sum.

Local assembly and the remaining comparison

Suppose presentable stable R-linear categories $C_v, \mathcal{D}_v$ have chosen objects c_v, d_v at each place. For a finite set F take their tensor products over R. Use insertion of the chosen objects as transition functors. Compatible local equivalences $\Psi_v : C_v \simeq \mathcal{D}_v$ with coherent identifications $\Psi_v(c_v) \simeq d_v$ give an equivalence

$$\varinjlim_{F} \bigotimes_{v \in F, R} C_v \simeq \varinjlim_{F} \bigotimes_{v \in F, R} \mathcal{D}_v.$$

Indeed they give an equivalence at every finite tensor stage and commute with its transition maps. Colimits preserve this equivalence of diagrams.

For arithmetic categories one must construct the common coefficient action, local functors and compatible pointings. A unital map $\mathbb{F}_p \to \mathbb{C}$ cannot supply a coefficient comparison, since it would send $p \cdot 1 = 0$ to $p \cdot 1 \neq 0$. A common integral base with two derived fibers is a different, possible construction. Identifying the categorical colimit with an analytic restricted tensor product also requires its own map.

Question 19.12.3 *(Completed arithmetic duality and evaluation).* Construct the archimedean coefficient complex and the pairing of a functorial completed arithmetic Koszul duality. Construct an operation-preserving comparison to theta and Mellin reflection with its specified half-density normalization and adjoint. The comparison must transport both polar terms and the native vacuum, as well as the products, collision operations and completions on its declared domain.

The first missing map is from this arithmetic coefficient complex and its duality pairing to the analytic recipient with the evaluation above. To obtain a level criterion, it must also supply the defect identity and detect its defect line. The coefficient anti-equivalence, the marked native examples and the scalar theta theorem each provide positive structures. Their comparison remains the mathematical construction asked for in the question.

Chapter 20

Centers, actions, and representation tensors

A center records operations that commute with a specified action. Its definition therefore depends on the objects allowed to act and on the meaning of commutation. An algebra homomorphism need not transport even an ordinary center. An equivalence of module categories can transport a derived center, provided it retains the coefficient action. These two facts determine the first comparison we need.

For collision coefficients there is another choice. Convolution combines inputs on disjoint configurations, whereas diagonal tensor combines coefficients at the same configuration. Their units differ. The center of a convolution algebra and the universal diagonal actor thus solve different problems. Factorization and a specified local vacuum impose further conditions on an actor.

We first construct scalar Hochschild centers and their Morita comparisons. Normal differential modules then give explicit centers whose products, brackets, and coefficient dependence can be computed. We next compare the word and collision constructions and examine diagonal actions. The finite fusion example retains both its braided center and the distinguished algebra that recovers its boundary category. These data specify what the arithmetic comparison must preserve.

20.1 Maps and centers

Let k be a field and let A be a unital associative k-algebra. Its *ordinary center* is

$$Z_{\mathrm{alg}}(A) = \{a \in A : ab = ba \text{ for every } b \in A\}.$$

It is a commutative algebra. A homomorphism $f : A \to B$ sends it into the centralizer of $f(A)$ in B. That centralizer can be larger than the center of B.

Example 20.1.1 *(A central element with noncentral image).* Take

$$A = k \times k, \qquad B = M_2(k), \qquad f(a,b) = \begin{pmatrix} a & 0 \\ 0 & b \end{pmatrix}.$$

The element $(1,0)$ belongs to $Z_{\mathrm{alg}}(A)$. Its image is E_{11}, and

$$E_{11}E_{12} - E_{12}E_{11} = E_{12} \neq 0.$$

Thus f does not restrict to a map $Z_{\mathrm{alg}}(A) \to Z_{\mathrm{alg}}(B)$. The centralizer of the diagonal subalgebra is the diagonal subalgebra itself, whereas $Z_{\mathrm{alg}}(B) = kI_2$.

The derived construction retains this distinction. Put $A^e = A \otimes_k A^{\mathrm{op}}$, so that left A^e-modules are A-bimodules. The *scalar Hochschild center* is

$$Z_k(A) = R\,\mathrm{Hom}_{A^e}(A, A).$$

For a differential graded algebra the tensor and Hom in this formula are derived. We use cohomological grading, with $M[r]^i = M^{i+r}$.

For an ordinary algebra, a Hochschild p-cochain is a k-linear map $A^{\otimes p} \to A$. Its differential is

$$\begin{aligned}(bf)(a_1, \dots, a_{p+1}) = {} & a_1 f(a_2, \dots, a_{p+1}) \\ & + \sum_{i=1}^{p} (-1)^i f(a_1, \dots, a_i a_{i+1}, \dots, a_{p+1}) \\ & + (-1)^{p+1} f(a_1, \dots, a_p) a_{p+1}.\end{aligned} \tag{20.1}$$

In degree zero this is $b(a)(x) = xa - ax$. Hence $H^0 Z_k(A) = Z_{\mathrm{alg}}(A)$.

PROPOSITION 20.1.2 *(The first two Hochschild groups).* For an ordinary unital algebra,

$$H^0 Z_k(A) = Z_{\mathrm{alg}}(A), \qquad H^1 Z_k(A) = \mathrm{Der}_k(A)/\mathrm{Inn}(A).$$

Here a derivation satisfies $D(ab) = aD(b) + D(a)b$, and an inner derivation has the form $b \mapsto ab - ba$.

Proof. The degree-zero calculation was just made. For a one-cochain D,

$$(bD)(a, b) = aD(b) - D(ab) + D(a)b.$$

Its vanishing is the derivation identity. The image from degree zero consists exactly of the inner derivations, with an immaterial change of sign in their parameter. □

A map $f : A \to B$ gives a mixed complex $C^\bullet(A, B)$, in which A acts on B through f. It receives two natural cochain maps:

$$C^\bullet(A, A) \longrightarrow C^\bullet(A, B) \longleftarrow C^\bullet(B, B). \tag{20.2}$$

The first applies f to the output. The second restricts all inputs along f. Both preserve cup products. They need not give a map between the two endpoint centers.

The mixed complex also explains a limitation of insertion operations. A cochain $A^{\otimes p} \to B$ outputs an element of B. Another such cochain expects an element of A in each input. Inserting the first into the second is therefore undefined without additional data. The cup product uses multiplication in B and has no such typing problem.

20.2 The full cochain structure

The derived center remembers more than its cohomology ring. The bar resolution makes its additional operations explicit. For an ordinary unital algebra its normalized cochains are those that vanish whenever an input is 1. Normalization does not remove degree-zero cochains.

The cup product of cochains of arities p and q is

$$(f \smile g)(a_1, \dots, a_{p+q}) = f(a_1, \dots, a_p)\, g(a_{p+1}, \dots, a_{p+q}). \tag{20.3}$$

For an ungraded algebra, define

$$f \circ g = \sum_{i=0}^{p-1} (-1)^{i(q-1)} f(1^{\otimes i} \otimes g \otimes 1^{\otimes (p-1-i)}).$$

The *Gerstenhaber bracket* is

$$[f, g]_{\mathrm{G}} = f \circ g - (-1)^{(p-1)(q-1)} g \circ f. \tag{20.4}$$

It has cohomological degree -1. On one-cochains it is the commutator of endomorphisms.

Higher *braces* $f\{g_1, \dots, g_r\}$ insert the g_i into disjoint slots of f, in the indicated order. The sum runs over all allowed positions. For a differential graded algebra, suspend the inputs and use the Koszul sign of each insertion. This convention includes the internal differential and avoids assigning signs by arity alone.

An E_n-algebra is an algebra over chains on the little n-disks operad, or its equivalent derived operad.

Theorem 20.2.1 *(The cochain center).* The Hochschild center has an E_2-algebra structure. Its product and degree--1 bracket on cohomology are (20.3) and (20.4). In particular, the cup product is graded commutative on cohomology, and the bracket is a graded derivation of that product.

This is the cochain form of the Deligne theorem. McClure–Smith identify the unit, cup, and brace operad with little two-cubes chains. Their result is Theorem 1.1 of *A solution of Deligne's Hochschild cohomology conjecture*. Their construction is integral. In the derived setting, apply the construction to a suitable cofibrant algebra model.

The E_2 structure is not the assertion that a selected cochain cup product is strictly commutative.

The obstruction to a higher disk structure

Let $A = k[x, y, z]$ in characteristic zero. The derivation $D = \partial_x$ is a Hochschild one-cocycle, and x is a degree-zero cocycle. Direct insertion gives

$$[D, x]_{\mathrm{G}} = 1. \tag{20.5}$$

There are no inner derivations in this commutative algebra, and 1 is nonzero in its center.

Proposition 20.2.2 *(A restriction obstruction).* The specified Hochschild E_2 structure on $Z_k(k[x, y, z])$ cannot be obtained by restriction of an E_3 structure along the standard inclusion of little disks.

Proof. The space of two little two-disks has the homotopy type of S^1. Its degree-one homology class gives the Gerstenhaber bracket. The corresponding space for three-disks has the homotopy type of S^2, whose degree-one homology is zero. Restriction of an E_3 structure would therefore make that bracket zero. Equation (20.5) contradicts this consequence. □

A volume form can identify polyvectors with differential forms and furnish additional operators. It does not change the degree of this nonzero bracket. The proposition concerns the specified E_2 structure and the specified restriction map. It does not exclude every differently structured object with the same underlying graded vector space.

Completion in cochain length

For an augmented differential graded algebra, write $\bar{A}$ for the augmentation ideal and $BA = \bigoplus_{q \geq 0} (\bar{A}[1])^{\otimes q}$ for its bar coalgebra. Its differential combines the internal differential with multiplication, using suspended signs. The complete Hochschild cochain complex is

$$\mathrm{Hom}(BA, A) = \prod_{q \geq 0} \mathrm{Hom}((\bar{A}[1])^{\otimes q}, A).$$

The product is forced by Hom from a direct sum. Replacing it by a direct sum can remove cochains.

Let $\tau : BA \to A$ be the universal twisting cochain. Convolution uses deconcatenation in BA and multiplication in A. The Hochschild differential is

$$d_{\mathrm{Hoch}} = \partial + [\tau, -].$$

The equation $\partial\tau + \tau * \tau = 0$ implies $d^2_{\mathrm{Hoch}} = 0$. The two exterior terms in (20.1) are part of this twist.

At each fixed input length, convolution has finitely many cuts. The complete product therefore defines these operations without a convergence assumption on the sequence of cochain lengths. A completion in state weight, pole order, or coefficient parameters is a separate choice.

20.3 Coefficient-linear Morita comparison

We now specify the structure that transports the center. Let $(C, \star, K)$ be a presentable stable k-linear symmetric monoidal category. Assume that $\star$ preserves colimits separately. An algebra and its module actions are unital, and relative tensors are derived.

For algebras A, B in C, let ${}_B\mathrm{Bimod}_A(C)$ denote the category of objects with a left B-action and a commuting right A-action. Write $\mathrm{Mod}_A(C)$ for left A-modules. A B-A bimodule P defines

$$P \star_A - : \mathrm{Mod}_A(C) \longrightarrow \mathrm{Mod}_B(C).$$

It preserves colimits and is C-linear: tensoring by a coefficient object commutes coherently with this functor.

THEOREM 20.3.1 *(Coefficient-linear Eilenberg–Watts comparison).* The assignment $P \mapsto P \star_A -$ gives an equivalence

$${}_B\mathrm{Bimod}_A(C) \simeq \mathrm{Fun}^L_C\big(\mathrm{Mod}_A(C), \mathrm{Mod}_B(C)\big). \tag{20.6}$$

For a C-linear colimit-preserving functor F, the inverse sends F to $F(A)$ with its induced right A-action. Composition corresponds to relative tensor.

Proof. The free left A-module on $X \in C$ is $A \star X$. Every module M is the geometric realization of its free simplicial bar resolution. Its terms have the form $A \star A^{\star q} \star M$, with faces supplied by multiplication and the action.

Put $P = F(A)$. Right multiplication on the regular module A is an A-module action. Applying F gives the right A-action on P. The left B-action is part of its value in $\mathrm{Mod}_B(C)$. Coefficient linearity identifies $F(A \star X)$ with $P \star X$.

Apply F to the free simplicial resolution. Preservation of colimits identifies its realization with $F(M)$. The resulting simplicial object is the two-sided bar construction computing $P \star_A M$. This gives a natural equivalence $P \star_A M \simeq F(M)$.

A natural transformation between two such functors is determined on the free modules by its value at A and coefficient linearity. Compatibility with right multiplication says precisely that this value is a bimodule map. The free resolutions extend it to all modules, including its higher homotopies.

Finally, the two iterated bar realizations for a composite can be realized in either order. Their common bisimplicial object gives $(Q \star_B P) \star_A M \simeq Q \star_B (P \star_A M)$. Its associativity is inherited from the same multibar construction. □

The identity functor corresponds to the regular A-bimodule. Its endomorphisms have composition and the coherent multiplication induced by composition of functors. Their interaction is the E_2 structure on the center. Thus the coefficient action is part of the comparison, even when the underlying module categories are equivalent as abstract categories.

Definition 20.3.2. The *internal convolution center* of A, denoted $Z^{\mathrm{int}}_{\star}(A)$, represents the functor

$$W \longmapsto \mathrm{Map}_{A\text{-}A}(W \star A, A). \tag{20.7}$$

The bimodule structure on $W \star A$ uses the symmetry to move A past W. Representation means a natural equivalence with $\mathrm{Map}_{\mathcal{C}}(W, Z^{\mathrm{int}}_{\star}(A))$ for every $W \in \mathcal{C}$.

The functor $W \mapsto W \star A$ preserves colimits. Its right adjoint therefore supplies the representing object. The center theorem gives this object its E_2 structure. In Lurie's *Higher Algebra*, Corollary 5.3.1.15 gives existence, and Theorem 5.3.1.30 identifies its underlying object through module maps. For associative algebras these modules are bimodules.

The coefficient action gives the scalar center

$$Z_k(A) = R\,\mathrm{Hom}_{\mathcal{C}}(K, Z^{\mathrm{int}}_{\star}(A)).$$

The internal center is an object of $\mathcal{C}$. The scalar center is a complex over k. Evaluating at K does not identify these two recipients.

Theorem 20.3.3 *(Morita invariance with coefficients).* Suppose that P is a B-A bimodule and Q an A-B bimodule, with coherent equivalences

$$P \star_A Q \simeq B, \qquad Q \star_B P \simeq A.$$

Then conjugation gives equivalences of internal and scalar E_2 centers:

$$Z^{\mathrm{int}}_{\star}(A) \simeq Z^{\mathrm{int}}_{\star}(B), \qquad Z_k(A) \simeq Z_k(B).$$

The equivalences depend on the supplied Morita data and commute with their composition.

Proof. The functor $M \mapsto P \star_A M \star_A Q$ identifies the categories of A- and B-bimodules. It takes A to B. For every coefficient object W, symmetry and coefficient linearity identify its value on $W \star A$ with $W \star B$. It therefore identifies the functors represented in (20.7). The internal equivalence follows by Yoneda.

Conjugation also identifies composition of coefficient-linear endofunctors. Under (20.6), both centers are endomorphisms of the corresponding identity functor. Thus the equivalence preserves the coherent operations giving the E_2 structure. Evaluation at K gives the scalar assertion.

For a composite Morita equivalence, both constructions are the same iterated relative tensor. The multibar associativity in the preceding theorem identifies them, with its full coherence. □

For differential graded algebras this also has a cochain description. Keller, *Derived invariance of higher structures on the Hochschild complex*, Section 4.6, constructs the comparison in the homotopy category of brace algebras. Its hypotheses include the required fully faithful derived tensor functors. An arbitrary homomorphism such as Example 20.1.1 does not satisfy this conclusion.

Matrices retain the scalar center

Let $B = M_n(A)$. The column module $P = A^n$ is a B-A bimodule. Its right-A dual is the row A-B bimodule

$$Q = \mathrm{Hom}_{\mathrm{Mod}\text{-}A}(P, A).$$

Matrix multiplication gives $P \otimes_A Q \simeq B$ and $Q \otimes_B P \simeq A$. Hence $Z_k(M_n(A)) \simeq Z_k(A)$ as E_2 algebras.

An explicit cochain comparison uses matrix paths. For a p-cochain f on A, define

$$\big(\widetilde{f}(X_1, \dots, X_p)\big)_{i_0 i_p} = \sum_{i_1, \dots, i_{p-1}} f\big((X_1)_{i_0 i_1}, \dots, (X_p)_{i_{p-1} i_p}\big).$$

For $p = 0$ put $\widetilde{a} = a I_n$. Matrix multiplication is concatenation of these paths.

PROPOSITION 20.3.4. The matrix-path map preserves the Hochschild differential, cup product, and all braces. It induces the Morita equivalence on scalar centers.

Proof. Each inner term of the Hochschild differential contracts two neighboring edges. Summing their common index is matrix multiplication. The first and last terms attach an edge at the corresponding endpoint. These descriptions prove compatibility with the differential.

The cup product splits a path into two consecutive pieces and multiplies their values. A brace inserts shorter paths into selected slots of a longer one. The index sums are the same before and after either operation. Matrix units have degree zero, so the suspended signs are unchanged.

The corner $E_{11} B E_{11} = A$ and the two bimodules above implement the inverse derived equivalence. The matrix-path formula is its map on the bar cochains. One can also compare ordinary cochains with cochains relative to $M_n(k)$ using the separability element

$$\sum_{i=1}^{n} E_{i1} \otimes E_{1i}.$$

Its product is I_n, and it commutes with the two actions of $M_n(k)$. Inserting it contracts the complement of the relative bar resolution. This identifies the displayed map with the Morita quasi-isomorphism. □

No factor $1/n$ occurs. The comparison is valid even when the coefficient characteristic divides n. It concerns the scalar Hochschild center of the matrix algebra. If a geometric algebra is required to have scalar empty coefficient, replacing that coefficient by $M_n(k)$ changes the geometric class.

20.4 RELATIVE SCALAR EXTENSION

Let C now carry a central action of $D(k)$, compatible with its tensor. Let A_0 be an algebra in C. For a differential graded k-algebra B, set

$$A_B = A_0 \otimes_k B.$$

For a B'-B bimodule P, set $J(P) = A_0 \otimes_k P$ with its induced $A_{B'}$-A_B actions.

Assume the coefficient action has the relative-tensor comparison

$$(A_0 \otimes Q) \star_{A_{B'}} (A_0 \otimes P) \simeq A_0 \otimes (Q \otimes^{\mathbf{L}}_{B'} P).$$

Its coherence is part of the central coefficient action. It can be checked on the common two-sided bar construction.

Suppose also that empty evaluation $e_\varnothing : C \to D(k)$ is strong monoidal, preserves the realizations in question, and satisfies $e_\varnothing(A_0) = k$. It then sends $J(P)$ back to P, including its two coefficient actions.

Theorem 20.4.1 *(A relative center retract).* Under these hypotheses there are maps of scalar E_2 algebras

$$Z_k(B) \xrightarrow{J_B} Z_C(A_B) \xrightarrow{e_\varnothing} Z_k(B), \qquad e_\varnothing J_B = \mathrm{id}.$$

Here $Z_C(A_B) = R\,\mathrm{Hom}_{A_B\text{-}A_B}(A_B, A_B)$ is formed in C. The statement makes $Z_k(B)$ a retract. It does not assert that J_B is essentially surjective on geometric bimodules.

Proof. The relative-tensor comparison makes J a monoidal functor on the endomorphism category of the object B in the bimodule bicategory. It sends the regular B-bimodule to the regular A_B-bimodule. It therefore induces a map on endomorphisms of these units, preserving their E_2 operations.

Empty evaluation gives the reverse monoidal functor on these objects. The identity $e_\varnothing J(P) = P$ is natural and compatible with composition. Its value on unit endomorphisms proves the retract identity.

On bar cochains the forward map multiplies the A_0 inputs and applies the coefficient cochain to the B inputs. Centrality moves the coefficients past the A_0 factors. The resulting Koszul signs are exactly those in the tensor product and suspended insertion conventions. The same formula commutes with every cut, cup, and brace. □

In particular, a nonzero coefficient-center class remains nonzero after extension. Its empty evaluation recovers the original class. A class supported on nonempty configurations may lie outside the image of J_B.

This construction is useful for arithmetic coefficient algebras: it places their actual Hochschild operations in a geometric recipient. It does not construct an identification with every internal center, every diagonal actor, or a chosen physical bulk algebra. Each such identification has its own mapping property.

20.5 The center of a homomorphism diagram

The two arrows in (20.2) have a common target. Their homotopy fiber can therefore be formed as a complex. To obtain its higher operations, we realize the diagram by one algebra.

Let $f : A \to B$ be a unital homomorphism of ordinary k-algebras. Regard B as a B-A bimodule by right multiplication through f. Define the *triangular algebra*

$$T_f = \begin{pmatrix} A & 0 \\ B & B \end{pmatrix}, \qquad \begin{pmatrix} a & 0 \\ m & b \end{pmatrix}\begin{pmatrix} a' & 0 \\ m' & b' \end{pmatrix} = \begin{pmatrix} aa' & 0 \\ mf(a') + bm' & bb' \end{pmatrix}.$$

Its unit is $\mathrm{diag}(1, 1)$. The two diagonal idempotents are denoted e_A, e_B.

Put $u \mapsto f_* u$ for the first map of (20.2), and $v \mapsto f^* v$ for the second. Define a cochain complex $\mathcal{F}_f$ by

$$\mathcal{F}_f^n = C^n(A, A) \oplus C^n(B, B) \oplus C^{n-1}(A, B),$$

with differential

$$d(u, v, h) = (bu, bv, f_* u - f^* v - bh). \tag{20.8}$$

The sign on bh is the shift sign. Since both comparison maps commute with b, one has $d^2 = 0$.

Theorem 20.5.1 *(A triangular realization).* There is a quasi-isomorphism of complexes

$$Z_k(T_f) \simeq \mathcal{F}_f.$$

Consequently the homotopy fiber has an E_2 structure through the center of T_f. This assertion does not assign the ordinary brace formulas to mixed cochains.

Proof. The subalgebra $S = ke_A \oplus ke_B$ is separable over k. Its separability element is $e_A \otimes e_A + e_B \otimes e_B$. Inserting this element gives the usual contraction from the ordinary bar resolution to the relative bar resolution over S. Thus relative Hochschild cochains compute $Z_k(T_f)$.

An S-balanced tensor is a composable sequence of matrix entries. Such a sequence either stays at one diagonal vertex or crosses once through the B-A entry. It cannot cross twice, because the opposite off-diagonal entry is zero. The two constant-vertex parts are $C^\bullet(A, A)$ and $C^\bullet(B, B)$.

The part with one crossing has terms

$$\mathrm{Hom}_k(B^{\otimes q} \otimes B \otimes A^{\otimes p}, B), \qquad p, q \geq 0.$$

It occupies total Hochschild degree $p + q + 1$. Its differential is the two-sided bar differential for the bimodule B, together with the two endpoint actions. Without those endpoint terms, it computes $R\,\mathrm{Hom}_{B\text{-}A}(B, B)$ shifted by one.

Resolve the right A-action on B by the bar resolution, retaining its free left B-action. Evaluation on $1 \in B$ then identifies this derived Hom with $C^\bullet(A, B)$. The extra left-B bar direction contracts by its unit degeneracy. The contraction respects the right-A differential, so the same comparison applies to the total complex.

The remaining endpoint maps apply an A-cochain through f and restrict a B-cochain along f. Their orientations are opposite. With the shifted mixed term, the total differential is exactly (20.8). This proves the quasi-isomorphism. Transport the E_2 structure from $Z_k(T_f)$ along this equivalence. No mixed insertion with mismatched source and target is required. □

The degree-zero part can be read directly from the algebra.

PROPOSITION 20.5.2. There is an isomorphism

$$Z_{\mathrm{alg}}(T_f) = \{(a, b) \in Z_{\mathrm{alg}}(A) \times Z_{\mathrm{alg}}(B) : f(a) = b\}.$$

For the diagonal homomorphism of Example 20.1.1, this center is k.

Proof. Commutation with e_A and e_B forces the off-diagonal entry of a central element to vanish. Commutation with the two diagonal subalgebras makes its remaining entries central. Commutation with an off-diagonal element $m \in B$ is $mf(a) = bm$ for every m. Taking $m = 1$ gives $f(a) = b$, and centrality of b makes this condition sufficient.

For the stated example, $b = \lambda I_2$. The equality $\mathrm{diag}(a_1, a_2) = b$ forces $a_1 = a_2 = \lambda$. □

The triangular center thus retains the compatibility of the two actions. Merely taking the product of the endpoint centers would lose that condition. Conversely, it would be incorrect to call every ordinary fiber of cochain complexes a strict brace algebra. The triangular model supplies the operations that make the comparison meaningful.

20.6 THE REGULAR AND PUNCTURED NORMAL LINES

The simplest collision coordinate already gives a center with a nontrivial bracket. Let k have characteristic zero, and put

$$D = k\langle u, \partial\rangle/(\partial u - u\partial - 1), \qquad R = k[u], \qquad L = k[u, u^{-1}].$$

Both R and L are left D-modules with their derivative connections. Write $C_2 = \mathrm{thick}_D(R \oplus L)$ for the full differential graded category obtained by shifts, finite cones, and direct summands. Its scalar center

is the derived endomorphism complex of its diagonal bimodule. We will compute the center together with its cup product and Gerstenhaber bracket.

For $v \in D$, let r_v denote right multiplication by v. This is a map of free left D-modules. The two resolutions

$$P_0 = [D \xrightarrow{r_\partial} D] \longrightarrow R, \qquad P_1 = [D \xrightarrow{r_{u\partial+1}} D] \longrightarrow L \tag{20.9}$$

have terms in degrees -1, 0 and augmentations 1, u^{-1}. The term 1 in the second differential is essential: $(u\partial + 1)u^{-1} = 0$, whereas $u\partial(u^{-1}) = -u^{-1}$.

Lemma 20.6.1. The resolutions in (20.9) are exact. They give

$R\operatorname{Hom}_D(-,-)$	R	L
R	k	$k \oplus k[-1]$
L	0	$k \oplus k[-1]$.

Proof. The Weyl algebra is a domain, so the two differentials are injective. The first cokernel is the polynomial module. In the second cokernel the Euler relation reduces mixed monomials to powers of u and powers of ∂. Their images are

$$u^{m-1} \quad (m \geq 0), \qquad (-1)^n n! u^{-n-1} \quad (n \geq 1).$$

These form a Laurent basis, proving the second assertion about cokernels.

Applying Hom to the resolutions gives the operators ∂ and $u\partial + 1$ on R and L. Polynomial integration makes $\partial : R \to R$ surjective with kernel k. On L its cokernel is the residue line represented by u^{-1}. Finally, $(u\partial + 1)u^m = (m+1)u^m$. This operator is invertible on R, and on L it has the single exceptional mode $m = -1$ in both kernel and cokernel. □

The four complexes alone do not specify their composition. To retain composition, take the graded path algebra T on two objects. Give it an arrow $a : 0 \to 1$ of degree zero and a loop $\theta : 1 \to 1$ of degree one. Set

$$\theta^2 = 0, \qquad b = \theta a, \qquad T^0 = ke_0 \oplus ke_1 \oplus ka, \qquad T^1 = k\theta \oplus kb.$$

The differential is zero.

Products are written in composition order. Apart from identities, the sole nonzero product of basis elements is $\theta a = b$.

Proposition 20.6.2. There is a strict quasi-isomorphism

$$T \longrightarrow \operatorname{End}_D(P_0 \oplus P_1).$$

Consequently C_2 is equivalent to $\operatorname{Perf}(T)$, using right T-modules.

Proof. Send e_i to the two projections. The arrow a is represented by a map $\alpha : P_0 \to P_1$ with $\alpha^{-1} = 1$ and $\alpha^0 = r_u$. Its chain equation is $\partial u = u\partial + 1$. Represent θ by the degree-one identity $\Theta : P_1^{-1} \to P_1^0$ and b by $\Theta\alpha$.

These maps are closed and satisfy the multiplication relations strictly. After augmentation, α is the inclusion $R \to L$, while Θ and $\Theta\alpha$ represent the two residue classes. Thus the map induces isomorphisms in all four Hom corners. Hom from $P_0 \oplus P_1$ and its tensor adjoint identify the generators and their Hom complexes. The identification extends to their thick closures. □

The completed center and its bracket

Use the normalized two-sided bar relative to the separable algebra $S = ke_0 \oplus ke_1$. Its middle term is the direct sum of finite composable words in $(T/S)[1]$. Taking Hom therefore gives a product over arities. We denote the resulting complete cochain algebra by $C(T)$.

Here are explicit sign conventions for the calculation. An n-cochain of internal degree r has total degree $n + r$. Its differential is $D = (-1)^r b_H$, where

$$\begin{aligned}(b_H f)(v_1, \dots, v_{n+1}) = {} & (-1)^{r|v_1|} v_1 f(v_2, \dots, v_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i f(v_1, \dots, v_i v_{i+1}, \dots, v_{n+1}) \\ & + (-1)^{n+1} f(v_1, \dots, v_n) v_{n+1}.\end{aligned}$$

For an m-cochain g of internal degree s, the cup product is

$$(f \smile g)(v_1, \dots, v_{n+m}) = (-1)^{s(\sum_{i=1}^{n} |v_i| - n)} f(v_1, \dots, v_n) g(v_{n+1}, \dots, v_{n+m}).$$

These formulas express the suspended-bar operations on unsuspended inputs.

THEOREM 20.6.3. The scalar center of C_2 has a continuous associative differential graded model

$$k[[x]] \otimes \Lambda(\eta), \qquad |x| = 0, \quad |\eta| = 1, \qquad d = 0.$$

Its Gerstenhaber bracket is determined by

$$[\eta, x] = -x, \qquad [x, x] = [\eta, \eta] = 0.$$

Proof. Give θ, b weight one and e_0, e_1, a weight zero. For a cochain let d be input weight minus output weight. Every nonempty composable word has one of the forms

$$\theta^{\otimes n}, \qquad \theta^{\otimes (n-1)} \otimes a, \qquad \theta^{\otimes (n-1)} \otimes b.$$

The output has the same endpoints.

For each $d \geq 1$, the cochain block in total degrees 0, 1, 2 is

$$k^2 \xrightarrow{M} k^3 \xrightarrow{N} k, \qquad M = \begin{pmatrix} 0 & 0 \\ -1 & 1 \\ -1 & 1 \end{pmatrix}, \quad N = \begin{pmatrix} 1 & 1 & -1 \end{pmatrix}. \tag{20.10}$$

The degree-zero basis sends $\theta^{\otimes d}$ to e_1 and $\theta^{\otimes (d-1)} \otimes b$ to a. The degree-one basis has outputs θ, a, b on the corresponding words of input weights $d + 1, d, d + 1$. The degree-two basis sends $\theta^{\otimes (d+1)} \otimes a$ to b. The multiplication $\theta a = b$ gives the interior faces, and the endpoint faces give the other entries of (20.10).

For $d = 0$ the degree-zero basis is e_0, e_1 and the first matrix is $-M$. Weight -1 consists of an identity map $k \to k$ in degrees one and two. Its source is the nullary θ and its target sends a to b. There are no further blocks.

For $d \geq 0$ choose representatives and projections

$$\begin{aligned} i_0(c) &= (c, c), & p_0(p, q) &= p, \\ i_1(c) &= (c, 0, c), & p_1(r, s, t) &= t - s. \end{aligned}$$

A homotopy on the complement is

$$h_1(r,s,t) = \begin{cases} (0,s), & d>0, \\ (0,-s), & d=0, \end{cases} \qquad h_2(z) = (z,0,0).$$

The matrices give $Dh + hD = 1 - ip$ and $h^2 = hi = ph = 0$. Use the inverse identity in weight -1. The maps preserve weight, so their product contracts the complete cochain complex.

To identify the product, define derivations X, Y by

	e_0	e_1	θ	a	b
X	0	0	e_1	0	a
Y	0	0	θ	0	b.

Their internal degrees are $-1, 0$ and their total degrees are $0, 1$. They are closed, $X \smile Y = Y \smile X$, and $Y \smile Y = 0$. The cochains $X^{\smile d}$ and $Y \smile X^{\smile d}$ give the representatives just chosen. Thus $x \mapsto X$, $\eta \mapsto Y$ is a continuous multiplicative quasi-isomorphism. On each fixed word, only finitely many terms of a formal series contribute.

The unary insertion bracket is the graded commutator. Since $YX - XY = -X$, it gives $[\eta, x] = -x$. The biderivation identity determines the remaining brackets. □

In this description η acts as $-x\partial_x$. For formal series f, g,

$$[\eta f, g] = -xfg', \qquad [\eta f, \eta g] = \eta x(gf' - fg').$$

The associative model and this cohomology bracket do not assert formality of the full E_2 structure. The braces still live on the complete bar cochains. Replacing their product by a direct sum would give $k[x]$ in place of $k[[x]]$ and would omit legitimate maps from the bar.

Restriction to the full subcategory generated by L has target $\Lambda(\theta)[[x]]$. It is

$$x \longmapsto x, \qquad \eta \longmapsto \theta x.$$

Restriction to R sends x, η to zero and preserves constants. The regular object therefore forces the odd coefficient at the punctured object to vanish at the formal origin.

The same conclusion follows from the relative bar triangle

$$C(T) \longrightarrow k \oplus C(\Lambda(\theta)) \longrightarrow R\operatorname{Hom}_{\Lambda(\theta)}(\Lambda(\theta)a, \Lambda(\theta)a).$$

A composable word crosses from 0 to 1 at most once. Its crossing terms form the shifted module bar. The module $\Lambda(\theta)a$ is free, so this bar contracts to $\Lambda(\theta)$. On the diagonal models, the last map is $(c, f) \mapsto c - f(0)$. Its kernel is $k \oplus x\Lambda(\theta)[[x]]$, which recovers $\eta = \theta x$.

Removing nullary cochains

Deformation problems can impose conditions that exclude the primitives used by the full center. Fix the two objects, hence the inclusion $S \subset T$, and retain only positive-arity cochains. These describe uncurved S-linear deformations with zero nullary comparison term. Write their complex as $C_{\geq 1,S}(T)$.

PROPOSITION 20.6.4. The only nonzero groups of $C_{\geq 1,S}(T)$ are

$$H^0 = xk[[x]], \qquad H^1 = k[[x]]\eta \oplus k\sigma, \qquad H^2 = kq.$$

Here $\sigma(a) = a$, $\sigma(b) = b$, and $q(a) = b$, with other generator values zero. For the normalized positive-arity complex relative to k, they are instead

$$\begin{aligned} H^0 &= xk[[x]], \\ H^1 &= k[[x]]\eta \oplus k\sigma \oplus kDa, \\ H^2 &= kD\theta \oplus kDb. \end{aligned}$$

The symbol D in the last expressions is the Hochschild differential of a nullary element in the full complex.

Proof. The positive-weight blocks do not change. Removing the two nullary identities leaves their former boundary σ in degree one and removes the constant degree-zero class. Removing the nullary θ leaves q in degree two.

For the k-relative complex, use the exact sequence

$$0 \to C_{\geq 1,k}(T) \to C_k(T) \to T \to 0.$$

The map on degree-zero cohomology is $f(x) \mapsto f(0)1_T$, and the classes $\eta k[[x]]$ have zero nullary component. The long exact sequence contributes $T^0/k1_T$ in degree one and T^1 in degree two. Represent the former by e_0, a. The connecting maps give the displayed classes. They are distinct: $(Db)(e_0) = b$, while $(D\theta)(e_0) = 0$ and $(D\theta)(a) = b$. □

Let $A = k[[s]]$ and give $T \otimes_k A$ the differential

$$d_s a = sb, \qquad d_s\theta = d_s b = d_s e_i = 0. \tag{20.11}$$

This is a differential graded algebra, since $d_s = s[\theta, -]$ and $\theta^2 = 0$. Its underlying graded module is free, but

$$H^0(T_s) = Ae_0 \oplus Ae_1, \qquad H^1(T_s) = A\theta \oplus (A/(s))b.$$

Even modulo s^2, there is no uncurved A_∞ map $T_s \to T \otimes A$ with $F_0 = 0$ and $F_1 = 1 \bmod s$. Its unary equation would give $F_1 d_s = 0$, whereas its value on a is $sb \neq 0 \bmod s^2$. Higher components do not enter this equation. The identity $D\theta = q$ in the full center does not remove the obstruction when the nullary term is forbidden.

Changing the connection residue

The deformation has a geometric realization. Let $D_A = A\langle u, \partial\rangle/(\partial u - u\partial - 1)$, take $R_A = A[u]$ with its derivative connection, and put

$$L_s = A[u, u^{-1}], \qquad \partial f = f' - \frac{s}{u} f.$$

These are polynomial and Laurent polynomial modules over A. There is no completion in u.

Theorem 20.6.5. The category generated by $R_A \oplus L_s$ is equivalent to $\mathrm{Perf}(T_s)$. For $K = k((s))$,

$$\mathrm{Perf}(T_s \otimes_A K) \simeq \mathrm{Perf}(K) \oplus \mathrm{Perf}(\Lambda_K(\theta)).$$

The family T_s is not A-linearly Morita equivalent to the constant family $T \otimes_k A$.

Proof. Replace P_1 by

$$P_{1,s} = [D_A \xrightarrow{r_{u\partial+1+s}} D_A], \qquad P_{1,s} \longrightarrow L_s, \quad 1 \longmapsto u^{-1}.$$

Its cokernel calculation uses

$$\partial^n u^{-1} = (-1)^n \prod_{j=1}^{n} (j+s) u^{-n-1}.$$

All $j + s$ are units of A, so these vectors and the nonnegative powers give a Laurent basis.

Keep the maps $\alpha, \Theta, \Theta\alpha$ used above. Now

$$d_{\mathrm{Hom}}\alpha = r_{u\partial+1+s} - r_{\partial u} = s\Theta\alpha.$$

Thus they define a strict map from T_s to the endomorphism algebra of the two resolutions.

In the corner from R_A to L_s, all Laurent modes except $m = 0$ contract under $u^m \mapsto (m - s)u^{m-1}$. The remaining complex is $[A \xrightarrow{s} A]$, with the Hom sign chosen as in (20.11). The reverse corner is acyclic because $m + 1 + s$ is a unit for $m \geq 0$. The two diagonal corners are A and $A \oplus A[-1]$. The map is therefore a quasi-isomorphism, and the generator argument proves the categorical equivalence.

Over K, the ideal spanned by a, b is contractible. Quotienting gives the algebra $K \times \Lambda_K(\theta)$. Its degree-zero Hochschild center is $K \times K[[x]]$. The constant family, computed directly over K, has center $K[[x]]$.

The former ring has a nontrivial idempotent and the latter has none. Morita equivalence would preserve these rings. An A-linear equivalence would remain one over K, so it is also excluded. □

The ordinary inclusion $R_A \to L_s$ fails to respect the connections by $-s/u$. The equation $d_s a = sb$ records that failure. The proof computed the two generic centers directly. It did not interchange completed Hochschild cochains with extension of scalars.

20.7 Independent directions and a triple collision

Independent normal coordinates allow the preceding calculation to tensor. Let D_d be the Weyl algebra of $R_d = k[u_1, \ldots, u_d]$ and set

$$G_d = \bigoplus_{I \subseteq \{1,\ldots,d\}} R_d\left[\left(\prod_{i \in I} u_i\right)^{-1}\right].$$

Every summand has its derivative connection, and the empty product is one.

Theorem 20.7.1. The scalar center of $\mathrm{thick}_{D_d}(G_d)$, with product-total Hochschild cochains, has the associative differential graded model

$$k[[x_1, \ldots, x_d]] \otimes \Lambda(\eta_1, \ldots, \eta_d), \qquad d = 0,$$

where $|x_i| = 0$, $|\eta_i| = 1$. The cohomology bracket is

$$[\eta_i, x_j] = -\delta_{ij} x_j, \qquad [\eta_i, \eta_j] = [x_i, x_j] = 0.$$

Proof. The generator is the external tensor product of the d modules $k[u_i] \oplus k[u_i, u_i^{-1}]$. Tensor the bounded free resolutions and their strict endomorphism models. They identify the generated category with $\mathrm{Perf}(T^{\otimes d})$.

Resolve the diagonal bimodule by the tensor product of the relative bars. At each multiweight the cochain spaces are finite dimensional and bounded. Their contractions tensor: for two factors the homotopy is $h_1 \otimes 1 + t_1 p_1 \otimes h_2$, with the graded tensor sign. Taking the product over multiweights gives precisely the displayed formal series.

The multiplicative representatives tensor as well. The shuffle comparison with the bar of $T^{\otimes d}$ identifies insertions up to coherent homotopy. The bracket is the sum of the factor brackets, with zero brackets between different factors. □

This theorem applies to two independent pair collisions, for example $12|34$ with constant tangential coefficients. At a triple collision the equations u, v, and $u - v$ are dependent. There is an additional shape coordinate.

The separated shape

Write three distinct points as

$$z_3 = z, \qquad z_1 = z + u, \qquad z_2 = z + ut.$$

Their configuration space is $\mathbb{A}^1_z \times \mathbb{G}_{m,u} \times V$, where

$$V = \operatorname{Spec} k[t, t^{-1}, (t-1)^{-1}].$$

The coordinate u measures scale, and t retains the two finite collision channels.

The algebraic de Rham algebra of V has a strict multiplicative model

$$B = k \oplus k\epsilon_0 \oplus k\epsilon_1, \qquad |\epsilon_i| = 1, \qquad \epsilon_i \epsilon_j = 0,$$

via $\epsilon_0 \mapsto dt/t$ and $\epsilon_1 \mapsto dt/(t-1)$. Partial fractions integrate all polynomial terms and all poles of order at least two. The two simple residues remain independent. This proves the quasi-isomorphism. The scale factor contributes $\Lambda(du/u)$, giving de Rham dimensions $1, 3, 2$.

PROPOSITION 20.7.2. Let $F = k\langle\langle x, y \rangle\rangle$ be the completed free associative algebra. The complete normalized Hochschild cochains of B identify with

$$F \xrightarrow{d} F \oplus F, \qquad df = ([x, f], [y, f]),$$

in degrees zero and one. The degree-one ideal has square zero and componentwise left and right F-actions. Consequently

$$H^0 C(B) = k, \qquad H^1 C(B) = (F \oplus F)/\{([x, f], [y, f]) : f \in F\}.$$

There is no other cohomology. The component of H^1 of output word length m has dimension

$$2 \quad (m = 0), \qquad 4 \quad (m = 1), \qquad 3 \cdot 2^{m-1} \quad (m \geq 2).$$

Proof. The two suspended augmentation generators have degree zero. Scalar outputs give the series F in total degree zero, and the two odd outputs give $F \oplus F$ in degree one. All interior bar faces vanish. The endpoint faces are the two commutators, while the cup product concatenates words and multiplies outputs.

A homogeneous word polynomial commuting with x is a polynomial in x. Comparing xf with fx first excludes words ending in y. Moving each final x to the front then excludes every occurrence of y. Commutation with y leaves only constants. Applying this in each length gives $Z(F) = k$.

At output length $m \geq 2$, the differential is injective on scalar words of length $m-1$, hence has rank 2^{m-1}. Its rank is zero for $m = 1$, and it has no source for $m = 0$. Subtract these ranks from $2 \cdot 2^m$. All maps respect the finite length components, so the image is the product of its images in these components. The computation therefore respects the completion. □

This is the center of the separated shape corner. Identifying the full triple coefficient category requires its remaining objects and collision maps.

A class invisible to every pair

The difference also appears in ordinary global de Rham cohomology. For charges $q_i \in k$, consider the connection

$$\nabla_n = d + c \sum_{i<j} q_i q_j \, d\log(z_i - z_j)$$

on the distinct n-point configuration. After separating a scale coordinate u, its radial residue is $\lambda_n = c \sum_{i<j} q_i q_j$. The differential on the Laurent mode u^m is multiplication by $m + \lambda_n$, followed by du/u. If $\lambda_n \notin \mathbb{Z}$, division by these scalars contracts the radial complex.

Proposition 20.7.3. For $c = 1/3$ and $q_1 = q_2 = q_3 = 1$, all two-point global algebraic de Rham complexes are acyclic. The three-point complex has exactly

$$H^1 = k\left[u^{-1}\frac{dt}{t}\right], \qquad H^2 = k\left[u^{-1}\frac{du}{u} \wedge \frac{dt}{t}\right].$$

Proof. The pair residue is $1/3$ and the triple residue is one. In the coordinates above, the connection is

$$d + \frac{du}{u} + \frac{1}{3}\left(\frac{dt}{t} + \frac{dt}{t-1}\right).$$

Let $D_{\mathrm{sh}} f = f' + (1/(3t) + 1/(3(t-1)))f$.

A pole of order $j \geq 2$ at $p = 0, 1$ with leading coefficient a is removed by subtracting

$$D_{\mathrm{sh}}\left(\frac{a(t-p)^{1-j}}{1/3 - (j-1)}\right).$$

This introduces at most a simple pole at the other point. Remove a polynomial leading term at^j with $D_{\mathrm{sh}}(at^{j+1}/(j+1+2/3))$.

The remainder is $A_0/t + A_1/(t-1)$. Subtracting $D_{\mathrm{sh}}(3A_1)$ leaves $(A_0 - A_1)/t$. For example,

$$\frac{1}{t^2(t-1)^2} = D_{\mathrm{sh}}\left(\frac{3-6t^2}{2t(t-1)}\right) + \frac{2}{t}.$$

There is no nonzero rational horizontal function: its order at zero would have to be $-1/3$. Nor is $1/t$ in the image. A primitive with a pole would produce a pole of higher order with nonzero coefficient. It must therefore be polynomial. A positive degree would produce a polynomial part, and a constant gives equal coefficients at the two simple poles. Thus the shape cohomology is exactly $k\,dt/t$ in degree one.

The radial contraction removes all modes except u^{-1} and $u^{-1}du/u$. Polynomial integration contracts the translation coordinate. Tensoring the three contractions gives the stated result. □

The exceptional integral residues can all be included in the calculation. Let $a_{12}, a_{13}, a_{23} \in k$ and $\lambda = a_{12} + a_{13} + a_{23}$. All functions and forms in the following statement have finite Laurent support.

PROPOSITION 20.7.4. For the connection $d + \sum_{i<j} a_{ij}\, d\log(z_i - z_j)$, the global de Rham dimensions are

	H^0	H^1	H^2
$\lambda \notin \mathbb{Z}$	0	0	0
$\lambda \in \mathbb{Z},\ (a_{12}, a_{13}, a_{23}) \notin \mathbb{Z}^3$	0	1	1
$(a_{12}, a_{13}, a_{23}) \in \mathbb{Z}^3$	1	3	2.

All other groups vanish.

Proof. The scale differential is $m + \lambda$ on u^m. When λ is integral it retains one class in degrees zero and one. The shape operator is

$$Df = \left(f' + \left(\frac{a}{t} + \frac{b}{t-1}\right)f\right)dt, \qquad a = a_{23}, \quad b = a_{12}.$$

Choose an integer $M \geq 1$ such that $a - j, b - j$, and $j + a + b$ are nonzero for every integer $j > M$. Let V_M consist of functions with poles of order at most M at each puncture and polynomial degree at most M. Let W_M consist of one-forms with pole orders at most $M + 1$ and polynomial degree at most $M - 1$. Then

$$D(V_M) \subset W_M, \qquad \dim V_M = 3M + 1, \qquad \dim W_M = 3M + 2.$$

The leading coefficients just listed remove every pole or polynomial term outside this finite complex. Conversely, a function outside V_M has a leading term whose derivative lies outside W_M with nonzero coefficient. Thus the finite inclusion induces an isomorphism on cohomology.

A nonzero horizontal rational function has orders $-a, -b$ at the two punctures, so it exists exactly when both residues are integral. In that case it is a scalar multiple of $t^{-a}(t-1)^{-b}$. The dimension difference gives shape dimensions $(1, 2)$ in the integral case and $(0, 1)$ otherwise. Tensor with the two scale classes. For integral λ, integrality of a_{12}, a_{23} is equivalent to integrality of all three residues. □

Pairwise global cohomology therefore does not recover the complete coefficient diagram. The example does not negate factorization at the coefficient level. Its conclusion concerns the loss caused by taking global cohomology separately on pairs.

The relative residue class

Localization also gives a relative complex

$$\mathcal{R} = \operatorname{fib}(R\operatorname{Hom}_D(R, R) \longrightarrow R\operatorname{Hom}_D(R, L)).$$

It records a map to the regular coefficient together with a nullhomotopy after localization. The constant terms cancel, while the residue line survives one degree higher:

$$\mathcal{R} \simeq k[-2].$$

In $\mathrm{Cone}(k \to \Omega^\bullet(L))[-1]$ the generator is $(0, du/u)$. It cannot be a boundary because no Laurent polynomial has derivative u^{-1}.

Thus a relative map can be nonzero even when forgetting its specified nullhomotopy kills the underlying map. An application to pointed actions must supply its actual input maps into $\mathcal{R}$ and their normalizations. The one-dimensional cohomology does not choose them.

20.8 Centers over a parameter ring

A finite bar model makes coefficient change especially explicit. It also separates the cup product from the insertion bracket. Let

$$R = k[h_1, \dots, h_r], \qquad I = (h_1, \dots, h_r), \qquad S = R/I,$$

where $r \geq 1$ and k has characteristic zero. Let W have basis $u_1, \dots, u_r$, all in cohomological degree one. Write L_i for exterior multiplication by u_i, and form the complex

$$M = R \otimes_k \Lambda W, \qquad d_M = \sum_i h_i L_i.$$

The anticommutation of the L_i gives $d_M^2 = 0$. The complex M is an arrow complex. Its differential is not a derivation of the auxiliary exterior multiplication. Its cohomology is S in degree r.

Take the triangular differential graded algebra

$$T_R = R\varepsilon_0 \oplus R\varepsilon_1 \oplus M, \qquad \varepsilon_1 M \varepsilon_0 = M, \qquad M^2 = 0.$$

We compute its relative scalar center $Z_R(T_R) = R\,\mathrm{Hom}_{T_R \otimes_R T_R^{\mathrm{op}}}(T_R, T_R)$. All cochains here are R-linear.

A finite model with both operations

Put $E = \mathrm{End}_R(M)$, with differential $\delta f = d_M f - (-1)^{|f|} f d_M$. The normalized bar relative to $S_0 = R\varepsilon_0 \oplus R\varepsilon_1$ has just two terms,

$$T_R \otimes_{S_0} T_R, \qquad T_R \otimes_{S_0} M[1] \otimes_{S_0} T_R.$$

There are no longer terms because $M \otimes_{S_0} M = 0$. Reversing the sign of its one-arrow generator gives the finite free cochain model

$$\begin{aligned} Z^n &= (R^2)^n \oplus E^{n-1}, \\ d(a, b; f) &= (0, 0; (b - a)\,\mathrm{id} - \delta f). \end{aligned} \tag{20.12}$$

The endpoint summands occur only in degree zero. The model has total rank $2 + 4^r$ over R.

Use the source-first opposite-cup convention. The cup product and unit are

$$(a, b; f)(a', b'; f') = (aa', bb'; fb' + af'), \qquad 1 = (1, 1; 0). \tag{20.13}$$

The differential identity on endpoints is $bb' - aa' = (b - a)b' + a(b' - a')$. Together with R-linearity of δ, it proves the differential Leibniz rule. Associativity follows from the commuting endpoint scalar actions.

Let $\sigma f = (0, 0; f)$, of degree $|f| + 1$. The insertion convention is

$$[\sigma f, \sigma g] = \sigma\big(f g - (-1)^{|f||g|} g f\big).$$

Endpoint scalars have zero bracket with one-arrow cochains.

These formulas follow by inserting an arrow operation into another arrow operation. They give a bracket of degree -1. Its differential and Jacobi identities reduce to the graded commutator identities in E. In particular, composition in E remains visible even though two pure one-arrow cochains have zero cup product.

Integral cohomology and contraction brackets

Let ι_i be contraction by the dual of u_i. The operators satisfy

$$L_i L_j + L_j L_i = 0, \qquad \iota_i \iota_j + \iota_j \iota_i = 0, \qquad \iota_i L_j + L_j \iota_i = \delta_{ij} \,\mathrm{id}\,.$$

The ordered operators $L_A \iota_B$, for subsets $A, B \subseteq \{1, \dots, r\}$, form an R-basis of E. For one generator, 1, L, ι, $L\iota$ span all two-by-two matrices. Graded tensor products give the general assertion.

Moreover,

$$\delta L_i = 0, \qquad \delta \iota_i = h_i \,\mathrm{id}\,.$$

For fixed L_A, the contraction factors therefore form a Koszul resolution. Hence

$$H^q(E) = S \otimes_k \Lambda^q W \quad (0 \le q \le r),$$

with no other cohomology.

THEOREM 20.8.1. The relative Hochschild groups are

$$\begin{aligned} \mathrm{HH}^0_R(T_R) &= R \times_S R, \\ \mathrm{HH}^1_R(T_R) &= 0, \\ \mathrm{HH}^{q+1}_R(T_R) &= S \otimes_k \Lambda^q W \quad (1 \le q \le r). \end{aligned}$$

They vanish in all other degrees. The positive-degree ideal has square-zero cup product, and a degree-zero pair acts through its common residue in S.

Writing $t_i = [(0, h_i; \iota_i)]$, the degree-zero ring has presentation

$$R[t_1, \dots, t_r]/(h_i t_j - h_j t_i,\ t_i t_j - h_i t_j : 1 \le i, j \le r).$$

Proof. The fiber complex (20.12) gives the map $R^2 \to H^0(E) = S$, $(a, b) \mapsto b - a$. It is surjective with kernel $R \times_S R$. Its remaining cohomology is the positive cohomology of E shifted by one. The cup formula proves the product statements.

Each representative t_i is closed and maps to $(0, h_i)$. Every element of the fiber product is a diagonal scalar plus $(0, c)$ with $c \in I$. Thus these elements generate. The quadratic relations reduce a polynomial to $a + \sum_i b_i t_i$. It maps to zero exactly when $a = 0$ and $\sum_i b_i h_i = 0$. The Koszul syzygies of the regular sequence generate these relations, giving the presentation. □

The exterior powers in the theorem describe modules of classes. Their exterior product is not the cup product in the center. The proof works for any regular sequence in a commutative $\mathbb{Q}$-algebra, with the corresponding free exterior module.

For $A = \{a_1 < \cdots < a_q\}$, let $\alpha_A = [\sigma L_{a_1} \cdots L_{a_q}]$. It has degree $q + 1$. The contraction relations give, for $q \geq 2$,

$$[t_i, \alpha_A] = \begin{cases} (-1)^{j-1} \alpha_{A \setminus \{i\}}, & i = a_j, \\ 0, & i \notin A. \end{cases}$$

For $q = 1$ the result is zero in cohomology: the commutator is a scalar identity, which is the boundary of an endpoint difference. The L_i supercommute, as do the ι_i, so brackets between two positive classes or two degree-zero classes vanish. The bracket with R also vanishes.

For two parameters, put $\omega = \alpha_{\{1,2\}}$. Then

$$[t_1, \omega] = \alpha_{\{2\}}, \qquad [t_2, \omega] = -\alpha_{\{1\}}.$$

The positive classes have zero mutual cup products, and the t_i annihilate them under cup product. The bracket still detects the contraction of an arrow operation.

Derived specialization

The finite model gives an operation-preserving base-change theorem. For every commutative derived R-algebra B,

$$Z_R(T_R) \otimes^{\mathbb{L}}_R B \simeq Z_B(T_R \otimes^{\mathbb{L}}_R B). \tag{20.14}$$

Indeed, both terms of the bimodule bar are induced from bounded finite free R-complexes. Tensor–Hom base change holds on each term and commutes with the bar differential, evaluation, and insertions. If one h_i is inverted, $h_i^{-1}\iota_i$ contracts M. The center then reduces to the two scalar endpoint sectors.

At the common zero of the parameters, put $V = \Lambda W$ and $T_0 = T_R \otimes_R k$. The arrow differential becomes zero.

Theorem 20.8.2. The entire singular-fiber center has cohomology

$$\mathrm{HH}^*_k(T_0) = k \ltimes \big(\mathrm{End}_k(V)/k\,\mathrm{id}\big)[-1].$$

The ideal has square-zero cup product and the shifted graded-commutator bracket. The unit has zero bracket. Its dimensions are

$$\dim_k \mathrm{HH}^n_k(T_0) = \begin{cases} 1 + \binom{2r}{r-1}, & n = 0, \\ \binom{2r}{r} - 1, & n = 1, \\ \binom{2r}{r+n-1}, & \text{otherwise}, \end{cases}$$

where out-of-range binomial coefficients are zero. The total dimension is 4^r.

Proof. In (20.12), the remaining differential sends the endpoint difference to id, now in center degree one. The diagonal scalar is the unit. All other classes are one-arrow cochains modulo this identity. The formulas for cup products and brackets descend to the stated operations.

For internal degree p,

$$\dim_k \mathrm{End}^p(\Lambda W) = \sum_j \binom{r}{j}\binom{r}{j+p} = \binom{2r}{r+p}.$$

Shift by one, remove the scalar identity in degree one, and add the unit in degree zero. This gives the formula. □

For $r = 2$, the dimensions in degrees $-1, 0, 1, 2, 3$ are $1, 5, 5, 4, 1$. Ordinary specialization of the integral degree-zero ring has dimension only three, with basis $1, t_1, t_2$. Thus (20.14) requires derived specialization before cohomology.

There is also no R-linear deformation retraction of the displayed finite complex onto its integral cohomology with zero differential. The nonzero group $\mathrm{HH}^2_R(T_R)$ is annihilated by I, while Z^2 is free. Every R-linear map from that group into Z^2 is zero, since h_1 acts injectively on Z^2. Such a map cannot have a left inverse. This excludes the specified contraction, without deciding all possible formality zigzags.

A nonzero bracket obstruction

Take $r = 2$ and the basis $v_0 = 1, v_1 = u_1, v_2 = u_2, v_3 = u_1u_2$, of degrees $0, 1, 1, 2$. Define a degree-one endomorphism by

$$f(v_0) = v_1, \qquad f(v_1) = v_3, \qquad f(v_2) = f(v_3) = 0.$$

The arrow differential ϵf defines a first-order deformation over $k[\epsilon]/(\epsilon^2)$. Its square vanishes modulo ϵ^2, and no two arrows compose.

PROPOSITION 20.8.3. This first-order deformation has no extension over $k[\epsilon]/(\epsilon^3)$ on the same graded module, even with uncurved A_∞ corrections having the same first-order Hochschild class. The obstruction is

$$\frac{1}{2}[\sigma f, \sigma f] = \sigma f^2 \neq 0 \quad \text{in } \mathrm{HH}^3_k(T_0).$$

Its cup square is zero.

Proof. The endomorphism square is nonzero: $f^2(v_0) = v_3$. Adding $\epsilon^2 g$ to the arrow differential leaves its square $\epsilon^2 f^2$ modulo ϵ^3.

Allowing higher-arity operations gives the second-order equation

$$d_{\mathrm{Hoch}} g + \tfrac{1}{2}[\sigma f, \sigma f] = 0.$$

The class of σf^2 is nonzero in Theorem 20.8.2: its internal degree is two, so it cannot be a scalar identity. The obstruction class depends only on the first-order cohomology class. No such correction exists. The cup square vanishes by (20.13). □

The original Koszul directions do integrate: $(xL_1 + yL_2)^2 = 0$ over $k[x, y]$. The insertion bracket distinguishes these directions from f. Under the scalar extension and empty-coefficient retraction constructed earlier, the nonzero obstruction remains nonzero in the scalar center of the extended algebra. Applying the retraction recovers it, including its bracket. Interpreting that image as a diagonal action still requires a map between the two action problems.

20.9 DUALITY CHANGES THE VARIANCE OF A CENTER

Return to the ordered collision category $(C, \star, K)$. Its convolution combines coefficients on disjoint subsets, and K is supported at the empty configuration. Let A be an augmented associative algebra with $A_\varnothing = k$, and let $C = BA$. The full coefficient duality of Chapter 19 is an anti-equivalence

$$(-)^\sharp : C^{\mathrm{op}} \simeq C^\sharp, \qquad (V \star W)^\sharp \simeq V^\sharp \star_\sharp W^\sharp.$$

It retains the entire pro-perfect diagram, including its transition maps. Write S for the inverse anti-equivalence and $E = C^\sharp$ for the transposed bar algebra.

A central operation is a bimodule map $V \star A \to A$. The coefficient-linear bar comparison carries it to $V \star C \to C$ in bicomodules. Transposition gives

$$E \longrightarrow V^\sharp \star_\sharp E.$$

Thus the coefficient has moved from the source to the target. This is the variance of a central coaction.

Theorem 20.9.1. Let $Z^{\mathrm{int}}(A)$ be the internal center and put $Q_A = Z^{\mathrm{int}}(A)^\sharp$. For every $W \in C^\sharp$,

$$R\,\mathrm{Hom}_{C^\sharp}(Q_A, W) \simeq R\,\mathrm{Hom}_{E\text{-}E}(E, W \star_\sharp E).$$

The object Q_A has the counital coalgebra structure dual to composition in the center. Its universal map is a coherent coaction in E-bimodules,

$$\gamma_A : E \longrightarrow Q_A \star_\sharp E.$$

Proof. The three natural equivalences are

$$\begin{aligned} R\,\mathrm{Hom}(Q_A, W) &\simeq R\,\mathrm{Hom}_C(\mathsf{S}W, Z^{\mathrm{int}}(A)) \\ &\simeq R\,\mathrm{Hom}^{C\text{-}C}((\mathsf{S}W) \star C, C) \\ &\simeq R\,\mathrm{Hom}_{E\text{-}E}(E, W \star_\sharp E). \end{aligned}$$

The middle step is the coefficient-linear bar comparison, and the last transposes the actual bicomodule maps. The identity of Q_A gives γ_A. Naturality says that the map associated with $q : Q_A \to W$ is $(q \star_\sharp \mathrm{I}_E)\gamma_A$.

Composition makes the evaluation of the internal center an associative unital action. Transpose its identities and coherent homotopies. They become the coassociativity and counit identities of γ_A. Every comparison respects the original collision diagram. □

An arbitrary map $q : Q_A \to W$ gives a bimodule map with coefficient W. Suppose W is counital. The displayed map is a counital coaction precisely when q is a coalgebra map. Explicitly, this requires

$$\epsilon_W q = \epsilon_{Q_A}, \qquad \Delta_W q = (q \star_\sharp q)\Delta_{Q_A},$$

together with their higher coherences. Apply the natural equivalence of the theorem to K, $W \star_\sharp W$, and all higher tensor powers to obtain this equivalence of coherent structures. The zero bimodule map, for example, fails the counit identity when $E \neq 0$.

An internal center of E would represent the different functor $W \mapsto R\,\mathrm{Hom}_{E\text{-}E}(W \star_\sharp E, E)$. The existence of Q_A does not settle that representability question.

Scalar centers and reflection

Scalarization tests only the tensor unit. For bounded holonomic coefficients, Verdier duality gives the algebra $\mathsf{K}_* A = \mathbb{D}BA$ for the transported product $\star_!$. There is an equivalence

$$Z^{\mathrm{sc}}(A) \simeq Z^{\mathrm{sc}}(\mathsf{K}_* A)^\sigma$$

of E_2-algebras, where σ reflects one multiplication direction.

To see the reflection, first use the coefficient-linear equivalence between bimodules over A and bicomodules over BA. The regular bimodule becomes the regular bicomodule. The derived cotensor of two bicomodules is computed by normalized terms $P \star \overline{C}^{\star q} \star Q$. At a configuration I, positivity of $\overline{C}$ leaves only $q \leq |I|$.

Verdier duality therefore transposes a finite limit into the finite realization that computes the balanced tensor product over $\mathbb{D}C$. It preserves the units and iterated interface compositions with their coherences. It reverses the vertical composition of maps. The two compositions that give the E_2 structure consequently have one direction reflected.

On cohomology this preserves the cup product and reverses the Gerstenhaber bracket. Multiplication by $(-1)^n$ in degree n identifies the resulting graded Gerstenhaber algebras abstractly. That observation alone supplies no chain-level E_2 comparison without the reflection. Internal polarity, scalar reflection, and opposite algebra formation remain separately typed constructions.

A point-supported test

Fix a point x of the curve. Put the same differential-module point direct image on each positive ordered chart, at the tuple $(x, \dots, x)$, with its Kashiwara collision identifications. Such systems, together with an arbitrary empty coefficient, form a category $D(k) \times D(k)$. Write an object as (U_0, U_1). Its tensor is

$$(U_0, U_1) \star (V_0, V_1) = \big(U_0 \otimes V_0,\ (U_0 \otimes V_1) \oplus (U_1 \otimes V_0)\big).$$

Two positive factors have zero product: the disjoint open misses their common support. The remaining collision identifications have no extra mapping data, since positive ordered sets and monotone surjections have the singleton as terminal object.

For a vector space M, take

$$A_M = (k, M[-1]), \qquad E_M = (BA_M)^\sharp = (k, M^\sharp).$$

The bar has only the empty and singleton terms. Here $M^\sharp$ is the pro-object of duals of finite-dimensional subspaces of M.

LEMMA 20.9.2. For $W(V) = (V^\sharp, 0)$, there is a natural equivalence

$$R\operatorname{Hom}_{E_M\text{-}E_M}(W(V) \star_\sharp E_M, E_M) \simeq V \oplus \operatorname{Hom}_k(M, V \otimes M)[-1].$$

For vector spaces V, M, these summands lie in degrees zero and one with zero differential.

Proof. Let $N = (0, M^\sharp)$. Since $N \star_\sharp N = 0$, the bimodule bar has two free terms. Its positive part is the split exact sequence

$$M^\sharp \xrightarrow{n \mapsto (n,-n)} M^\sharp \oplus M^\sharp \xrightarrow{(a,b) \mapsto a+b} M^\sharp.$$

The first free term has resolution degree -1.

Tensoring by $W(V)$ and applying free bimodule adjunction gives the two coefficient mapping objects V and $\operatorname{Hom}_k(M, V \otimes M)$. The left and right scalar actions agree, so the Hom differential is zero. The resolution degree places the second summand in degree one. □

For $M = k$, all relevant internal objects exist within these point categories, but they have different coefficients:

$Z^{\mathrm{int}}(A_k)$	$(k \oplus k[-1], k[-1])$
Q_{A_k}	$(k \oplus k[1], k[1])$
$Z^{\mathrm{int}}(E_k)$	$(k \oplus k[-1], k)$.

The positive test has no additional bar term, while the empty test acquires the shifted endomorphism term. Duality reverses its shift. Maps from the unit to the center and maps from the coHom to the unit still give the same scalar complex $k \oplus k[-1]$.

Proposition 20.9.3. For $M = \bigoplus_{r \geq 0} k e_r$, the algebra E_M has no internal center representing all pro-perfect coefficient tests. Its universal central coaction still exists.

Proof. A representing object would turn the restricted tests into $R\operatorname{Hom}_k(T, V)$, where T is its transposed empty coefficient. This functor preserves products in V. So would its degree-one cohomology.

The product comparison in the lemma would then be surjective:

$$\operatorname{Hom}_k\left(M, \left(\prod_{r \geq 0} k\right) \otimes M\right) \longrightarrow \prod_{r \geq 0} \operatorname{End}_k(M).$$

It misses the family $f_r(e_0) = e_r$, $f_r(e_j) = 0$ for $j > 0$. The value at e_0 on the left is a finite tensor sum. All its coordinates lie in one finite-dimensional subspace of M, whereas the e_r do not. This contradicts product preservation. The coaction follows independently from Theorem 20.9.1. □

20.10 A holonomic representing kernel

Finite-dimensional duality suggests a positive criterion: $\operatorname{Hom}(M, V \otimes N) \simeq \operatorname{Hom}(M \otimes N^*, V)$. The output N is dualized, while the test V remains arbitrary. For holonomic differential modules, direct image and Verdier duality give the corresponding relative kernel.

Work over $\mathbb{C}$ on smooth schemes of finite type. Let $\mathsf{H}(Y) = D^b_{\mathrm{hol}}(\mathcal{D}_Y)$. Use $P \otimes^! Q = \Delta^!_Y(P \boxtimes Q)$, with its density and shift conventions. The two required identities are

$$R\operatorname{Hom}_{\mathcal{D}_Y}(M, L) \simeq R\Gamma_{\mathrm{dR}}(Y, \mathbb{D}_Y M \otimes^! L),$$
$$p_*(P \otimes^! p^! L) \simeq p_* P \otimes^! L.$$

The first allows bounded coherent M and arbitrary L. The second is the projection formula for quasi-compact morphisms.

These are the Verdier pairing and projection formula of Drinfeld–Gaitsgory, *On some finiteness questions for algebraic stacks*, Sections 5.2.6 and 5.3.1. We use preservation of bounded holonomicity under inverse image, direct image, and duality. On affine space the first two are Miličić, *Lectures on Algebraic Theory of D-Modules*, Chapter I, Theorems 14.6 and 14.7.

Lemma 20.10.1. For $p : U \to Y$, $q : U \to Z$, and $M \in \mathsf{H}(U)$, $N \in \mathsf{H}(Z)$, put

$$P_{p,q}(M, N) = \mathbb{D}_Y\, p_*(\mathbb{D}_U M \otimes^! q^! N).$$

This object is bounded holonomic and, for every $V \in \mathrm{DMod}(Y)$,

$$R\operatorname{Hom}_{\mathcal{D}_U}(M, p^! V \otimes^! q^! N) \simeq R\operatorname{Hom}_{\mathcal{D}_Y}(P_{p,q}(M, N), V).$$

Proof. External product, inverse image, and duality preserve bounded holonomicity. So does algebraic direct image. The tensor product is the inverse image of an external product along the diagonal. This proves the first assertion.

For the mapping equivalence, apply the Verdier pairing, then the projection formula:

$$R\Gamma_{\mathrm{dR}}(U, \mathbb{D}_U M \otimes^! p^! V \otimes^! q^! N) \\ \simeq R\Gamma_{\mathrm{dR}}(Y, V \otimes^! p_*(\mathbb{D}_U M \otimes^! q^! N)).$$

Apply the pairing again to the bounded holonomic kernel. At no step was V required to be holonomic. Naturality gives the coherent composition comparisons. □

In particular, $f_! M = \mathbb{D}_Z f_* \mathbb{D}_Y M$ is left adjoint to $f^!$ on these source objects, against arbitrary targets. Properness is not required for this assertion.

Retaining the collision diagram

Call a coefficient system *configurationwise holonomic* if its empty coefficient is perfect and each nonempty coefficient is bounded holonomic. The bounds may depend on the configuration. Let $\mathcal{C}_{\mathrm{h}}$ be the ordered collision category formed from $\mathrm{Ind}\,\mathsf{H}(\mathscr{R}_I)$, with a $D(k)$ empty coefficient.

Bounded holonomic modules are compact in $\mathrm{DMod}(\mathscr{R}_I)$: they are bounded coherent, and the compactness statement is Drinfeld–Gaitsgory, Section 5.1.17. Thus the inclusion $b_I : \mathrm{Ind}\,\mathsf{H}(\mathscr{R}_I) \to \mathrm{DMod}(\mathscr{R}_I)$ is fully faithful, preserves colimits, and has a right adjoint r_I. For every collision morphism f,

$$r_Y f^! \simeq f^! r_Z.$$

Indeed, testing both sides on bounded holonomic H gives

$$R\,\mathrm{Hom}(H, f^! L) \simeq R\,\mathrm{Hom}(f_! H, L) \simeq R\,\mathrm{Hom}(f_! H, r_Z L).$$

These tests generate the ind-category. The equivalences are adjunction mates of the coherent composition maps.

On ind-holonomic modules, $f^!$ preserves colimits and is also a right adjoint to the ind-extension of $f_!$, so it preserves limits. The coherent limit category $\mathcal{C}_{\mathrm{h}}$ is therefore presentable with componentwise limits and colimits. Its inclusion b has right adjoint r, and evaluation e_I has a left adjoint $e_{I,!}$.

PROPOSITION 20.10.2. For configurationwise holonomic M, N, there is an object $\mathsf{T}(M, N) \in \mathcal{C}_{\mathrm{h}}$ such that, for every $V \in \mathcal{C}$,

$$R\,\mathrm{Hom}_{\mathcal{C}}(b\mathsf{T}(M, N), V) \simeq R\,\mathrm{Hom}_{\mathcal{C}}(M, V \star N).$$

Proof. For a split $I = A \sqcup B$, let j be its disjoint open immersion and p, q the projections from that open to $\mathscr{R}_A, \mathscr{R}_B$. The split summand of the mapping object on the right is

$$R\,\mathrm{Hom}_{\mathcal{D}_{\mathscr{R}_A}}(P_{p,q}(j^! M_I, N_B), V_A).$$

This follows from open adjunction and the preceding lemma. The kernel is bounded holonomic, so these maps depend only on $r_A V_A$.

Define the finite sum

$$T_I = \bigoplus_{I = A \sqcup B} e_{A,!} P_{p,q}(j^! M_I, N_B).$$

Its mapping functor gives the mapping object at I. The collision maps induce, by enriched Yoneda, the contravariant coherent diagram of the T_I. Take its colimit, including the separate empty term, to obtain $\mathsf{T}(M, N)$.

Mapping out of the colimit gives the required coherent limit over configurations. The adjunction $b \dashv r$ extends the equivalence from ind-holonomic tests to all V. The construction retains the collision homotopies. □

The center of the transposed algebra

Let A be configurationwise holonomic, augmented, with $A_{\varnothing} = k$. For $s \geq 0$ form $T_s = \mathsf{T}(A^{\star s}, A)$, where $A^{\star 0} = K$. Finite convolution powers remain configurationwise holonomic. The two-sided bar gives a simplicial object $T_\bullet$, with faces and degeneracies induced by multiplication and unit. Put $T_A = b|T_\bullet|$.

Theorem 20.10.3. For $E = (BA)^\sharp$, the object $T_A^\sharp$ represents the internal center on every pro-perfect probe:

$$R\operatorname{Hom}_{C^\sharp}(W, T_A^\sharp) \simeq R\operatorname{Hom}_{E\text{-}E}(W \star_\sharp E, E).$$

The equivalence includes evaluation, the internal E_2 operations, and the ordered collision coherences.

Proof. The augmented two-sided bar contracts by its unit. Free bimodule adjunction and the proposition give

$$\begin{aligned} R\operatorname{Hom}_{A\text{-}A}(A, V \star A) &\simeq \operatorname*{Tot}_s R\operatorname{Hom}(A^{\star s}, V \star A) \\ &\simeq \operatorname*{Tot}_s R\operatorname{Hom}(bT_s, V) \\ &\simeq R\operatorname{Hom}(T_A, V). \end{aligned}$$

This keeps the entire realization. It assumes neither a uniform arity bound nor bounded holonomicity of T_A itself.

Set $V = \mathsf{S}W$. Coefficient-linear bar comparison and transposition identify the first line with $R\operatorname{Hom}_{E\text{-}E}(W \star_\sharp E, E)$. The last line becomes $R\operatorname{Hom}_{C^\sharp}(W, T_A^\sharp)$. These identifications are natural for all probes.

The identity of T_A corresponds to a universal map $\rho : A \to T_A \star A$. Its iteration gives the coproduct of T_A, and the identity of A gives the counit. There is a second composition from $\rho \star_A^{\mathbb{L}} \rho$, using

$$(T_A \star A) \star_A^{\mathbb{L}} (T_A \star A) \simeq (T_A \star T_A) \star A.$$

Convolution preserves the bar realization of the balanced product. The two compositions share a unit and satisfy coherent interchange. They give the E_2-coalgebra operations on T_A, which transpose to the center operations on $T_A^\sharp$. The same adjunctions retain collision coherences. □

The universal central coaction and this internal center now coexist. They solve the two mapping problems with opposite variance. Neither construction identifies the actor of an independently specified bulk theory.

20.11 Free generators and their support

A two-term bimodule resolution computes the center of a free algebra without suppressing the support of its generators. First work in the word category $(\mathcal{W}_X, \otimes_{\mathrm{cut}}, K)$, where the tensor uses consecutive cuts. For an object M, put

$$A = T_{\mathrm{cut}}(M) = \bigoplus_{n \geq 0} M^{\otimes_{\mathrm{cut}} n}, \qquad M^{\otimes_{\mathrm{cut}} 0} = K.$$

This is an algebraic direct sum. Multiplication concatenates the factors, with no permutation.

PROPOSITION 20.11.1. There is a cofiber sequence of bimodules

$$A \otimes_{\mathrm{cut}} M \otimes_{\mathrm{cut}} A \xrightarrow{\partial} A \otimes_{\mathrm{cut}} A \xrightarrow{\mu} A,$$

where $\partial(a \otimes m \otimes b) = am \otimes b - a \otimes mb$. Consequently the scalar center is

$$Z_{\mathrm{word}}(A) \simeq \mathrm{fib}\big(R\,\mathrm{Hom}_{\mathcal{W}_X}(K, A) \longrightarrow R\,\mathrm{Hom}_{\mathcal{W}_X}(M, A)\big).$$

On a degree-zero coefficient $c : K \to A$, the arrow is $m \mapsto mc - cm$.

Proof. Fix tensor length n. The middle term has one copy of the word coefficient for each cut $c_0, \dots, c_n$. The first term has one copy for each marked factor $e_0, \dots, e_{n-1}$. The maps are

$$\partial e_i = c_{i+1} - c_i, \qquad \mu c_i = 1.$$

This is the augmented interval complex. The section $1 \mapsto c_0$ has homotopy $h(c_i) = e_0 + \cdots + e_{i-1}$. Tensoring with the word coefficient preserves the contraction, including its internal differential. Summing over n proves the cofiber sequence. Apply the derived free bimodule adjunction to obtain the fiber formula. □

For a differential module N, let iN be its positive diagonal insertion, with coefficient $\Delta_{n*}N$ on a word of length n. Kashiwara equivalence identifies all these coefficients with N. The collision index has the singleton as terminal object, so

$$R\,\mathrm{Hom}_{\mathcal{W}_X}(iN, G) \simeq R\,\mathrm{Hom}_{\mathcal{D}_X}(N, G_1).$$

For $A = T_{\mathrm{cut}}(iN)$, $A_\varnothing = k$ and $A_1 = N$. The scalar commutator is zero. Thus

$$Z_{\mathrm{word}}(T_{\mathrm{cut}}(iN)) \simeq k \oplus R\,\mathrm{Hom}_{\mathcal{D}_X}(N, N)[-1].$$

Any internal self-extension of N remains in this formula, shifted by one center degree.

Example 20.11.2 *(Two diagonal generators).* On $X = \mathbb{A}^1_k$, take $N = \omega_X \otimes_k k^2$ with trivial connection. As a right differential module, $\omega_X = D/\partial_z D$. Its free resolution has differential $P \mapsto \partial_z P$. Applying Hom into ω_X gives $k[z] \xrightarrow{-\partial_z} k[z]$. Polynomial integration therefore gives

$$H^0 Z_{\mathrm{word}}(A) = k, \qquad H^1 Z_{\mathrm{word}}(A) = M_2(k),$$

and no further groups.

A matrix acts by the derivation that applies it in each tensor position. The bracket is the matrix commutator. No nonzero matrix is an inner boundary, because the only degree-zero coefficients are scalars. Positive cup products vanish, since $H^2 = 0$.

On $\mathbb{G}_m$, the derivative on $k[z, z^{-1}]$ has the additional cokernel generated by z^{-1}. The same two generators then give $H^2 = M_2(k)$ as well, from the de Rham residue dz/z.

Placing the two generators at the empty word gives a different result. Let $M = K \otimes_k (kx \oplus ky)$. Then $A = K \otimes_k F$ for the ordinary free algebra $F = k\langle x, y\rangle$, and its center complex is

$$F \longrightarrow F \oplus F, \qquad c \longmapsto (xc - cx, yc - cy).$$

It has $H^0 = k$ and $H^1 = \mathrm{Der}(F)/\mathrm{Inn}(F)$, with no higher groups. The degree-one space is infinite dimensional: the derivations $x \mapsto y^m$, $y \mapsto 0$ are independent modulo inner derivations. Abelianization kills commutators and sends their first components to the independent polynomials y^m.

The difference comes from support. A diagonal generator can only take values compatible with the diagonal mapping adjunction. A generator at the empty word can take values in the entire ordinary free algebra.

Perfect differential modules

The same interval resolution applies to the full collision convolution. Let M be a perfect right $\mathcal{D}_X$-complex on $X = \mathbb{A}^1_{\mathbb{C}}$. Let G_M be its positive diagonal family, with one small-diagonal direct image of M on each ordered chart. Define

$$\mathfrak{A}_M = T_\star(G_M), \qquad \mathfrak{C}_M = K \oplus G_M[1], \qquad \mathfrak{E}_M = \mathfrak{C}_M^\sharp.$$

The reduced coproduct of $\mathfrak{C}_M$ is zero. Its cobar is $\mathfrak{A}_M$, and its map to $B\mathfrak{A}_M$ sends $g[1]$ to the singleton bar word. Bar–cobar comparison identifies these coalgebras. At a fixed configuration the word filtration is finite.

Write $[G, N]_\star$ for internal Hom and $B_M = R\,\mathrm{Hom}_{\mathcal{D}_X}(M, M)$ for the scalar endomorphism complex. The interval resolution, tested on every coefficient, gives

$$Z^{\mathrm{int}}(\mathfrak{A}_M) \simeq \mathrm{fib}\Big(\mathfrak{A}_M \xrightarrow{\mathrm{ad}} [G_M, \mathfrak{A}_M]_\star\Big).$$

Here ad is adjoint to the graded commutator. Transposing this fiber gives the coHom

$$Q_{\mathfrak{A}_M} \simeq \mathrm{cofib}\Big([G_M, \mathfrak{A}_M]^\sharp_\star \longrightarrow \mathfrak{A}_M^\sharp\Big),$$

with its universal central coaction.

Lemma 20.11.3. For every complex V over $\mathbb{C}$,

$$R\,\mathrm{Hom}_{\mathfrak{A}_M\text{-}\mathfrak{A}_M}(\mathfrak{A}_M, (VK) \star \mathfrak{A}_M) \simeq V \oplus (V \otimes B_M)[-1].$$

Proof. Apply the free bimodule resolution to the indicated target. The resolution-degree-zero term is V. The two endpoint actions agree, so the map to the other term is zero.

Only the length-one part of $\mathfrak{A}_M$ contributes to maps from G_M. Every longer word is extended by j_* from an open missing the small diagonal. Open adjunction makes its mapping complex from G_M zero. The empty word also receives no map from this positive object. These vanishings respect every collision map.

Kashiwara equivalence and the contractible index of ordered surjections identify the remaining maps with $R\,\mathrm{Hom}_{\mathcal{D}_X}(M, V \otimes M)$. On the affine line, a perfect M is a retract of a finite complex of finite free modules. Thus V can be moved through this finite Hom complex, giving $V \otimes B_M$. The bar degree shifts it by one. □

Theorem 20.11.4. If $\mathfrak{E}_M$ has an internal center on all pro-perfect probes, then B_M is perfect over $\mathbb{C}$. In particular, $\mathfrak{E}_{\mathcal{D}_X}$ has no such center, although each configuration coefficient is the dual of a perfect differential-module complex.

Proof. Coefficient-linear bar comparison and transposition turn the lemma into the tests of a proposed center on $W(V) = (VK)^\sharp$. Representability would make $V \mapsto V \oplus (V \otimes B_M)[-1]$ preserve products. Its second summand would also preserve them.

The complex B_M is bounded. If $H^q(B_M)$ contained independent vectors $b_0, b_1, \ldots$, the family (b_i) would not lie in the image of

$$\left(\prod_{i\ge 0} \mathbb{C}\right) \otimes H^q(B_M) \longrightarrow \prod_{i\ge 0} H^q(B_M).$$

Every tensor on the left uses one finite-dimensional span for all coordinates. Products of vector spaces are exact, so this is also the product obstruction on cohomology. Every $H^q(B_M)$ must therefore be finite dimensional.

For $M = \mathcal{D}_X$, the complex B_M is the Weyl algebra $\mathbb{C}\langle z, \partial\rangle/(\partial z - z\partial - 1)$ in degree zero. The sequence ∂^i violates the common finite differential-order bound.

The coefficient perfectness is a different statement. On a smooth chart the direct image of the free module along a small diagonal has a finite Koszul resolution in its normal coordinates. The normal coordinate operators form a regular sequence by Weyl normal ordering. Finite sums, shifts, cones, retracts, and the finite-cell dual preserve perfectness. This proves the coefficient assertion. □

For scalar probes alone the condition is also sufficient. If B is a bounded complex over k, the functor $V \mapsto V \oplus (V \otimes B)[-1]$ is corepresented by $k \oplus B^\vee[1]$ exactly when B is perfect. Finite duality proves sufficiency, and the same product argument proves necessity. Extending this scalar representation to all collision probes still requires compatible geometric kernels.

The scalar center of $\mathfrak{A}_{\mathcal{D}_X}$ remains $k \oplus B_M[-1]$. A right-linear endomorphism a extends to a derivation D_a of the free convolution algebra. Its bracket is

$$[D_a, D_b] = D_{ab-ba}, \qquad [D_\partial, D_z] = D_1 \neq 0.$$

Here D_1 multiplies a word by its length. It is not an inner boundary, since degree-zero coefficients are scalars.

Coefficient transposition sends z to z and ∂ to $-\partial$. Hence the transposed commutator is -1, displaying the reflected bracket sign on a nonzero class.

These free-algebra examples have no prescribed field realization or normalized local vacuum. To apply the same test to a field algebra, its actual relations must enter the endomorphism and representability calculation.

20.12 Heisenberg states and the word center

The Heisenberg residue algebra has the entire vacuum module at one position. It is therefore different from a free word algebra on two diagonal current generators. The vacuum, products of currents, and all translations must remain in the coefficient module.

Let k have characteristic zero. Take $B = k[\kappa]$, or a field over k with a specified level κ. Let $g = (g_{ij})$ be a nondegenerate symmetric form on a rank-two current space. The even currents satisfy

$$[a^i_\lambda a^j] = \kappa g_{ij} \lambda \mathbf{1}.$$

Their state module and translation are

$$V_\kappa = B[x^i_m : i = 1, 2,\ m \ge 1], \qquad x^i_m = a^i_{-m}\mathbf{1}, \qquad T = \sum_{i,m\ge 1} m x^i_{m+1} \partial_{x^i_m}.$$

Every state is a polynomial in finitely many variables. There is no completion in state weight. The right differential module $\mathscr{V}_\kappa$ has action

$$(f\,dz \otimes v)\partial_z = -f'\,dz \otimes v - f\,dz \otimes Tv.$$

All maps are relative to B.

Let $C(V_\kappa)$ be the word residue coalgebra and $A_\kappa = \Omega_{\mathrm{cut}} C(V_\kappa)$. The equation $xy - yx = \kappa \mathbf{1}_K$ cannot present this algebra on positive generators at nonzero level. Applying the augmentation would give $0 = \kappa$. The Heisenberg bracket instead takes values in the positive local vacuum line inside $\mathscr{V}_\kappa$. That line is distinct from the empty-word unit.

The full degree-one kernel

Put $\nabla = \partial_z + T$. For a pair of polynomials $P = (P_1, P_2) \in B[z, x_m^i]^2$, define

$$\mathcal{K}_{ij}(P) = \sum_{s=1}^{2} \sum_{m \geq 1} \frac{1}{(m-1)!} \Big(g_{is} \lambda^m \partial_{x_m^s} P_j - g_{js} (-\lambda - \nabla)^m \partial_{x_m^s} P_i \Big). \tag{20.15}$$

The operator ∇ in the second term acts on its coefficient to the right. All sums are finite. A *chiral derivation* is a differential-module endomorphism δ such that

$$\delta r_{12} = r_{12}(\delta \boxtimes 1 + 1 \boxtimes \delta)$$

on the entire localized two-input coefficient, for every multiplier.

Theorem 20.12.1. The full scalar word center satisfies

$$\begin{aligned} H^q Z_{\mathrm{word},B}(A_\kappa) &= 0 \quad (q < 0), \\ H^0 Z_{\mathrm{word},B}(A_\kappa) &= B, \\ H^1 Z_{\mathrm{word},B}(A_\kappa) &\cong \{P \in B[z, x_m^i]^2 : \kappa \mathcal{K}_{ij}(P) = 0 \text{ for all } i, j\}. \end{aligned}$$

The degree-one class has $\delta_z a^i = P_i(z)$ and acts by the sum of δ over the state blocks of every partition. There is no quotient by non-scalar inner derivations.

Proof. Use the field retract in the normalized two-sided bar. A map from a partition with r blocks to one with t blocks vanishes unless the source partition refines the target. Otherwise some coordinate difference annihilates the source and is inverted on the target. Open adjunction gives zero.

For q consecutive positive factors, the source shift is $r - q$, the target shift is $t - 1$, and Hochschild length adds q. Thus a coefficient Ext class of degree e has total degree $e + r - t + 1$. This is at least one. For $q \geq 2$, a cut source can map to an indecomposable target only after a merger, so the degree is at least two.

The uniform lower bounds survive the complete products and coherent collision limits. The length-zero term is B, with zero scalar commutator. This proves the first two claims.

In degree one only ordinary unary maps on equal partitions remain. Their one-block restriction is one map $\delta : \mathscr{V}_\kappa \to \mathscr{V}_\kappa$. The binary equation says precisely that it is a chiral derivation. The simple-pole two-vacuum input also gives $\delta \mathbf{1} = 0$.

Subtract its blockwise sum. Induct on the number of blocks. Every merger of an indecomposable partition remains indecomposable, so commutation with residues makes every merger of the difference

zero. The Heisenberg field map is faithful on polynomial states, with arbitrary spectators and Laurent multipliers. Consequently the difference is zero.

For completeness, this faithfulness can be checked before quantization. In the associated graded by current number, the field is $(e^{uT}a)b$. On any finite collection of jets, sufficiently high translated jets give an invertible coefficient minor: the binomial coefficient matrix has nonzero Vandermonde leading determinant. Hence the two-field map is injective.

Wick contractions lower current number by two, so the same filtered argument proves injectivity at every level. Over $k[\kappa]$, torsion-freeness reduces to the fraction field. Multiplying by every power of the separation tests every field coefficient through its residue.

It remains to characterize δ. The differential-module and field identities are

$$\begin{aligned} \partial_z \delta_z + [T, \delta_z] &= 0, \\ \delta_z Y(v,u)w &= Y(\delta_{z+u}v, u)w + Y(v,u)\delta_z w. \end{aligned}$$

The positive current modes are $a^i_m = m\kappa \sum_s g_{is}\partial_{x^s_m}$, while $a^i_0 = 0$. Applying δ to the current bracket gives exactly $\kappa\mathcal{K}_{ij}(P) = 0$. Skew symmetry on a moving coefficient replaces T by ∇, explaining the second term of (20.15).

Conversely, put

$$\begin{aligned} Q^i_n(P;z) &= \sum_{\ell \ge 0} \frac{(\partial_z^\ell P_i(z))_{(n+\ell)}}{\ell!}, \\ \delta_P \mathbf{1} &= 0, \\ \delta_P(x^i_m v) &= x^i_m \delta_P(v) + Q^i_{-m}(P;z)v. \end{aligned} \tag{20.16}$$

Over $B[\epsilon]/(\epsilon^2)$, the kernel equation says that $Y(a^i,u) + \epsilon Y(P_i(z+u),u)$ satisfies the Heisenberg commutators. Its nonnegative modes kill the vacuum. The induced vacuum module therefore makes the recursion independent of the order of negative modes. Commuting through normally ordered differentiated fields proves the derivation identity on every state, including all contractions.

Finally

$$[T, Q^i_n] = -nQ^i_{n-1} - \partial_z Q^i_n$$

shows that $\partial_z\delta_P + [T, \delta_P]$ commutes with the currents and kills the vacuum, hence vanishes. The blockwise sum commutes with cuts, residues, and the first-cut contraction, so it is a cocycle for all transferred operations. The degree bounds leave no additional degree-one classes or inner identifications. □

Constant linear images $P_i = \sum_j M_{ij}x^j_1$ give the subspace

$$\kappa(Mg + gM^{\mathrm{t}}) = 0.$$

For the hyperbolic form this has dimension one at a nonzero field-valued level, and dimension four at level zero. It is only a subspace of the full kernel. For every level, $P_i = c_i(z)$ gives

$$\delta_P x^i_m = \frac{c_i^{(m-1)}(z)}{(m-1)!},$$

and $P_i = x_2^i$ gives translation. At level zero every pair of differential polynomials is allowed, with

$$\delta_P = \sum_{i,m\geq 1} \frac{\nabla^{m-1} P_i}{(m-1)!} \partial_{x_m^i}.$$

At nonzero level, reconstructing nonlinear current images requires the quantum terms in (20.16). For one current, the image $P = x_1 x_2$ is allowed and

$$\delta_P(x_1^2) = 2x_1^2 x_2 + \kappa x_4.$$

A polynomial derivation of the state multiplication alone would miss the last term.

A central state also need not extend to a center endomorphism of the word cobar. The regular right module is free on K, so its degree-zero right-module endomorphisms are $\mathrm{Hom}(K, A) = B$. If such an endomorphism restricts to $c_{(-1)}$ on states, evaluation on the vacuum forces $c = b\mathbf{1}$. At level zero every state is vertex-central, but only these scalar states extend in this manner. Applying a scalar separately to each block is a different assignment. The scalar 2 would act by 4 on two blocks, whereas 2 id acts by 2.

The level variation

In the strict word cobar, the state modules and concatenation are independent of κ. Only the residue differential D_κ varies. Define the B-linear family of cochains $L_\kappa = \partial_\kappa D_\kappa$. The derivative here defines a family of maps. A cochain does not differentiate its scalar coefficients. Let N count current factors in every state block.

Differentiating $D_\kappa^2 = 0$ and the differential derivation identity shows that L_κ is a degree-two Hochschild cocycle. A Wick term with c contractions contains κ^c and lowers current number by $2c$. Hence

$$bN = 2\kappa L_\kappa.$$

At a nonzero field-valued level the class is zero.

At level zero, its value on two holomorphic currents has a nonzero double-pole vacuum coefficient. Every undeformed field is regular there, so the binary boundary of a state endomorphism has zero such coefficient. The degree bounds in the preceding proof exclude additional derived primitives. Thus the class is nonzero at zero level. Over $k[\kappa]$, reduction modulo κ detects every coefficient not divisible by κ. Its annihilator is exactly (κ).

Varying the symmetric pairing similarly gives $(B/(\kappa))^3$ in degree two for rank two. Higher poles give further classes, as follows.

20.13 Degree two on words and collision coefficients

Let $\mathcal{V}_\pi$ denote the localized partition coefficient with its normal differential operators and residue maps $r_{ij} : \mathcal{V}_\pi \to \mathcal{V}_{\pi/(i\sim j)}$. We first give a presentation of the entire word degree-two group. It permits one component for every finite word.

Let $\mathfrak{G}_B$ consist of differential-module maps $\psi_\pi : \mathcal{V}_\pi \to \mathcal{V}_\pi$ compatible with monotone collisions, zero at the empty word, and additive at every admissible cut:

$$\psi_{\pi'|\pi''} = \psi_{\pi'} \boxtimes 1 + 1 \boxtimes \psi_{\pi''}.$$

Let $\mathfrak{R}_B$ consist of maps $h_{\pi;ij} : \mathcal{V}_\pi \to \mathcal{V}_{\pi/(i\sim j)}$ with the residue cut-coderivation and collision-base-change identities, and the following linearized residue equations:

$$\begin{aligned} 0 &= h_{kl}r_{ij} + r_{kl}h_{ij} - h_{ij}r_{kl} - r_{ij}h_{kl}, \\ 0 &= h_{(ij),l}r_{ij} + r_{(ij),l}h_{ij} - h_{i,(jl)}r_{jl} - r_{i,(jl)}h_{jl} \\ &\quad + h_{j,(il)}r_{il} + r_{j,(il)}h_{il}. \end{aligned} \tag{20.17}$$

The first equation is for disjoint pairs and the second for $i < j < l$. Each subscript after a merger denotes the surviving root. No skew-symmetry or fixed-vacuum condition is added to h. Define

$$(\partial\psi)_{\pi;ij} = r_{ij}\psi_\pi - \psi_{\pi/(i\sim j)}r_{ij}.$$

THEOREM 20.13.1. For the full Heisenberg word residue algebra,

$$H^2 Z_{\mathrm{word},B}(A_\kappa) \cong \mathfrak{R}_B/\partial\mathfrak{G}_B.$$

Every class is represented on the unchanged partition modules by replacing r_{ij} with $r_{ij} + \epsilon h_{\pi;ij}$. Two such representatives give the same class exactly when they differ by $\partial\psi$.

Proof. The two displayed equations are the first-order terms in the disjoint-merger and three-block residue identities. The cut and collision identities make the new differential a compatible coderivation. Thus each h defines a residue coalgebra over the dual numbers and a Hochschild class of its cobar. Conjugating coefficients by $1 - \epsilon\psi$ gives the stated boundary.

To account for derived classes, identify the bar of the field retract with the cofree cut coalgebra. Its degree-two coderivations have only two possible components: ordinary maps for a single merger and Ext^1 between equal partitions. Represent the latter by flat module extensions E_π over the dual numbers. The cocycle equation says precisely that residues lift between these extensions and that the lifted differential squares to zero.

There are no extra attaching maps between pieces separated by two or more mergers: their internal degrees would be negative. Negative Ext vanishes, and the opposite support direction vanishes by open adjunction. The same argument removes higher attaching homotopies. Degree-zero coproducts allow only equal-partition cut maps, which remain isomorphisms over the dual numbers.

The one-position extension is trivialized by its vacuum attachment. Explicitly, if its connection perturbation is S, the lifted vacuum identity gives $(\partial_z + T)F_0 = S\mathbf{1}$. This is the condition that kills its class in $\mathrm{coker}(\partial_z + T)$. A splitting of the free complement then gives the module trivialization. Collision compatibility trivializes every one-block coefficient.

For a larger indecomposable partition, split off position one from its block. The remaining indecomposable intervals have smaller word size, so induction trivializes their extensions. The lifted residue that merges the new singleton back, restricted to its horizontal vacuum, gives a splitting of the target extension. The simple-pole vacuum residue is surjective on principal parts, so this splitting is an isomorphism modulo ϵ and on both steps of the ϵ-filtration. It is therefore an isomorphism.

Choose the trivializations first on block patterns with no adjacent positions in the same block. Every other pattern contracts to one of these by collapsing maximal constant intervals. Kashiwara equivalence transports the choice, and the terminal contraction removes additional descent choices. Extend across cuts by tensor products. All extensions are now trivial, leaving just the single-merger changes h.

Finally, a degree-one primitive can have only ordinary equal-partition components. Its coderivation and collision conditions are exactly those defining $\mathfrak{G}_B$. Its boundary is $\partial\psi$. The constructions are finite at each word size, and their product retains the full quotient. □

All finite central-polynomial variations

Let $\boldsymbol{Q}_B$ be the space of polynomial bilinear forms

$$Q(\lambda) = \sum_{d \geq 0} C_d \lambda^d, \qquad Q(\lambda) = -Q(-\lambda)^{\mathrm{t}}.$$

Thus $C_d^{\mathrm{t}} = (-1)^{d+1} C_d$: even powers have alternating coefficients and odd powers have symmetric coefficients. Only finite polynomials are allowed. Over $B[\epsilon]/(\epsilon^2)$, consider

$$[a_\lambda^i a^j]_\epsilon = (\kappa g_{ij} \lambda + \epsilon Q_{ij}(\lambda))\mathbf{1}.$$

The state module, vacuum, and translation are fixed. No requirement of conformal weight preservation is imposed.

This is a flat field deformation on every polynomial state. To construct it explicitly, write $(p)_d = p(p-1)\cdots(p-d+1)$ and set

$$J_p^i = x_{-p}^i \cdot \quad (p < 0),$$

$$J_p^i = \kappa p \sum_j g_{ij} \partial_{x_p^j} + \epsilon \sum_{d=0}^{p} (p)_d \sum_j (C_d)_{ij} \partial_{x_{p-d+1}^j} \qquad (p \geq 0).$$

The first term is zero for $p = 0$. The commutator is

$$[J_p^i, J_q^j] = \kappa p g_{ij} \delta_{p+q,0} + \epsilon \sum_{d \geq 0} (p)_d (C_d)_{ij} \delta_{p+q,d-1}.$$

For the reversed order, use $(d-1-q)_d = (-1)^d (q)_d$. When both indices are nonnegative and $p + q = d - 1$, the factor $(p)_d$ is zero. This checks all mode pairs.

The commutator is central and has finite pole order. Moreover, $[T, J_p^i] = -p J_{p-1}^i$ and $J^i(u)\mathbf{1} = e^{uT} a^i$. The first identity uses $(p)_d (p-d) = p(p-1)_d$.

Assign to a polynomial state the normally ordered product of its differentiated current fields. Moving nonnegative modes through negative modes gives a finite Wick expansion. The commutators are central, so regrouping three collections of modes gives the same expansion. This proves the field identities on all states, with the prescribed vacuum and translation.

Differentiate all residues to obtain a word cocycle Γ_Q^{w}. For collision coefficients, put $L = \iota_{\mathrm{ord}} \mathscr{V}_\kappa$. Its residue bracket is a Lie bracket for $\star$, and the collision cobar is the envelope $U_\star L$. Differentiating its bracket gives the Chevalley cocycle

$$\Gamma_Q^{\mathrm{c}} : \Lambda_\star^2 L \longrightarrow L \longrightarrow U_\star L.$$

Its differential is the linearized Jacobi identity.

Write $Q = C_0 + Q_+$ with $Q_+(0) = 0$. Set

$$M(t) = -\frac{Q_+(-t)}{2t} g^{-1}, \qquad P(z) = M(T)a + z C_0 g^{-1} a,$$

and define the polynomial state endomorphism N_Q by

$$N_Q \mathbf{1} = 0, \qquad N_Q x_m^i = \frac{(\partial_z + T)^{m-1} P_i(z)}{(m-1)!}.$$

Extend by the polynomial derivation rule and then by sums over blocks. Sesquilinearity gives

$$\kappa\lambda\big(M(-\lambda)g + gM(\lambda)^{\mathrm{t}}\big) = \kappa Q_{+}(\lambda).$$

For the constant alternating term, the two moving points give

$$\frac{\kappa}{u^{2}}\big((z+u)C_{\mathrm{o}} + zC_{\mathrm{o}}^{\mathrm{t}}\big) = \frac{\kappa C_{\mathrm{o}}}{u}.$$

The all-state Wick construction then proves

$$bN_{Q} = \kappa\Gamma_{Q}^{\mathrm{w}}, \qquad d_{\mathrm{CE}}N_{Q} = \kappa\Gamma_{Q}^{\mathrm{c}}. \tag{20.18}$$

At level zero, evaluating on holomorphic currents gives the independent principal parts

$$\sum_{d} d!(C_{d})_{ij}[u^{-d-1}]\mathbf{1}.$$

All undeformed fields are regular, so every incoming ordinary binary boundary vanishes on this input.

The degree bounds exclude derived alternatives. In the collision Chevalley filtration, a total-degree-one primitive is an ordinary map $L \to U_{\star}L$. Support forces its values into L. The same word bound was used above. Thus the kernel of $Q \mapsto [\Gamma_{Q}]$ is exactly $\kappa\boldsymbol{Q}_{B}$ on either carrier.

For $Q = \lambda^{3}H$ with H symmetric, the primitive is $P = \frac{1}{2}Hg^{-1}T^{2}a$. The mode variation is $p(p-1)(p-2)H$ and its value at $p = 3$ is $6H$, the coefficient of the fourth-order pole. The falling factorial is required by translation.

Products of the full derivation kernel

Let $\mathfrak{d}_{B}$ be the entire kernel in Theorem 20.12.1. Let Z_{w} be the word scalar center and Z_{c} the scalar center of $U_{\star}L$. The collision Chevalley resolution identifies its degree-one group with the same chiral derivations. Support puts a map $L \to U_{\star}L$ in the primitive part. Its cocycle equation is the chiral derivation identity. The empty term is B, so it introduces no inner quotient.

THEOREM 20.13.2. For $\alpha = \mathrm{w}, \mathrm{c}$ there are injections

$$\Lambda_{B}^{2}\mathfrak{d}_{B} \oplus \boldsymbol{Q}_{B}/\kappa\boldsymbol{Q}_{B} \longrightarrow H^{2}Z_{\alpha},$$

given by derivation cup products and the classes Γ_{Q}^{α}. Their common parameter module identifies these submodules canonically. On the exterior summands, the identification preserves the degree-one Gerstenhaber action.

Proof. External products of independent differential-module endomorphisms at two distinct positions are independent. Over a field, finitely many evaluations on states and output coordinate functionals detect any finite independent family. Apply them separately in the two variables. Over $k[\kappa]$, the derivation module and its tensor square are torsion-free, since this ring is a principal ideal domain. The fraction-field argument then proves the assertion. Antisymmetrization embeds the exterior square.

For words, the two-singleton component of a cup is $r_{12}(\delta \boxtimes \eta)$. Its sum with the exchanged component is

$$r_{12}(\delta \boxtimes \eta - \eta \boxtimes \delta).$$

This detector vanishes on boundaries with zero unary component. Faithfulness of the field map with all Laurent multipliers, followed by the external-product injection, detects every finite wedge sum. Central-polynomial variations have zero detector because their local brackets remain skew-symmetric.

For collision coefficients, the Chevalley cup is

$$(\delta \smile \eta)(x, y) = \delta x\, \eta y - \delta y\, \eta x.$$

Its PBW-degree-two symbol on separated positions is $\delta \boxtimes \eta - \eta \boxtimes \delta$. A degree-two boundary with zero unary component comes from an ordinary map $L \to U_\star L$. Support forces this map into L, so its boundary has zero separated PBW-degree-two symbol. The cocycle Γ^{c}_Q also takes values in L.

The symbol therefore detects the wedge coefficient of any relation. The pole detector and (20.18) then detect its central coefficient.

The constructions retain the current space, pairing, vacuum, coordinate, and state module and commute with changes of current basis. Finally,

$$[\theta, \delta \smile \eta] = [\theta, \delta] \smile \eta + \delta \smile [\theta, \eta]$$

on both carriers. This is the natural action on $\Lambda^2 \mathfrak{d}_B$. □

At nonzero field-valued level the central-polynomial summand vanishes. At level zero it is the entire Q_k. In particular, cubic central polynomials lie outside the span of pairing variations and all derivation cups. The theorem does not classify the remaining word residue quotient or extend the comparison to it. Nor does it claim that arbitrary nonlinear derivations preserve the central-polynomial summand.

20.14 The collision center at every configuration

The internal collision center admits a stronger support theorem. Work over a characteristic-zero field on $X = \mathbb{A}^1_k$. Let V be an ordinary unital vertex algebra, $\mathscr{V}$ its right differential module, and

$$L = \iota_{\mathrm{ord}} \mathscr{V}, \qquad U = U_\star L, \qquad C = \mathrm{CE}_\star(L), \qquad Z = Z^\star(U).$$

The envelope and its coefficients lie in the heart. Its center uses the complete Chevalley cochains, equivalently the twisted bar Hom.

Theorem 20.14.1. For every such V, $Z_I = 0$ at every nonempty configuration I. The empty coefficient gives an equivalence of algebras

$$Z_\varnothing K \xrightarrow{\sim} Z.$$

Proof. For right differential modules $T_1, \dots, T_n$, use the positive spectator object

$$W_n = \iota_{\mathrm{ord}} T_1 \star \cdots \star \iota_{\mathrm{ord}} T_n.$$

Distinguish its first factor. In each partition summand, let B be that factor's block and a its first coordinate.

Insert a new vacuum at z_q, with simple pole u^{-1}, $u = z_q - a$. Retain the output block containing B. In the normal direction this uses the quotient

$$k[u, u^{-1}] \longrightarrow \Delta_u = k[u, u^{-1}]/k[u].$$

Writing $e_j = \partial_u^j[u^{-1}]$, the Euler operator $u\partial_u + 1$ has eigenvalue $-j$ on e_j. Its degree-zero normal projection selects e_0.

Apply this projection before taking the remaining tangential derived Hom. It therefore defines an extraction operator R_p for arbitrary spectator modules, with no compactness assumption on them.

The Chevalley differential has three kinds of terms. Vacuum action on the output block containing B gives the normal quotient above, whose projection is the identity. Old actions and brackets commute with the normal projection and contribute $-dR_p$. The bracket of the new vacuum with an old generator has zero residue. The old separation t from B is invertible, so $(s+t)^{-1}$ is regular in the new collision parameter s. Thus

$$R_{p+1}d + dR_p = 1.$$

A target partition that splits a source block receives no map, by the support argument used above. A collision across two spectator blocks annihilates the source summand, since it is an open direct image and $\delta^! j_* = 0$ there. Chart changes preserve the internal order of B. These observations make the extraction compatible with the full collision diagram.

They also apply before the coefficient resolutions are totalized, so the identity holds in derived Hom. The Chevalley filtration has $p, q \geq 0$ and only finitely many terms in each total degree. Its contracted rows imply $R\operatorname{Hom}(W_n, Z) = 0$.

We now detect the coefficients inductively. Let F be positive and vanish at all configurations of size less than n. Stratify each ordered collision scheme by the number of distinct coordinates. On a stratum with $r < n$ coordinates, collision compatibility identifies the exceptional restriction with that of $F_{[r]}$, which is zero. Hence local cohomology on the locus of at most $n-1$ coordinates vanishes.

On the n-coordinate stratum, the labeled partition index has the collapse to $[n]$ as terminal object. Its coherent mapping limit is therefore the identity decomposition at $[n]$. If O_n is the distinct configuration open, this gives

$$R\operatorname{Hom}(W_n, F) \simeq R\operatorname{Hom}_{\mathcal{D}_{O_n}}((T_1 \boxtimes \cdots \boxtimes T_n)|_{O_n}, j_n^! F_{[n]}).$$

All overlap homotopies remain in this equivalence.

Apply the formula to the positive part of Z, assuming the lower coefficients already vanish, and take $T_i = \mathcal{D}_X$. The source on O_n is $\mathcal{D}_{O_n}$. The open O_n is affine, so the vanishing of this derived Hom forces $j_n^! Z_{[n]} = 0$. The lower-coordinate local cohomology also vanishes. The localization triangle gives $Z_{[n]} = 0$. Induction proves the claim, and the isolated empty factor gives the algebra equivalence. □

The simple pole is necessary in the contraction. Replacing it by u^{-2} gives $[u^{-2}] = -e_1$, whose projection to e_0 is zero. The identity term in the contraction then disappears. The theorem also uses the envelope of an ordinary unital vertex algebra in the heart. It makes no claim for arbitrary convolution algebras outside that domain.

For any $W \in C$, the theorem gives

$$R\operatorname{Hom}_C(W, Z) \simeq R\operatorname{Hom}_k(W_\varnothing, Z_\varnothing).$$

Thus the scalar center contains all the surviving information, while its positive evaluation is zero. If an algebra $\mathcal{B}$ has $\mathcal{B}_\varnothing = k$, every algebra map $Z \to \mathcal{B}$ factors through its unit and an augmentation $Z_\varnothing \to k$. For the diagonal actor cobar introduced below, the augmentation matching the convolution evaluation therefore gives a coherent scalar comparison. The normalized homotopy complex has an empty-supported source and positive target, so it is zero. The corresponding homotopy is unique up to a contractible choice.

Global modes in degree one

The support theorem does not make the scalar center small. The Chevalley filtration gives

$$H^i Z_\varnothing = 0 \ (i < 0), \qquad H^0 Z_\varnothing = k, \qquad H^1 Z_\varnothing = \mathrm{Der}(L).$$

Indeed, in total degree one the term $\mathrm{Ext}^1(K, U)$ is zero. An ordinary map $L \to U$ has primitive values by support, and its Chevalley differential is the derivation equation. The incoming scalar commutator is zero.

In coordinates a derivation is an endomorphism h_z of $k[z] \otimes V$ commuting with $\partial_z + T$. Put $\psi = h_0$. Then $h_z = e^{-z \operatorname{ad}_T}\psi$, polynomial on each state, and the residue condition is equivalent to

$$[\psi, Y(a,x)] = Y(e^{-x \operatorname{ad}_T}\psi(a), x).$$

All Laurent multipliers are required to recover this field identity from residues.

For any state a and $n \geq 0$, its global mode is

$$h_z^{a,n} = \sum_{m=0}^{n} \binom{n}{m} z^m a_{(n-m)} = \mathrm{Res}_y (y+z)^n Y(a,y).$$

The translation identity $[T, a_{(j)}] = -j a_{(j-1)}$ and the mode commutator formula prove the criterion. Thus every global mode is a degree-one class.

For the rest of this section take the rank-one Heisenberg algebra with $[J_\lambda J] = \kappa\lambda$, and put $u^{(m)} = m! x_{m+1}$. Then $V = k[u, u', u'', \ldots]$, $T u^{(m)} = u^{(m+1)}$, and

$$J_n = \kappa n! \frac{\partial}{\partial u^{(n-1)}} \quad (n \geq 1).$$

At level zero a derivation is determined freely by its image of x_1, so $H^1 Z_\varnothing \cong k[z] \otimes V_0$. At nonzero level there is a complete global-mode description.

Theorem 20.14.2. Suppose $\kappa \neq 0$. On $V[t]$ put $\nabla = \partial_t + T$. The map

$$\gamma : V[t] \longrightarrow \mathrm{Der}(L), \qquad \sum_n t^n a_n \longmapsto \sum_n h^{a_n, n},$$

is surjective with kernel $\nabla V[t] + k x_1$. Consequently

$$H^1 Z_\varnothing \cong V[t] / (\nabla V[t] + k x_1).$$

Proof. For a polynomial v define its linearization and variational derivative by

$$\ell_v = \sum_{m \geq 0} \frac{\partial v}{\partial u^{(m)}} \nabla^m, \qquad \frac{\delta v}{\delta u} = \sum_{m \geq 0} (-\nabla)^m \frac{\partial v}{\partial u^{(m)}}.$$

The formal adjoint of $\sum p_m \nabla^m$ is $\sum (-\nabla)^m \circ p_m$. Integration by parts gives $\varphi P(\chi) - P^*(\varphi)\chi \in \nabla V[t]$. Inspection of the highest jet gives $\ker \nabla = k$ and $\ell_{\nabla v} = \nabla \ell_v$.

The variational kernel is exactly $\nabla V[t]$. To prove the reverse inclusion, decompose v by polynomial current degree. For a homogeneous piece v_r with $r > 0$, Euler's identity and integration by parts give $r v_r \equiv u \, \delta v_r / \delta u$ modulo $\nabla V[t]$. The current-degree-zero part lies in $k[t] = \partial_t k[t]$. Also, if ℓ_f is self-adjoint, then

$$f = \frac{\delta}{\delta u}\left(\int_0^1 u \, f(\lambda u) \, d\lambda \right),$$

where $f(\lambda)$ scales every current jet by λ. Differentiating $\lambda f(\lambda)$ under the polynomial integral proves this identity.

For a derivation h, write $h_z x_1 = \sum_j z^j v_j$ and $v = \sum_j t^j v_j$. The field criterion gives $[\psi, J(x)] = \sum_j x^j Y(v_j, x)$. This commutator determines h: it determines its action on every negative-mode monomial and h kills the vacuum.

Since $[J(y), J(w)]$ is scalar, its commutator with ψ vanishes. Expand the resulting identity in derivatives of the formal delta function. The coefficient identity is

$$\sum_{i \geq 1} \frac{\lambda^i}{i!} J_i v = \sum_{i \geq 1} \frac{(-\lambda - \nabla)^i}{i!} J_i v.$$

The coefficients are unique by residue extraction. Using the displayed formula for J_i, this says that $\ell_v \nabla$ is self-adjoint.

Apply both sides to 1. It follows that $\partial v / \partial u = c \in k$, so $v = cu + \nabla f$. Self-adjointness becomes

$$2c\nabla = \nabla(\ell_f^* - \ell_f)\nabla.$$

If the middle operator were nonzero, the right side would have order at least two, because leading coefficients multiply in the domain $V[t]$. Hence $c = 0$ and $\ell_f = \ell_f^*$. The polynomial integral above gives $f = \partial a / \partial u$.

Skew symmetry and the global-mode formula give the current image associated with $\gamma(a)$ as $\kappa \nabla(\partial a / \partial u)$. Thus $h = \gamma(\kappa^{-1} a)$. Finally $\gamma(a) = 0$ exactly when $\partial a / \partial u \in k$. The variational kernel identifies these a with $\nabla V[t] + ku$. □

The energy operator is also visible here. For the Heisenberg conformal vector $\omega = J_{-1}^2 \mathbf{1}/(2\kappa)$, one has $\omega_{(0)} = T$ and $\omega_{(1)} = E$. Its first global mode is $E + zT$. Scalar polynomial current images give infinitely many further classes. Thus degree one is infinite dimensional at every level.

The part of highest PBW degree

The PBW splitting is $U = \bigoplus_{r \geq 0} \operatorname{Sym}_\star^r L$. Let $Z_\varnothing^{(r)}$ denote cochains whose values lie in the rth summand. The internal differential acts through the inputs, and the twisting term is the adjoint action of L on the outputs. Both preserve PBW degree. Therefore

$$Z_\varnothing = \prod_{r \geq 0} Z_\varnothing^{(r)}, \qquad Z_\varnothing^{(0)} = k.$$

Support forces a cochain with r output blocks to have at least r input blocks. Hence

$$H^i Z_\varnothing^{(r)} = 0 \quad (i < r).$$

In degree r, the entire group is the space of closed ordinary maps

$$\Lambda_\star^r L \longrightarrow \operatorname{Sym}_\star^r L.$$

There is no boundary to divide by in this part.

Let $k[O_r] = k[z_1, \dots, z_r, (z_l - z_m)^{-1}]$. Such maps are equivalent to $k[O_r]$-linear endomorphisms P of $k[O_r] \otimes V^{\otimes r}$ that commute with $\nabla_l = \partial_{z_l} + T^{(l)}$ and alternate under simultaneous permutation

of positions and factors. The Chevalley cocycle condition is the derivation identity in each factor. In the first factor it is

$$\begin{aligned} P(Y(a,x)b\otimes w) &= Y^{(1)}(a,x)P(b\otimes w)\\ &\quad + Y^{(1)}(P_{z_1+x}(a\otimes w),x)b. \end{aligned} \tag{20.19}$$

Here the subscript $z_1 + x$ denotes Taylor expansion, and $Y^{(1)}$ acts on the first state factor.

The detection lemma in the support theorem identifies the maps on O_r. In the Chevalley differential, choose the component in which two specified inputs merge. Its three terms are exactly (20.19). All components arise this way. This proves the criterion with all collision maps retained.

Proposition 20.14.3. For every $r \geq 1$, cup product gives an injection

$$\Lambda^r_k \operatorname{Der}(L) \hookrightarrow H^r Z_\varnothing.$$

Its highest-PBW-degree component is the alternating external product of the derivations.

Proof. The alternating product satisfies (20.19) and commutes with the connections. It is therefore closed.

Evaluate at distinct points $c_1, \dots, c_r$. A derivation is determined by its value at one point, since $h_{c+x} = e^{-x\,\mathrm{ad}_T} h_c$. Tensor products of independent state endomorphisms remain independent, as in the preceding cup calculation. Thus the alternating external product is injective. The highest-PBW-degree part has no incoming boundaries.

The cup uses the unshuffle coproduct. Under the suspension convention $\widetilde{P}(s y_1 \cdots s y_r) = (-1)^{r(r-1)/2} P(y_1, \dots, y_r)$, its symbol is precisely this alternating product. This identifies the cup class asserted. □

For rank-one Heisenberg, every positive degree is consequently infinite dimensional. At level zero the highest-PBW-degree part is all alternating values $F \in k[O_r] \otimes V_0^{\otimes r}$ on $x_1^{\otimes r}$, extended as differential derivations in each factor. At nonzero level the analogous description has a variational condition.

Mode sequences and rational classes

A *mode sequence* is a sequence $(A_m)_{m\geq 0}$ of endomorphisms of V, eventually zero on each state, satisfying

$$[T, A_m] = -m A_{m-1}, \qquad [A_m, Y(b,x)] = \sum_{j\geq 0} \binom{m}{j} x^{m-j} Y(A_j b, x),$$

where $A_{-1} = 0$. For sequences $A^1, \dots, A^r$ and $f \in k[O_r]$, define

$$P^f_{A^1,\dots,A^r} = \sum_{m_1,\dots,m_r\geq 0} \partial_{z_1}^{(m_1)} \cdots \partial_{z_r}^{(m_r)} f\; A^1_{m_1} \otimes \cdots \otimes A^r_{m_r}. \tag{20.20}$$

The sum is finite on each tensor of states. The first sequence identity cancels the two terms in $[\nabla_l, P]$. The second, together with Taylor's formula, gives (20.19). Alternating this operator therefore gives a closed map of highest PBW degree.

At nonzero level, the current sequence and $f = (z_1 - z_2)^{-1}$ give an already alternating operator with

$$P^f_{J,J}(x_1 \otimes x_1) = -2\kappa^2 (z_1 - z_2)^{-3} \mathbf{1} \otimes \mathbf{1}.$$

Every finite sum of derivation cups has polynomial value on this input. Thus this rational class lies outside their span.

There is one additional type of sequence:

$$\varphi_m = -\frac{J_{m+1}}{m+1}.$$

It satisfies the sequence identities because $J_0 = 0$. For the same f,

$$P^f_{\varphi,\varphi}(x_1 \otimes x_1) = \frac{\kappa^2}{z_1 - z_2}\mathbf{1} \otimes \mathbf{1}.$$

This class cannot be a sum of operators using only state mode sequences. Their vacuum coefficient on this input lies in $\partial_{z_1}\partial_{z_2}k[O_2]$, by skew symmetry and $J_0 = 0$. Writing $w = z_1 - z_2$, no ∂_w-derivative of a Laurent polynomial has a w^{-1} term.

PROPOSITION 20.14.4. At nonzero rank-one Heisenberg level, every mode sequence is

$$A_m = a_{(m)} + c\varphi_m$$

for a state a and $c \in k$. The scalar c is unique and a is unique modulo the vacuum line.

Proof. Each A_m gives a global derivation by the sequence identities. A translation-commuting derivation has constant h_z. The global-mode classification and its variational kernel then express its value as $a_{(0)} + cJ_1$: the variational derivative of a representing polynomial has the form $f_0 + ct$.

Grade states by energy, $\deg x_n = n$. Take a homogeneous sequence whose A_m has degree $\delta - m$. If it vanishes before $m = p$, then A_p commutes with translation and is $b_{(0)} + cJ_1$. For $p \geq 1$, the states

$$b' = \frac{(-T)^p b}{p!}, \qquad e = \frac{(-T)^{p-1}x_1}{p!}$$

have mode sequences vanishing before p and taking values $b_{(0)}, J_1$ at p. Subtract them. For $p = 0$, subtract the modes of b and the appropriate multiple of φ.

Energy forces this procedure to terminate once $p \geq \delta + 2$. Only the component $\delta = -1$ can retain φ.

There are only finitely many nonzero homogeneous sequences. Their values on x_1 have finitely many energy components and eventually vanish in m. These values determine all the endomorphisms. For uniqueness, energy -1 separates the φ term. If all nonnegative modes of a vanish, skew symmetry on x_1 and the largest nonzero $J_n a$ force every $J_n a$ to vanish. Then a is scalar. □

THEOREM 20.14.5. At nonzero rank-one Heisenberg level, every closed map $\Lambda^r_\star L \to \mathrm{Sym}^r_\star L$ is a finite sum of alternations of (20.20), using state modes or φ in each factor.

Equivalently, evaluation on $x_1^{\otimes r}$ identifies $H^r Z^{(r)}_\varnothing$ with alternating $F \in k[O_r] \otimes V^{\otimes r}$ such that $\ell^{(1)}_F \nabla_1$ is self-adjoint. The superscript means linearization in the first state factor, with all other factors as coefficients.

Proof. The slot identity first makes P vanish when an input is the vacuum. Commuting a negative current mode through it then reduces its value to its value on x_1 in that factor. Induction over the state energies shows that F determines P. The formal-delta commutator calculation used for global modes, now over the coefficient ring of the other factors, proves self-adjointness of $\ell^{(l)}_F \nabla_l$ for every l.

The variational argument works over any differential domain (B, ∂). Its kernel statements become

$$\ker(\partial + T) = B^{\partial}, \qquad \ker(\delta/\delta u) = (\partial + T)(B \otimes V) + B.$$

If $\ell_v(\partial + T)$ is self-adjoint, then $v = (\partial + T)f + b$ with $b \in B$ and ℓ_f self-adjoint. The proof is the same integration by parts and leading-order calculation as above. The current-degree-zero term now remains in B.

Apply this to a homogeneous current-multidegree component of F. In every factor with positive current degree, F lies in the image of ∇_l. These images intersect as their product: if $F = \nabla_1 \cdots \nabla_{s-1} g$ and $\delta_s F = 0$, injectivity of the other ∇_l on positive current degree gives $\delta_s g = 0$. Thus g also lies in the image of ∇_s.

Write $F = (\prod \nabla_l)\, g$ over those factors. Their injectivity and commutation with the other adjoints imply that $\ell_g^{(l)}$ is self-adjoint. Apply the polynomial variational integral in each factor to write $g = (\prod \delta_l)h$. It preserves the self-adjointness conditions in the other factors.

Expand h as a finite sum of pure state tensors with coefficients in $k[O_r]$. State-mode sequences evaluate on the current as $\kappa \nabla_l \delta_l$. φ evaluates as $-\kappa$ in factors of current degree zero. After dividing these nonzero scalar factors, (20.20) constructs a closed operator with value F. Alternation and division by $r!$ give the prescribed symmetry. Since F determines the operator, this proves both descriptions. □

20.15 Degree-two rigidity and the degree-three remainder

The highest-PBW-degree calculation does not by itself determine the lower-PBW-degree groups. For rank-one Heisenberg coefficients, the remaining degree-two group vanishes at nonzero level. In degree three, derived extension terms can be removed at every level, leaving two ordinary cohomology groups to compute.

Removing the derived term in degree two

At every level the state differential module splits as

$$\mathscr{V} = \omega_X \oplus \mathscr{F}, \qquad \mathscr{F} = W \otimes_k \mathcal{D}_X.$$

To obtain the splitting, take the vacuum projection along positive energy. Translation is injective on the positive-energy part. A graded complement W to its image gives $V_+ = \bigoplus_{n \geq 0} T^n W$, which is the free differential-module summand. Consequently

$$\operatorname{Ext}^1_C(L, L) \cong \operatorname{coker}(\partial_z + T : k[z] \otimes V \to k[z] \otimes V), \qquad \operatorname{Ext}^q_C(L, L) = 0 \quad (q \geq 2).$$

The free summand has no higher Ext, and the vacuum summand has its two-term de Rham resolution.

The first Chevalley differential is injective on this Ext^1. Represent a class by $[v] \circ p$, with p the vacuum projection. Restrict its differential to two vacuum inputs. The three terms become three signed copies of $\Delta_*[v] \circ \nu$, where

$$0 \to \omega_{X^2} \to j_* j^* \omega_{X^2} \xrightarrow{\nu} \Delta_* \omega_X \to 0.$$

Their coefficient is odd, hence nonzero in characteristic zero.

Composition with ν is injective on the relevant Ext group. The regular term has no map to $\Delta_* \mathscr{V}$. A normal derivative annihilates its vacuum generator and acts injectively on the diagonal target. Kashiwara equivalence then detects $[v]$.

It follows that $H^2 Z^{(1)}_{\varnothing}$ is the second cohomology of the ordinary complex

$$B^p = \operatorname{Hom}_C(\Lambda^p_\star L, L), \qquad d = d_\ell.$$

The possible derived term dies on the second page, and no later differential enters total degree two.

From all words to chiral operations

Let C^p_{ch} be the space of alternating differential-module operations

$$j_* j^*(\mathscr{V}^{\boxtimes p}) \longrightarrow \Delta_* \mathscr{V},$$

with the Chevalley differential of the chiral bracket. Here $p \geq 1$ and every localized multiplier is retained. A binary operation is *vacuum normalized* when it vanishes if either input lies in the local vacuum line.

An ordinary cocycle in B^2 has a two-block operation ρ_n for each reduced word of length n. Its linearized Jacobi equation is (20.17), with the lengths induced by the corresponding three-label word. The vacuum attachment

$$j_* j^*(\omega_X \boxtimes \mathscr{V}) \longrightarrow \Delta_* \mathscr{V}$$

has regular kernel. Every map from the regular kernel to the diagonal target is zero. Thus restriction of ρ_n to either vacuum axis is uniquely the attachment followed by an endomorphism λ_n or Υ_n.

The two families $(ij)^k l$ and $(ji)^k jl$ have six merger lengths

$$(2k, 2, 2; 2, 2k, 2k+1), \qquad (2k+1, 2, 2; 2, 2k+1, 2k+2).$$

Insert the vacuum in each of their three blocks, using a simple pole on just one attachment. The linearized Jacobi equation first makes $\lambda_n = \Upsilon_n = \ell$ one scalar, since the only horizontal state is the vacuum. Subtract $\ell\beta = d_\beta(\ell\,\mathrm{id})$. The remaining operations vanish on both vacuum axes. The same two families then give $\rho_n = \rho_2$ for every $n \geq 2$.

This common operation is alternating. With the vacuum in the third block, write the three iterated principal-part routes as L, R, N, in their residue orientations. They satisfy

$$L - R + N = 0.$$

The cocycle identity compares $L(G) - R(G) + N(H)$, where G, H are the two exchanged field series. Subtract the three-channel identity. All Laurent multipliers then give $N(H - G) = 0$, which detects every series coefficient. Thus $H = G$, the chiral skew-symmetry identity. The word 123 gives its chiral cocycle equation.

Restriction to the word 12 also detects boundaries. Therefore

$$H^2 C^\bullet_{\mathrm{ch}} \simeq H^2 B^\bullet. \tag{20.21}$$

This reduction uses the horizontal-state hypothesis. For the commutative vertex algebra $k[y]$ with $T = \partial_y$, the section $y - z$ is horizontal, so that hypothesis fails.

Vanishing at nonzero level

THEOREM 20.15.1. At nonzero rank-one Heisenberg level,

$$H^2 C^\bullet_{\mathrm{ch}} = 0, \qquad H^2 Z^{(1)}_{\varnothing} = 0.$$

Hence $H^2 Z_{\varnothing} = H^2 Z^{(2)}_{\varnothing}$, and the complete degree-two collision group is the space of closed maps described in Theorem 20.14.5 for $r = 2$.

Proof. Insert a global mode $\alpha \in V[t]$ as a first input and take its residue. This defines $\iota_\alpha : C^p_{\mathrm{ch}} \to C^{p-1}_{\mathrm{ch}}$ for $p \geq 2$. Expanding the Chevalley differential with this input gives the Cartan identity

$$\mathcal{L}_\alpha = d\iota_\alpha + \iota_\alpha d.$$

The output action and the actions on each old input give $\mathcal{L}_\alpha$. The remaining terms are the differential of the insertion. Residue commutes with the old operations by base change.

Give a separation and a position weight -1, and state x_n energy n. The mode $t\omega$ acts on a homogeneous binary cochain of degree e by multiplication by e. Every nonzero-degree cocycle component is therefore a boundary, with primitive $e^{-1}\iota_{t\omega}A_e$. The sum of these primitives is finite on each input and coefficient: the residue uses only two coefficients of the field series.

Use the word reduction to start with a vacuum-normalized degree-zero cocycle. The mode ω acts as minus the position derivative. On endomorphisms of the free complement $\mathscr{F}$, integration in z solves $\mathcal{L}_\omega B = \iota_\omega A$ with $B\mathbf{1} = 0$. Then $A - dB$ is translation invariant and remains vacuum normalized.

The corresponding first-order fields $Y_\epsilon = Y + \epsilon\Phi_A$ satisfy the Borcherds identities: these are the coefficients of the residue Jacobi identity with all Laurent multipliers. Energy and skew symmetry force the current bracket to be $[J^\epsilon_m, J^\epsilon_n] = (\kappa + \epsilon\eta)m\delta_{m+n,0}$. Higher singular terms have negative state energy, and the simple-pole coefficient is its own negative.

Rescale the current modes by $1 - \epsilon\eta/(2\kappa)$. They now satisfy the original Heisenberg relations and kill the vacuum in nonnegative degree. The induced Fock module gives an isomorphism $\theta = 1 + \epsilon\psi$ that fixes the vacuum and commutes with translation.

Conjugate Y_ϵ by θ. Its current modes are the original ones. The Borcherds identity reconstructs every negative-mode state field from these currents, so the conjugated fields are exactly Y. The coefficient of ϵ says $A = d(-\psi)$.

This proves $H^2C^\bullet_{\mathrm{ch}} = 0$. Equation (20.21) and the removal of the derived term give the second vanishing. The PBW degree bound leaves only the highest-degree part. □

At level zero the central-polynomial classes already show that the lower-PBW-degree group need not vanish.

Formal brackets on the fixed coefficient module

Let $R = k[[t_1, \dots, t_d]]$ for finitely many degree-zero parameters, with maximal ideal $\mathfrak{m}$. Complete only in these parameters. The polynomial state module and all word sizes remain as above. For an endomorphism $h \in B^1$, fix the sign convention

$$(d_\beta h)(x, y) = \beta(hx, y) + \beta(x, hy) - h\beta(x, y).$$

Theorem 20.15.2. At $\kappa \neq 0$, every formal Lie bracket

$$\beta_R = \beta + \sum_{|\alpha| \geq 1} \mathbf{t}^\alpha b_\alpha, \qquad b_\alpha \in B^2,$$

on the fixed $L[[\mathbf{t}]]$ has a continuous automorphism $\Phi = 1 \bmod \mathfrak{m}$ such that

$$\Phi\beta_R = \beta(\Phi \star \Phi).$$

If every correction is vacuum normalized, Φ fixes the local vacuum line.

Proof. Suppose the bracket has already been made equal to β modulo $\mathfrak{m}^n$. Its order-n error b_n is a d_β-cocycle: two correction terms have order at least $2n \geq n+1$. The space $\mathfrak{m}^n/\mathfrak{m}^{n+1}$ is finite dimensional, so the vanishing of $H^2B^\bullet$ gives h_n with $d_\beta h_n = b_n$. For $g_n = 1 + h_n$,

$$g_n(\beta + b_n)(g_n^{-1} \star g_n^{-1}) = \beta + b_n - d_\beta h_n = \beta \pmod{\mathfrak{m}^{n+1}}.$$

The sign follows from $g_n^{-1} = 1 - h_n$ to this order.

The products $g_N \cdots g_1$ stabilize modulo every power of $\mathfrak{m}$. Their limit is Φ, with inverse given by the compatible reverse products. Each parameter coefficient uses finitely many compositions of maps in C, so it preserves all collisions.

For a normalized error, every primitive annihilates the vacuum. Indeed, $h\mathbf{1} = c\mathbf{1}$ by horizontality. Evaluating $d_\beta h$ on the simple-pole two-vacuum input gives $c + c - c = c$. Normalization forces $c = 0$. Conjugation by $1 + h_n$ therefore preserves both vacuum attachments, by their naturality. Induction gives the last assertion. □

Tensor powers of $\Phi[1]$ give an isomorphism of the completed Chevalley coalgebras, and applying Φ in every cobar factor gives an isomorphism of their cobars. The unshuffle coproduct and all cut maps commute with these tensor powers. At a fixed configuration, only finitely many nonempty factors occur, so the maps commute with parameter completion. In the normalized case they are under the vacuum coalgebra and its cobar.

This is rigidity of strict Lie brackets on the fixed differential-module family. Deformations of the underlying module, or arbitrary higher algebra operations, are separate questions.

The remaining degree-three groups

Keep any level $\kappa \in k$. The vacuum splitting gives $L = L_0 \oplus L_F$, with $L_0 = \iota_{\mathrm{ord}}\omega_X$ and $L_F = \iota_{\mathrm{ord}}\mathscr{F}$. On the first page for PBW degree r, write

$$E_{(r)}^{a,b,q} = \mathrm{Ext}_C^q\Big(\Lambda_\star^a L_0 \star \Lambda_\star^b L_F, \mathrm{Sym}_\star^r L\Big).$$

The differential has parts adding a vacuum input, adding a free input, and replacing a vacuum input by two free inputs.

THEOREM 20.15.3. Every derived term of total degree three vanishes on the second Chevalley page. Thus

$$\begin{aligned} H^3 Z_\varnothing \cong\ & H^3 \mathrm{Hom}_C(\Lambda_\star^\bullet L, L) \\ & \oplus H^3 \mathrm{Hom}_C(\Lambda_\star^\bullet L, \mathrm{Sym}_\star^2 L) \\ & \oplus H^3 Z_\varnothing^{(3)}. \end{aligned}$$

The first two summands use ordinary maps and the Chevalley differential. The third consists of closed maps $\Lambda_\star^3 L \to \mathrm{Sym}_\star^3 L$.

Proof. First, two free inputs have no positive Ext into PBW degree one or two. For degree one, the normal source is the localization $\mathcal{D}_{X^2}[u^{-1}]$, the colimit of free modules under left multiplication by u. Its Hom into $\Delta_*\mathscr{V}$ is the derived inverse limit of right multiplication by u. On $\mathscr{V} \otimes k[\partial_u]$ this is $m\partial_u^n \mapsto n\, m\partial_u^{n-1}$, which is surjective.

The countable tower has no derived limit in positive degrees. Products over the free basis are exact. For PBW degree two, restriction to O_2 has free source on an affine scheme, giving the same vanishing.

To treat vacuum inputs, use the natural exact sequence

$$0 \to \omega_X \boxtimes N \to j_* j^*(\omega_X \boxtimes N) \xrightarrow{\nu_N} \Delta_* N \to 0.$$

Restriction in Ext has kernel the image of $\mathrm{Ext}^1_X(N, \mathscr{V})$ under composition with ν_N. For free N, restriction is therefore injective.

Replace every occurrence of a label a in a reduced two-label word w by two vacuum labels $y_0 y_1$. Localize only along $z_{y_0} = z_{y_1}$. Of the Chevalley terms adding a vacuum, exactly three survive. Naturality of the attachment identifies each with a signed copy of the restricted class followed by ν. Their sum is an odd multiple.

The same regular-to-diagonal Hom vanishing makes attachment injective on Ext. Thus a class with one vacuum and one free input in the kernel must vanish.

For two vacuum inputs and PBW degree one, the restricted class is likewise zero. It therefore has the form $\Delta_* \eta_n \circ \beta_n$ at a reduced word of length n, with $\eta_n \in \mathrm{Ext}^1_X(\omega_X, \mathscr{V})$. Let K_L, K_R, K_N be the three vacuum merger routes. They obey $K_L - K_R + K_N = 0$. The first two are independent: on $1/(s(s-t))$ their values are $s^{-1}t^{-1}$, 0, and on $1/(st)$ they are 0, $s^{-1}t^{-1}$.

This independence persists with the Ext coefficients. Separate the two normal coordinates from the tangential one. The normal localization is holonomic and has a bounded resolution by finite projectives. The tangential vacuum has its Spencer resolution. The Künneth map therefore embeds normal degree zero tensored with tangential degree one into total degree one.

The cocycle equation forces the three sums of the relevant η_n to agree. The two word families displayed above give $\eta_{2k+1} = \eta_{2k}$ and $\eta_{2k+2} = \eta_{2k+1}$. All η_n are one class, and its family is the boundary of that class in arity one.

For PBW degree two, restriction from the two-block open-image target loses no class. Apply the same three surviving terms to the component in which the two vacua merge. They force the restriction to vanish and hence the class itself to vanish.

Now take a cocycle in $E_1^{2,1}$. The two-free-input part is zero. In PBW degree one, subtract the boundary just constructed from its two-vacuum part. The one-vacuum part then vanishes by injectivity. In PBW degree two, both vacuum parts are already detected injectively. Thus $E_2^{2,1} = 0$.

The terms $E_1^{1,2}$ and $E_1^{0,3}$ also vanish. The only possible later source into $E^{3,0}$ is the degree-two derived term already removed. For PBW degree three only the highest-degree ordinary maps occur. First-quadrant connectivity excludes extra limit terms. □

The proof uses the vacuum splitting with free complement, not the numerical value of the level. At nonzero level the final summand has the explicit description of Theorem 20.14.5. The two ordinary degree-three groups remain to be computed. Their reduction to ordinary cochains is not a vanishing theorem.

20.16 The ordinary transverse endomorphism monoid

The diagonal action problem uses another tensor product. Write

$$(F \otimes^! G)_I = \Delta_I^!(F_I \boxtimes G_I)$$

on the ordered collision category. Its unit is the vacuum coefficient system J, whose empty coefficient is k. The convolution unit K is instead supported only at the empty configuration.

Both products come from the same external product at different relative positions. Convolution extends from the disjoint open. Diagonal tensor restricts to the ordered branch where each input position is stacked with its copy. For one position, the two ordered diagonal branches give the localization triangle

$$\delta_{12,*}(M \otimes^! N) \oplus \delta_{21,*}(M \otimes^! N) \longrightarrow q^!(M \boxtimes N) \longrightarrow j_* j^! q^!(M \boxtimes N).$$

The connecting maps are their residues. Thus diagonal tensor cannot be replaced by disjoint convolution.

Let Coalg denote the enhanced coaugmented convolution coalgebras in the bar–cobar domain, with fixed empty coefficient k. The forward interchange

$$\zeta : (F \star G) \otimes^! (H \star L) \longrightarrow (F \otimes^! H) \star (G \otimes^! L)$$

keeps common ordered decompositions. It tensors coproducts and makes $(\mathrm{Coalg}, \otimes^!, J)$ symmetric monoidal.

There is also a reverse binary map χ including the common-decomposition summands. It is compatible with collision pullback and all positive-arity associativity diagrams. Indeed, a final decomposition occurs precisely when the decompositions in every row agree, independently of parenthesization. On that summand the maps are the same external tensor identifications. Hence

$$\zeta\chi = 1, \qquad \chi\zeta = \text{projection to common decompositions.}$$

For a cut open j, consider $j_*M \otimes^! j_*N \to j_*(M \otimes^! N)$. The source has zero exceptional restriction to the complement and restricts to $M \otimes^! N$ on the open. The comparison is therefore an equivalence. This supplies the comparison on each summand. The binary reverse map alone gives no inverse to the full interchange or to its unit comparisons.

Definition 20.16.1. A *transverse monoid* is an associative unital algebra object F of $(\mathrm{Coalg}, \otimes^!, J)$. It has coalgebra maps

$$m : F \otimes^! F \to F, \qquad u : J \to F$$

with coherent associativity and unit constraints. A transverse action on C is a left module structure $F \otimes^! C \to C$ in this category.

The coalgebra condition on m is

$$\Delta_F m = (m \star m)\zeta(\Delta_F \otimes^! \Delta_F),$$

including its coherent homotopies. At one position, after converting right modules to left modules with the prescribed density shift, this is an ordinary horizontal associative multiplication over $\mathcal{O}_X$. It is not a product at distinct positions.

The closed category and its universal action

THEOREM 20.16.2. The category Coalg is presentable, and $- \otimes^! C$ preserves colimits. It has a right adjoint $\underline{\mathrm{Hom}}_{\mathrm{Coalg}}(C, -)$. The object

$$\mathcal{E}(C) = \underline{\mathrm{Hom}}_{\mathrm{Coalg}}(C, C)$$

is a transverse monoid with evaluation action. For every transverse monoid F, evaluation induces an equivalence between monoid maps $F \to \mathcal{E}(C)$ and transverse actions of F on C.

Proof. Bar–cobar identifies Coalg with augmented algebras having fixed empty coefficient. These are nonunital algebras on the positive ideal in a presentable category whose convolution preserves colimits separately. Their category is presentable.

Colimits of coalgebras are computed on reduced parts: in the opposite category this is the fact that limits of algebras are computed on underlying objects. The diagonal tensor has reduced part $c \otimes^! d$, and extraordinary inverse image and external product preserve colimits. Thus $- \otimes^! C$ preserves colimits and has the stated right adjoint.

Composition of the mapping object gives an associative unital endomorphism object. The unit corresponds to id_C. Under the adjunction, the associative and unital diagrams for a map into this object are exactly the module diagrams for its adjoint evaluation. Applying the same adjunction to all iterated products identifies their coherent homotopies. This proves the equivalence of action spaces. □

At one position,

$$\mathcal{E}(C)_{\{1\}} \simeq \underline{\mathrm{Hom}}_X(C_{\{1\}}, C_{\{1\}}).$$

To check this, a bar word with two positive factors vanishes at one position. The single remaining term is the pointwise mapping object, and the bar and cobar shifts cancel. Diagonal insertion and Kashiwara adjunction identify its evaluation with internal Hom on X.

Its untwisted cochains

For positive coefficient objects c, a, let $\underline{\mathrm{Hom}}_!(c, a)$ represent maps $V \otimes^! c \to a$. Take c to be the reduced part of a coalgebra C and a the augmentation ideal of an algebra A. The mapping object then has a convolution cup product. Its adjoint is the composite

$$\begin{aligned}(V \star W) \otimes^! c &\longrightarrow (V \star W) \otimes^! (c \star c) \\ &\xrightarrow{\zeta} (V \otimes^! c) \star (W \otimes^! c) \longrightarrow a \star a \xrightarrow{\mu_A} a,\end{aligned}$$

using the reduced coproduct and the two evaluations.

Proposition 20.16.3. There is a natural algebra equivalence

$$\Omega \underline{\mathrm{Hom}}_{\mathrm{Coalg}}(C, BA) \simeq K \oplus \underline{\mathrm{Hom}}_!(c, a).$$

On strict representatives, the differential on the right is the ordinary mapping-object differential and the product is the cup just defined.

Proof. For positive V, the bar of the free convolution algebra $T_\star V$ is $K \oplus V[1]$ with primitive positive part. Tensoring it diagonally with C still gives zero reduced coproduct. The interchange retains only common decompositions. The primitive factor has no decomposition into two positive parts. Its cobar is therefore $T_\star(V \otimes^! c)$.

The free adjunctions identify maps from V into the augmentation ideal on the left with maps $V \otimes^! c \to a$. This gives the underlying mapping object for every test V. The cup is associative because the coproduct, interchange, and product are coherent.

Let π be the bar twisting cochain of this cup algebra. Compose it with evaluation to get $\tau = \mathrm{ev}(\pi \otimes^! 1)$. The defining cup identity turns the Maurer–Cartan equation of π into the twisting equation of τ. Thus evaluation defines the coalgebra map to BA. Its adjoint is the identity on the augmentation mapping object, so it is the required algebra equivalence. □

Taking $A = \Omega C$ gives a concrete model for $\Omega\mathcal{E}(C)$. Its unit point $J \to \mathcal{E}(C)$ corresponds to the identity of C. The twisting cochain is the element expressing this point. It is not added to the differential of the pointwise cochain algebra. The convolution Hochschild center instead has its twisted differential $\partial + [\tau, -]$.

Constant symmetries and exchange

For a coassociative coalgebra H over k, put $H^J_\varnothing = k$ and $H^J_I = J_I \otimes_k H$ for nonempty I. For a decomposition into two nonempty parts, its coproduct is that of J tensored with Δ_H. For an empty part, it is the identity. This construction is symmetric monoidal. Thus a bialgebra H gives a transverse monoid H^J, with unit induced by 1_H.

An action of H^J is a family of horizontal actions $H \otimes C_I \to C_I$ compatible with collisions and

$$\Delta_{A,B}(h \cdot c) = \sum (h_{(1)} \otimes h_{(2)}) \cdot \Delta_{A,B}(c).$$

The universal property gives its map to $\mathcal{E}(C)$. Over the disjoint open, factorization of H^J would make Δ_H an equivalence. For an ordinary bialgebra this forces $H = k$: the two counit maps would be the same inverse, so $h \otimes 1 = 1 \otimes h$ and $h = \epsilon(h)1$.

If C is factorizing, its two ordered coproduct components define an exchange R_C. The coalgebra action identity gives

$$R_C \Delta_H(h) = \Delta_H^{\mathrm{op}}(h) R_C.$$

For a factorizing transverse actor F, the analogous identity is

$$R_C(\alpha_1 \boxtimes \alpha_1) = (\alpha_1 \boxtimes \alpha_1)(R_F \otimes^! R_C)$$

on the disjoint two-point locus. Both follow by commuting the action with the two coproduct components and inverting one factorization map. The first identity is a constraint on a given bialgebra action. It does not reconstruct a Hopf algebra from the exchange.

A dual for diagonal tensor

Transport diagonal tensor through bar–cobar and write the resulting product on algebras as $\diamond$, with unit $\mathbb{U} = \Omega J$. Define

$$A^\dagger = [A, \mathbb{U}]_\diamond.$$

Then

$$\mathrm{Map}(Y, A^\dagger) \simeq \mathrm{Map}(Y \diamond A, \mathbb{U}) \simeq \mathrm{Map}_{\mathrm{Coalg}}(BY \otimes^! BA, J).$$

The last expression is a pairing of bar coalgebras with values in the vacuum coalgebra. Its augmentation ideal is $\underline{\mathrm{Hom}}_!(\overline{BA}, \overline{\mathbb{U}})$. At one position,

$$(A^\dagger)_{\{1\}} \simeq \underline{\mathrm{Hom}}_X(a_{\{1\}}[1], \omega_X).$$

Evaluation and symmetry give a natural map $A \to A^{\dagger\dagger}$, and $\mathbb{U}^\dagger \simeq \mathbb{U}$. The bidual map requires its own hypotheses to be an equivalence. This internal diagonal dual retains positive configurations, whereas internal convolution Hom into K sees only the empty coefficient.

20.17 Factorization and the pointed action problem

Let $\mathrm{Coalg}_{\mathrm{fact}}$ be the full subcategory whose ordered coproduct maps are equivalences on every disjoint open. It is closed under diagonal tensor and contains J. A *local center* of a factorizing coalgebra C is a final transverse monoid acting on C within this subcategory. It is final in the category of actors together with their actions, not merely among the underlying coalgebras.

For a pointed factorizing coalgebra $u : J \to F$, define

$$\Phi_C(F, u) = \mathrm{Map}_{C/}(F \otimes^! C, C).$$

The source lies under C by $u \otimes^! 1_C$, and the target by its identity. Thus a point is a coalgebra map whose restriction along the specified vacuum is identified with the identity of C. Representability of this pointed functor supplies a local center and its monoid structure. This is the centralizer construction of Lurie's *Higher Algebra*, Proposition 5.3.1.8.

If L_C is a local center, its action gives $\beta : L_C \to \mathcal{E}(C)$. For every factorizing transverse monoid F,

$$\mathrm{Map}_{\mathrm{Alg}}(F, L_C) \xrightarrow{\sim} \mathrm{Map}_{\mathrm{Alg}}(F, \mathcal{E}(C)).$$

Indeed, the fiber over any action map is the space of maps to the final action, hence contractible. The ordinary endomorphism monoid $\mathcal{E}(C)$ is itself a local center exactly when it factorizes.

Obstructions to a factorization right adjoint

Factorizing coalgebras are closed under sifted colimits. For each ordered decomposition, the coproduct comparison commutes with colimits, and the diagonal of a sifted indexing category is cofinal in every finite power. Thus the factorization equivalences survive. Arbitrary coproducts do not have this property.

The reduced part of $J \sqcup J$ is the sum of two copies of that of J. At two distinct positions its factorization map has two summands in the source and four in the target. Its image consists of the two diagonal summands. The two cross terms remain in the cofiber. Therefore $J \sqcup J$ is not factorizing.

It follows that the full inclusion $\mathrm{Coalg}_{\mathrm{fact}} \subset \mathrm{Coalg}$ has no right adjoint. If it had one, the colimit of any diagram of objects in its image would again lie in that image. To see this, factor the colimit cocone through the counit. The universal property gives a section of the counit, and full faithfulness makes the reverse composite the identity. The coproduct just computed contradicts this consequence.

There is an independent obstruction already at the singleton algebra.

Proposition 20.17.1. On a connected nonempty curve, a factorizing transverse monoid cannot have singleton algebra $M_n(k) \otimes J_{\{1\}}$ for $n \geq 2$. Consequently, if B is a constant commutative algebra with $2 \leq \dim_k B < \infty$, then $\mathcal{E}(C_B)$ does not factorize.

Proof. For a constant singleton algebra R, the two-position localization boundary is the normal residue tensored with a linear map $\tau : R \otimes R \to R$. We check that diagonal tensor tensors these coefficient maps, including derived terms.

In a normal coordinate u, put $P = \mathcal{O}[u^{-1}]$ and $D = P/\mathcal{O}$. After the density and cohomological shifts, a coefficient map $\tau : V \to R$ has complex $[V \otimes P \to R \otimes D]$ in degrees zero and one. Split the linear map into the elementary arrows $k \xrightarrow{1} k$, $k \to 0$, and $0 \to k$. Their complexes are respectively $\mathcal{O}$, P, Q, where $Q = [\mathcal{O} \to P] \simeq D[-1]$.

Localization gives

$$P \otimes^{\mathbb{L}}_{\mathcal{O}} P = P, \qquad P \otimes^{\mathbb{L}}_{\mathcal{O}} Q = 0, \qquad Q \otimes^{\mathbb{L}}_{\mathcal{O}} Q \simeq Q.$$

The last identity follows by tensoring $Q \to O \to P$ with Q. These identities give the tensor of arbitrary coefficient arrows.

Naturality for the transverse product and its unit therefore makes τ a unital algebra homomorphism $R \otimes R \to R$. For $R = M_n(k)$, its source is $M_{n^2}(k)$, which is simple. A unital map must be injective, but $n^4 > n^2$. This is impossible.

For C_B, the singleton of the ordinary endomorphism monoid is $\mathrm{End}_k(B)$, with composition and identity. The first assertion applies. □

Linearity alone would not suffice for this obstruction. When n is invertible, the map $r \otimes s \mapsto n^{-1}\operatorname{tr}(s)r$ is unital and linear. It kills $1 \otimes E_{12}$ and $1 \otimes E_{21}$, but sends their product to $n^{-1}I$. It fails precisely the required multiplicativity.

The inclusion of factorizing transverse monoids also has no right adjoint. Take $B = k \times k$ and the coproduct of two copies of C_B as transverse monoids. Its singleton algebra is $B * B$, and its two-position open algebra is $(B \otimes B) * (B \otimes B)$. These free products also compute the derived coproducts: the augmentations split, and the alternating tensor description of the free product is over the field k.

Let x, y name the two inclusions and put $e = (1, 0)$. The factorization map to $(B * B) \otimes (B * B)$ kills

$$[x(e \otimes 1),\, y(1 \otimes e)],$$

because the images belong to different tensor factors.

The source element is nonzero. Represent its two idempotents by

$$P = \begin{pmatrix} 1 & 0 \\ 0 & 0 \end{pmatrix}, \qquad Q = \begin{pmatrix} 1 & 1 \\ 0 & 0 \end{pmatrix}.$$

Use a character on each unused tensor factor. The commutator maps to $PQ - QP = E_{12} \neq 0$. Thus the coproduct fails factorization, and the same counit argument excludes a right adjoint.

The positive result in the heart

Let $\mathcal{A}$ be an $\mathcal{O}_X$-flat chiral algebra. Its chiral center $Z_{\mathrm{ch}}(\mathcal{A})$ consists of sections z for which the chiral bracket vanishes on every regular tensor $z \boxtimes a$. This definition tests regular inputs. It does not require all meromorphic residues to vanish. Flatness makes the center a commutative chiral subalgebra. After changing to left modules, $Z_{\mathrm{ch}}(\mathcal{A})^{\ell}$ is a commutative differential algebra and acts on $\mathcal{A}$.

For a factorization algebra $\mathcal{B}$, let $C_{\mathcal{B}}$ be its shifted right-module coalgebra on the ordered collision schemes. Its vacuum is $J \to C_{\mathcal{B}}$. On a chart with $|I|$ positions, the module lies in degree $-|I|$. This is the factorization heart. Diagonal tensor of such objects lies in degrees at most $-|I|$, since in left-module notation it is derived tensor over functions.

Mapping spaces from those tensor powers into a heart object are discrete. They are determined by top cohomology on each chart. The maps agree on the disjoint open, and their difference would have diagonal-supported image. Factorization modules have no such sections, so the maps glue uniquely. Coalgebra maps are therefore maps of factorization structures, and being under J is exactly preserving units.

THEOREM 20.17.2. For every factorization algebra $\mathcal{B}$, the space

$$\mathrm{Map}_{C_{\mathcal{A}}/}(C_{\mathcal{B}} \otimes^{!} C_{\mathcal{A}}, C_{\mathcal{A}})$$

is discrete. Its points are the chiral algebra maps from the chiral algebra of $\mathcal{B}$ to $Z_{\mathrm{ch}}(\mathcal{A})$.

For a commutative unital differential algebra N, transverse actions of C_N on $C_{\mathcal{A}}$ are exactly the differential-algebra maps $N \to Z_{\mathrm{ch}}(\mathcal{A})^{\ell}$. The center coalgebra with its central action is final among these actors.

Proof. The factorization dictionary just described makes the mapping space discrete. The equivalence between factorization and chiral algebras, and the tensor universal property, are Beilinson–Drinfeld, *Chiral Algebras*, Sections 3.4.9 and 3.4.15. A map out of the tensor product corresponds to two commuting chiral maps. The condition under $C_{\mathcal{A}}$ fixes the second map as the identity. The first therefore takes values in the chiral center.

For commutative N, the two composites expressing associativity have the same restrictions to the three factors $N, N, \mathcal{A}$. Uniqueness in the tensor universal property makes them equal. Thus every central map is an action, with singleton formula $b \otimes a \mapsto \varphi(b) \cdot a$. Commutative chiral maps are commutative differential-algebra maps, by Sections 3.3.3 and 3.3.9 of the same reference.

An equivariant map of two such actors is a map $g : N \to N'$ with $\varphi' g = \varphi$. For $N' = Z_{\mathrm{ch}}(\mathcal{A})^{\ell}$ and $\varphi' = \mathrm{id}$, there is exactly one, namely $g = \varphi$. □

In the heart, a factorization coalgebra admits a transverse monoid structure exactly when its factorization algebra is commutative. The structure is then unique. Indeed, let e be a transverse unit. The sections $e \boxtimes \mathbf{1}$ and $\mathbf{1} \boxtimes e$ restrict to e on the diagonal. Their product away from the diagonal is $\mathbf{1} \boxtimes \mathbf{1}$. No diagonal-supported section can alter this equality.

Restriction gives $m(e, e) = \mathbf{1}$, while the unit law gives $m(e, e) = e$. Thus $e = \mathbf{1}$. The product is a factorization map restricting to the identity on each unit axis. This is equivalent to commutativity and determines the product uniquely (Beilinson–Drinfeld, Section 3.4.20).

The map from this center coalgebra to $\mathcal{E}(C_{\mathcal{A}})$ is injective on singleton cohomology. Evaluate its action on the vacuum: $z \cdot \mathbf{1} = z$. The composite is the inclusion of the chiral center into $\mathcal{A}$.

Every actor bounded above by the heart

The same central object represents more than the ordinary heart actors. Say that F is *bounded above by the factorization heart* if, on every chart, $H^j(F_I) = 0$ for $j > -|I|$. No uniform lower bound is required.

Theorem 20.17.3. For every pointed factorizing F with this bound, central action gives an equivalence of discrete spaces

$$\mathrm{Map}_{J/}(F, C_{Z_{\mathrm{ch}}(\mathcal{A})}) \xrightarrow{\sim} \Phi_{C_{\mathcal{A}}}(F, u).$$

Its inverse is restriction to the vacuum of $C_{\mathcal{A}}$. Consequently the center coalgebra is final among all factorizing transverse monoids with this bound that act on $C_{\mathcal{A}}$.

Proof. The degree bound makes all mapping spaces into the heart target discrete and reduces maps to top cohomology. In left-module notation, an action gives $a_I : M_I \otimes A_I \to A_I$. Let e be the image of the pointed unit and set $\zeta(f) = a_1(f \otimes \mathbf{1})$. The pointed condition says $a_1(e \otimes a) = a$.

The two-position localization boundary of F gives a chiral operation μ_F on M_1. Tensor the localization triangle with $C_{\mathcal{A},2}$ and use naturality of its connecting map under the action. Apply the resulting identity to $(f \boxtimes e)\varphi$ and to the two sections $\mathbf{1} \boxtimes a$, $a \boxtimes \mathbf{1}$ of A_2. Their diagonal restrictions agree, so

$$\mu_{\mathcal{A}}((\zeta(f) \boxtimes a)\varphi) = \mu_{\mathcal{A}}((a_1(f \otimes a) \boxtimes \mathbf{1})\varphi).$$

For $\varphi = 1$, the right side is zero, making $\zeta(f)$ central. For $\varphi = (z_1 - z_2)^{-1}$, the unit residue gives $a_1(f \otimes a) = \zeta(f) \cdot a$. Both sides are horizontal maps, so the result is coordinate independent.

Restriction to the vacuum gives a coalgebra map $g : F \to C_{\mathcal{A}}$. On distinct positions it is the external product of the central singleton maps. Inside the localized external state module, the center factorization module is

$$Z(\mathcal{A})^{\ell}_{X^I} = A_I \cap j_{I,*} j_I^*(Z(\mathcal{A})^{\ell \boxtimes I}).$$

This follows by restricting the first Chevalley–Cousin differential to the central subalgebra (Beilinson–Drinfeld, Sections 3.4.11–3.4.12). Thus g factors through the center coalgebra. Its collision and coproduct identities follow from those in $C_{\mathcal{A}}$ by the injective inclusion.

The reconstructed central action agrees with the original on the distinct locus. Their difference would have diagonal-supported image in A_I, which is zero. Evaluation on the vacuum recovers g, giving the inverse.

For a monoid F, apply the same equivalence to $F \otimes^! F$. Associativity of the action makes g preserve multiplication. The pointing makes it preserve the unit. All iterated mapping spaces remain discrete, so the coherences are unique. This proves finality. □

If a local center on all factorizing actors exists, it receives this ordinary center. Their mapping functors agree on actors with the stated bound. Above the heart, the reduction to top cohomology fails. Already $\pi_1 \operatorname{Map}(k[-1], k) = k$ although $H^0(k[-1]) = 0$. The following Heisenberg actions retain precisely such derived information.

20.18 Derived actions of the Heisenberg boundary

Fix a field k of characteristic zero. The degree-one operator in the following calculation comes from varying a charge. It is invisible in the ordinary center, although it acts on a resolution of the vacuum.

Let $\mathfrak{h}_\kappa$ have generators J_n, $n \in \mathbb{Z}$, and a central element $\mathbf{c}$, with

$$[J_m, J_n] = \kappa m \delta_{m+n,0} \mathbf{c}.$$

A *smooth module* has $\mathbf{c} = 1$, and each vector is annihilated by all sufficiently large J_n. Write Sm_κ for their abelian category. These are precisely the modules for the Heisenberg vertex algebra V_κ: normal products reconstruct the fields from the smooth current action. On the vacuum,

$$V_\kappa = k[x_1, x_2, \dots], \qquad J_{-n} = x_n, \quad J_n = \kappa n \partial_{x_n} \quad (n \geq 1), \qquad J_0 = 0.$$

Smoothness does not require local nilpotence of each positive mode.

PROPOSITION 20.18.1 *(Continuous vacuum cochains).* For $M \in \mathsf{Sm}_\kappa$, put

$$C^\bullet_{\mathrm{sm}}(M) = M \otimes \Lambda(\xi_0, \xi_1, \dots), \qquad |\xi_n| = 1, \qquad d(m \otimes \omega) = \sum_{n \geq 0} J_n m \otimes \xi_n \wedge \omega.$$

The exterior algebra consists of finite sums of monomials. Then

$$\operatorname{Ext}^i_{\mathsf{Sm}_\kappa}(V_\kappa, M) \simeq H^i C^\bullet_{\mathrm{sm}}(M).$$

Proof. The sum defining d is finite on every element. The nonnegative modes commute, so $d^2 = 0$. Let $\mathfrak{b}$ be their span and let $\mathfrak{a}_p$ be the span of J_n for $n \geq p$. The displayed complex is the filtered union of

$$C^\bullet(\mathfrak{b}/\mathfrak{a}_p, M^{\mathfrak{a}_p}).$$

Its degree-zero cohomology is $M^{\mathfrak{b}}$, which is $\mathrm{Hom}(V_\kappa, M)$ by the induced presentation of the vacuum.

It remains to check acyclicity on injectives in the smooth category. For $S_p = k[J_0, \dots, J_{p-1}]$, induction from $\mathfrak{b}$, with central charge one, is exact and takes S_p-modules to smooth modules. It is left adjoint to $M \mapsto M^{\mathfrak{a}_p}$. Thus an injective smooth module Y has $Y^{\mathfrak{a}_p}$ injective over S_p.

The finite Koszul complex has no positive cohomology on this module. Filtered unions are exact, so $C^\bullet_{\mathrm{sm}}(Y)$ has no positive cohomology. The exact cochain functors and dimension shifting now identify their cohomology with Ext. □

Theorem 20.18.2 *(Charge and vacuum extensions).* At nonzero level,

$$\mathrm{Ext}^*_{\mathsf{Sm}_\kappa}(V_\kappa, V_\kappa) = \Lambda(\xi_0)$$

as a graded algebra. Its nonzero degree-one class is the extension $V_\kappa[\varepsilon]/(\varepsilon^2)$ with $J_0 = \varepsilon$. For the Fock module F_μ with nonzero charge $J_0 = \mu$, all groups $\mathrm{Ext}^i(V_\kappa, F_\mu)$ vanish. At zero level the vacuum cochain differential vanishes, giving

$$\mathrm{Ext}^*_{\mathsf{Sm}_0}(V_0, V_0) \simeq V_0 \otimes \Lambda(\xi_0, \xi_1, \dots)$$

as graded vector spaces.

Proof. For $\kappa \neq 0$, the vacuum differential is $\sum_{n\geq 1} \kappa n \xi_n \partial_{x_n}$. The degree-minus-one derivation

$$\sigma(\xi_n) = \frac{x_n}{\kappa n} \quad (n \geq 1), \qquad \sigma(\xi_0) = \sigma(x_n) = 0$$

satisfies $d\sigma + \sigma d = N$, where N counts the x_n and the ξ_n with $n \geq 1$. Dividing by N contracts each positive-degree summand. The remaining complex is $\Lambda(\xi_0)$ with zero differential.

In the extension displayed in the statement, J_0 is nonzero. It would vanish on a split extension of two vacuum modules. The extension therefore spans the one-dimensional Ext group. Its square is zero because Ext in degree two vanishes.

For F_μ, the extra differential is $\mu \xi_0 \wedge$. $\mu^{-1}\partial_{\xi_0}$ contracts the complex. At $\kappa = 0$ every nonnegative mode kills the vacuum, proving the final assertion. □

The degree-one class differentiates the family F_μ at $\mu = 0$. Requiring $J_0 = 0$, or requiring it to act semisimply, excludes this extension. The ambient module category is therefore part of the answer. The smooth module

$$k[x_1, x_1^{-1}, x_2, x_3, \dots]$$

also shows why smoothness cannot be replaced silently by local nilpotence: $J_1 = \kappa \partial_{x_1}$ is not locally nilpotent when $\kappa \neq 0$.

The vacuum with a moving root

Let $X = \mathbb{A}^1_k$ with coordinate y. A *module with a moving root* is a left D_X-module with an $\mathcal{O}_X$-linear smooth mode action satisfying

$$[\nabla_{\partial_y}, J_n] = -nJ_{n-1}.$$

This equation makes the current horizontal when its argument is measured from the moving root. The vacuum is $\mathcal{V} = \mathcal{O}_X \otimes V_\kappa$, with connection $\partial_y + T$. On its cochains define

$$T x_n = n x_{n+1}, \qquad T\xi_n = (n+1)\xi_{n+1}.$$

This derivation commutes with d.

THEOREM 20.18.3 *(Internal endomorphisms of the moving vacuum).* The differential D_X-module

$$\mathcal{Z}^\ell = \mathcal{O}_X \otimes C^\bullet_{\mathrm{sm}}(V_\kappa), \qquad \nabla_{\partial_y} = \partial_y + T$$

represents the derived functor

$$R\,\mathrm{Hom}_{\mathrm{mov}}(N \otimes_{\mathcal{O}_X} \mathcal{V}, \mathcal{V}) \simeq R\,\mathrm{Hom}_{D_X}(N, \mathcal{Z}^\ell)$$

for every left D_X-module N. For $\kappa \neq 0$, translation is null-homotopic:

$$K(\xi_n) = \kappa^{-1} x_{n+1}, \qquad K(x_n) = 0, \qquad dK + Kd = T.$$

Consequently the cohomology is $\mathcal{O}_X \otimes \Lambda(\xi_0)$ with trivial connection.

Proof. The functor $N \mapsto N \otimes \mathcal{V}$ is exact. Its right adjoint takes nonnegative-mode invariants, with the induced connection. Thus the desired representing object is the derived invariant complex.

To compute it in the moving category, let $A_\kappa = U(\mathfrak{h}_\kappa)/(\mathbf{c} - 1)$ and adjoin y, D with relations

$$[D, y] = 1, \qquad [y, J_n] = 0, \qquad [D, J_n] = -nJ_{n-1}.$$

The last derivation preserves the Heisenberg relations: its value on the central commutator relation is $-\kappa m(m + n - 1)\delta_{m+n-1,0} = 0$. The Ore normal form is free as a right A_κ-module, with basis $y^a D^r$. Induction is therefore exact.

It also preserves smoothness. Indeed,

$$J_n D^r = \sum_{j=0}^{r} \binom{r}{j} n(n-1)\cdots(n-j+1) D^{r-j} J_{n-j}.$$

A vector killed by all modes of index at least p induces a vector $y^a D^r \otimes m$ killed by all modes of index at least $p + r$. Hence the forgetful functor preserves injectives.

Proposition 20.18.1 computes their derived invariants by the displayed cochains. The computation respects the connection. Applying an injective resolution proves the adjunction.

Finally, both $dK + Kd$ and T are derivations. On generators,

$$(dK + Kd)x_m = mx_{m+1}, \qquad (dK + Kd)\xi_m = (m+1)\xi_{m+1}.$$

Thus T acts trivially on cohomology, as asserted. □

This theorem gives an internal Hom in the moving module category. To obtain a transverse factorizing action, commutation must hold on a boundary resolution and across all configurations. We now construct that additional structure.

A quartet resolution

Assume $\kappa \neq 0$. Let $\Lambda[c]$ be the commutative vertex superalgebra on an odd degree-one field and its translates. Set

$$\mathcal{Z}_\kappa = V_\kappa \otimes \Lambda[c], \qquad \xi_n = \frac{T^n c}{n!}, \qquad d = (:cJ:)_{(0)}, \qquad dJ = \kappa Tc, \quad dc = 0.$$

A zero mode is a derivation of all vertex operations. These formulas therefore define a differential vertex algebra whose complex is $C^\bullet_{\mathrm{sm}}(V_\kappa)$. Its bracket $[J_\lambda J] = \kappa\lambda$ is retained.

Let E have even fields t, p of degree zero and odd fields η, ι of degrees 1, −1. Its nonzero generating brackets are

$$[p_\lambda t] = 1, \qquad [\iota_\lambda \eta] = 1,$$

together with those forced by graded skewsymmetry. Give this Weyl–Clifford vertex algebra the differential

$$Q = (:\eta p:)_{(0)}, \qquad Qt = \eta, \quad Q\iota = p, \quad Q\eta = Qp = 0.$$

All state spaces here are algebraic polynomial or exterior spaces. Each state involves finitely many jets.

Theorem 20.18.4 *(Commuting currents on a resolution).* In $W = V_\kappa \otimes E$, with differential Q, the maps

	J	c
$i : V_\kappa \longrightarrow W$	$J + p$	
$j : \mathcal{Z}_\kappa \longrightarrow W$	$J - \kappa T t$	$-\eta$

preserve the differential vertex operations and have commuting images. The map i is a quasi-isomorphism. If

$$W^{\mathfrak{b}} = \{w : (J + p)_n w = 0 \text{ for all } n \geq 0\},$$

then $j : \mathcal{Z}_\kappa \to W^{\mathfrak{b}}$ is also a quasi-isomorphism. The resulting derived endomorphism comparison takes $[c]$ to $[\xi_0]$ and preserves the Yoneda product.

Proof. Write $U = J - \kappa T t$. The decisive brackets are

$$[(J + p)_\lambda (J + p)] = [U_\lambda U] = \kappa\lambda, \qquad [(J + p)_\lambda U] = \kappa\lambda - \kappa\lambda = 0.$$

Here $[p_\lambda T t] = \lambda$. Also $Q(J + p) = 0$ and $QU = -\kappa T \eta$, proving compatibility with the differentials.

Use state coordinates x_n, π_n, τ_m, $\bar\eta_m$, $\bar\iota_n$ with $n \geq 1$, $m \geq 0$. They are respectively the creation modes of J, p, t, η, ι. The last two are odd. The differential on W is

$$Q = \sum_{m \geq 0} \bar\eta_m \partial_{\tau_m} + \sum_{n \geq 1} \pi_n \partial_{\bar\iota_n}.$$

The operator $\sum_m \tau_m \partial_{\bar\eta_m} + \sum_n \bar\iota_n \partial_{\pi_n}$ contracts the nonconstant quartet monomials after division by their total number of generators. Thus $H(E) = k$. Since $p = Q\iota$, the map i induces the identity on $H(W) = V_\kappa$.

The nonnegative modes of $J + p$ are

$$(J + p)_0 = \partial_{\tau_0}, \qquad (J + p)_n = \kappa n \partial_{x_n} + \partial_{\tau_n}.$$

In the coordinates $v_n = x_n - \kappa n \tau_n$ they become the derivatives ∂_{τ_m}. Their common kernel is

$$k[v_n, \pi_n : n \geq 1] \otimes \Lambda(\bar\eta_m : m \geq 0, \bar\iota_n : n \geq 1).$$

Its differential has $Qv_n = -\kappa n \bar\eta_n$ and $Q\bar\iota_n = \pi_n$.

The image of j consists of the v_n, $\bar\eta_m$ factors. The remaining pairs are contractible. This is a decomposition of complexes, without an assertion that the two vertex subalgebras commute.

The continuous invariant complex in the τ coordinates is a polynomial de Rham complex. Hence

$$\mathcal{Z}_\kappa \longrightarrow W^{\mathfrak{b}} \longrightarrow C^\bullet_{\mathrm{sm}}(W) \longleftarrow C^\bullet_{\mathrm{sm}}(V_\kappa)$$

is a zigzag of quasi-isomorphisms. To justify the totalizations, give each coordinate and each cochain generator weight equal to its mode index. At fixed weight r, the quartet degree lies between $-r$ and $r+1$, and the cochain degree lies between 0 and $r+1$. Both filtrations are finite.

Finally, in the total complex,

$$(Q + d_{\mathrm{CE}})\tau_0 = \bar{\eta}_0 + \xi_0.$$

The class of $j(c) = -\bar{\eta}_0$ is therefore $[\xi_0]$. Both cohomology algebras are exterior on this class, with the same unit, which proves the product assertion. □

The correction to the current is necessary. On the original cochain complex, $[d, J_{-1}]\mathbf{1} = \kappa\xi_1$. The field p makes the boundary current closed, and $-\kappa T t$ cancels its bracket with the cochain current.

There is also a binary product in the homotopy category. In $\mathcal{Z}_\kappa \otimes E$, with differential $d + Q$, the two commuting maps are

	J	c
b_1	$J + p$	c
b_2	$J - \kappa T t$	$c - \eta$.

Their product, followed by the inverse of the quartet quasi-isomorphism, is unital in the homotopy category. The two unit homotopies are explicit over $k[s, ds]$:

	J	c
$b_1(s)$	$J + s p + ds\, \iota$	c
$b_2(s)$	$J - s\kappa T t$	$c - s\eta - ds\, t$.

The signs follow from the tensor differential: $d(ds\, \iota) = -ds\, p$ and $d(ds\, t) = -ds\, \eta$. On cohomology this is the exterior product.

A binary operation and its unit homotopies do not yet give an associative object with all coherences. The construction below supplies them and specifies its order: its multiplication is the opposite of the binary operation just displayed.

A factorizing ghost action

For a differential vertex algebra B, write $C_B = C^{\mathrm{CE}}_\star(L_B)$ for its Chevalley collision coalgebra. Let $R = \Lambda[c]$, $F = C_R$, and $C = C_{V_\kappa}$. The multiplication of the commutative differential algebra R makes F a transverse monoid. Its vacuum is the pointing $J \to F$.

We first justify the tensor comparison used in the action. For a finite configuration I, put

$$P_I(t) = \prod_{i \in I} (t - z_i), \qquad H_I = \varinjlim_m \big(\mathcal{O}_{X^I}[t]/P_I(t)^m\big)^\vee.$$

The factorization lattice of R is $\Lambda_{\mathcal{O}_{X^I}}(H_I)$, with generators in degree one. The finite jet modules are free because P_I^m is monic. Exterior powers and filtered colimits give flat graded components. With zero differential this is a K-flat complex.

Chinese remainders give factorization on disjoint opens. On collision strata, the positive multiples of the changed root multiplicities are cofinal, giving the collision maps. The finite Cousin resolution identifies the lattice with C_R in the normalization used here. The same construction gives, naturally,

$$C_{R^{\otimes a}} \otimes^! C_B \simeq C_{R^{\otimes a} \otimes B}.$$

It respects multiplication, units, and polynomial homotopies.

The finite Cousin direction has at most $|I|$ terms, so its passage to the internal differential is valid. External tensor over k, localization, and finite symmetric-group coinvariants preserve quasi-isomorphisms. In particular, the maps C_{i_b} below are equivalences.

Let $W_b = V_\kappa \otimes E^{\otimes b}$ and $i_b(J) = K_b = J + \sum_{j=1}^{b} p_j$. On the cube of polynomial forms

$$\Omega_b = k[s_1, \dots, s_{b-1}] \otimes \Lambda(ds_1, \dots, ds_{b-1})$$

define rows recursively by

$$M_1 = e_1, \qquad M_i = s_{i-1}e_i + (1 - s_{i-1})M_{i-1}.$$

Every row has sum one. Put forms to the left of fields and set

$$\gamma_i = -\sum_j \big(M_{ij}\eta_j + (dM_{ij})t_j\big).$$

Proposition 20.18.5 *(The coherent ghost action).* The assignments $c_i \mapsto \gamma_i$ and $J \mapsto K_b$ give maps

$$R^{\otimes b} \otimes V_\kappa \longrightarrow W_b \otimes \Omega_b$$

whose faces define a unital transverse action of F on C. Its action map is the roof

$$C_R \otimes^! C_{V_\kappa} \longrightarrow C_{W_1} \xleftarrow{\sim} C_{V_\kappa}, \qquad c \mapsto -\eta_1, \quad J \mapsto J + p_1.$$

Proof. For the total differential $D = Q + d$, $D(M\eta + dM\, t) = 0$: the two $dM\,\eta$ terms cancel. The γ_i commute, and

$$[K_b \lambda \gamma_i] = -\sum_j dM_{ij} = 0.$$

Also $DK_b = 0$ and $[K_b \lambda K_b] = \kappa\lambda$. Thus the assignments preserve all generating operations.

At $s_i = 0$ the adjacent rows coincide. This face multiplies the corresponding ghost factors. The target comparison replaces one quartet by

$$p \mapsto p_i + p_{i+1}, \quad \iota \mapsto \iota_i + \iota_{i+1}, \quad t \mapsto t_i, \quad \eta \mapsto \eta_i.$$

It preserves brackets and differentials, lies under the boundary, and is a quasi-isomorphism.

At $s_i = 1$ the recurrence restarts at e_{i+1}. This face composes the actions of the two consecutive blocks. In a common resolution their boundary current is K_b.

These face identities agree on intersections. Repeated merges add p, ι and retain the first t, η, independently of parentheses. Repeated splits use the same separate quartets, and disjoint merges and splits commute. Thus the cubes give all associative coherences.

More explicitly, the cubical resolution of a nonunital monoid has terms $[0,1]^{b-1} \odot F^{\otimes^! b}$. Zero faces multiply adjacent inputs. Multiplication concatenates strings with intervening parameter one. Shrinking every parameter to zero contracts its augmentation to F. Our zero and one faces give a multiplicative map from this resolution.

Polynomial forms define actual mapping-space cubes as follows. Pull them back along every simplex of a cube. Each polynomial simplex algebra has cohomology k by its Euler contraction. The resulting diagrams $C_{W_b \otimes \Omega_n}$ receive objectwise equivalences from the constant boundary diagram. Invert this

natural transformation in the functor category. Naturality in faces, products, and target comparisons preserves all the identities already proved.

When every actor input is the vacuum, the roof is the identity under C, with its coherences. The quasi-unit theorem in *Higher Algebra*, Theorem 5.4.3.5, supplies the unital refinement with this pointed restriction. □

PROPOSITION 20.18.6 *(An action outside the ordinary center).* The ghost action does not factor through the diagonal tensor unit J. In particular, the ordinary center of V_κ does not represent the pointed action functor on all derived factorizing actors.

Proof. Put $\mathfrak{g} = L_{V_\kappa}$ and $\mathfrak{h} = L_{R\otimes V_\kappa}$. The one-ghost summand is $N[-1]$, where N has left state module

$$\bigoplus_{m\geq 0} k e_m \otimes V_\kappa, \qquad T(e_m \otimes v) = (m+1)e_{m+1}\otimes v + e_m \otimes Tv.$$

For a pointed map, bar–cobar gives a map $U_\star\mathfrak{h} \to U_\star\mathfrak{g}$ under $U_\star\mathfrak{g}$. Restrict to $\mathfrak{h}$, project by PBW symmetrization to $\mathfrak{g}$, and restrict to $N[-1]$. The adjoint action preserves symmetric degree, so this defines a homotopy invariant

$$\chi : \pi_0\Phi_C(F,u) \longrightarrow \operatorname{Ext}^1_{\mathfrak{g}\text{-Mod}}(N,\mathfrak{g}).$$

Negating the ghost negates χ.

For our roof, the extension is represented by

$$\nu(e_m\otimes v) = -\frac{1}{m!} : (T^m\eta)i(v) : .$$

A middle module is

$$\{(n,w)\in N\oplus W^0 : Qw = \nu(n)\}/\{(0,Qv) : v\in W^{-1}\}.$$

With kernel inclusion $v\mapsto [(0,-i(v))]$, it represents the indicated connecting class for the usual cochain cone $d(b,a) = (d_B b + f(a), -d_A a)$. Changing this kernel marking changes the sign, without changing whether it splits.

Lift $e_0\otimes \mathbf{1}$ by $-t$. Then

$$Q(-t) = -\eta, \qquad (J+p)_0(-t) = -\mathbf{1}.$$

The same zero mode vanishes on the quotient and on the kernel. Changing the lift cannot remove the displayed vacuum class. The vacuum is not a Q-boundary. Hence the extension is nonsplit.

Main-diagonal differential modules inherit their usual heart, and convolution with $\mathfrak{g}$ is exact there. This heart extension therefore gives a nonzero derived Ext class.

The automorphism negating the boundary current conjugates the action to the action with $c\mapsto -c$. It is realized on the resolution by negating J, t, p, η, ι. Thus conjugation negates the nonzero invariant χ. An action factoring through J is unchanged by boundary conjugation. In characteristic zero these conclusions are incompatible.

Finally, the positive modes on V_κ are the nonzero multiples of ∂_{x_n}, so its ordinary center is $k\mathbf{1}$ and its center coalgebra is J. This proves the asserted failure of representability. □

Tensor products and parameter algebras

The preceding tensor comparison extends to free fields over k. Suppose B has finitely many homogeneous generators, a PBW basis of their jets, central polynomial generating brackets, and a differential linear in the jets. Its factorization lattice has a PBW filtration whose graded pieces are symmetric powers of the free principal-parts modules. Each fixed PBW degree is a bounded complex of free modules. Extensions and filtered unions preserve K-flatness, so every lattice B_I is K-flat.

For two such algebras, the generating Lie algebras have a common constant and otherwise commute. Their vacuum modules give

$$(A \otimes_k B)_I = A_I \otimes_{\mathcal{O}_{X^I}} B_I.$$

The identities respect collisions, disjoint factorization, units, and symmetry. Realization contracts one diagonal tensor unit, giving a symmetric monoidal functor $B \mapsto C_B$. Polynomial homotopies of the form $B \otimes_k \Omega_b$ are also preserved.

The coefficient field in this assertion matters. A family over a differential parameter algebra need not be flat for derived tensor, even when its underlying graded algebra is free.

Proposition 20.18.7 *(A parameter tensor with extra cohomology).* Let $\Omega = k[s, ds]$, with $ds = ds$, and define

$$A_+ = \Omega[a_n : n \geq 0], \qquad A_- = \Omega[b_n : n \geq 0], \qquad Da_n = ds\, a_n, \quad Db_n = -ds\, b_n.$$

All generating vertex brackets vanish, and translation shifts each subscript by one and kills Ω. The augmentations $A_\pm \to \Omega$ are quasi-isomorphisms. Nevertheless,

$$H^0(A_+ \otimes_\Omega A_-) = B_0, \qquad H^{i\neq 0}(A_+ \otimes_\Omega A_-) = 0,$$

where B_0 is the charge-zero part of $k[a_i, b_j]$ for $\mathrm{ch}(a_i) = 1$, $\mathrm{ch}(b_j) = -1$. It has the presentation

$$B_0 = \frac{k[z_{ij} : i, j \geq 0]}{(z_{ij}z_{kl} - z_{il}z_{kj})}, \qquad z_{ij} = a_i b_j, \qquad Tz_{ij} = z_{i+1,j} + z_{i,j+1}.$$

For r row indices and s column indices, its polynomial degree-q dimension is

$$\binom{r+q-1}{q}\binom{s+q-1}{q}.$$

The derived-to-ordinary comparison on cohomology is $k \to B_0$. Neither A_+ nor A_- is K-flat over Ω.

Proof. On a monomial of charge c, the coefficient complex is

$$k[s] \xrightarrow{\partial_s + c} k[s]\, ds.$$

For $c \neq 0$ its inverse on a polynomial f is the finite sum

$$(\partial_s + c)^{-1} f = \sum_{n\geq 0} \frac{(-1)^n}{c^{n+1}} \partial_s^n f.$$

For $c = 0$, differentiation is surjective with kernel k. In each $A_\pm$, only the vacuum has charge zero. In the tensor, every balanced monomial does. This proves the cohomology calculation and, more precisely, the quasi-isomorphism $\Omega \otimes_k B_0 \to A_+ \otimes_\Omega A_-$.

Every balanced monomial is a product of $a_i b_j$. The minor relations exchange the paired column indices of two factors. They put each monomial into the pairing of its sorted row and column multisets. Distinct pairs of multisets have distinct images in $k[a_i, b_j]$, proving that these relations generate the kernel. This argument applies to infinitely many variables because each polynomial uses finitely many. Counting the two multisets gives the dimension formula, and the Leibniz rule gives translation.

The inclusions $\Omega \to A_{\pm}$ compute their derived tensor, whose cohomology is k. The comparison is the inclusion of constants into B_0. Tensoring either augmentation with the other algebra kills the nonzero class $a_0 b_0$. It therefore fails to preserve that quasi-isomorphism, proving both failures of K-flatness. □

The coherent cochain monoid

In the boundary resolution W_b, define

$$\mathcal{Z}^{(b)} = W_b^{\mathfrak{b}}, \qquad K_b = J + \sum_{j=1}^{b} p_j.$$

For an order-preserving surjection $\phi : \{1, \dots, b'\} \to \{1, \dots, b\}$, let $\phi_*(j) = \min \phi^{-1}(j)$. The merge map fixes J and sends

$$p_j \mapsto \sum_{\phi(l)=j} p_l, \quad \iota_j \mapsto \sum_{\phi(l)=j} \iota_l, \quad t_j \mapsto t_{\phi_*(j)}, \quad \eta_j \mapsto \eta_{\phi_*(j)}.$$

It maps W_b to $W_{b'}$ and preserves the boundary current. The shift $r_a : W_b \to W_{a+b}$ sends J to K_a and quartet j to quartet $a + j$. Define

$$\mu_{a,b} : \mathcal{Z}^{(a)} \otimes W_b \longrightarrow W_{a+b}, \qquad z \otimes w \longmapsto {:}\, z\, r_a(w) \,{:}.$$

LEMMA 20.18.8 *(Products through boundary resolutions).* The merge maps are quasi-isomorphisms on both W_b and $\mathcal{Z}^{(b)}$. The latter is freely generated by

$$J - \kappa T t_1, \quad t_j - t_1 \ (j \geq 2), \quad p_j, \eta_j, \iota_j.$$

The products $\mu_{a,b}$ preserve differentials and vertex operations, are strictly associative, and commute with merges. Their restrictions map $\mathcal{Z}^{(a)} \otimes \mathcal{Z}^{(b)}$ to $\mathcal{Z}^{(a+b)}$. The b cochain inputs and one boundary input have images

$$J^{(i)} \mapsto U_i = J + \sum_{l<i} p_l - \kappa T t_i, \qquad c^{(i)} \mapsto -\eta_i, \qquad J \mapsto K_b.$$

The currents $U_1, \dots, U_b, K_b$ commute pairwise, and each has level κ.

Proof. A merged sum of p_l pairs with the retained $t_{\phi_*(j)}$ through exactly one term. The same holds for ι, η. This checks brackets. The formulas also commute with Q.

Every quartet index occurs once, so K_b maps to $K_{b'}$. The least-element rule is compatible with composition. Since all i_b are quasi-isomorphisms, so are the merges.

The nonnegative boundary modes are $\sum_j \partial_{\tau_0^{(j)}}$ and $\kappa n \partial_{x_n} + \sum_j \partial_{\tau_n^{(j)}}$. Use coordinates $x_n - \kappa n \tau_n^{(1)}$ and $\tau_n^{(j)} - \tau_n^{(1)}$ for $j \geq 2$. The modes become derivatives in $\tau_n^{(1)}$, so their common kernel has the stated free generators. Continuous polynomial de Rham cochains in these variables compare each commutant

to the derived invariants of W_b. The finite weight filtrations used in Theorem 20.18.4 apply for every finite b. Naturality and the equivalences i_b then show that merges are equivalences on commutants.

The image of r_a commutes with $\mathcal{Z}^{(a)}$: its current is K_a, and its other fields use later quartets. Thus normal multiplication defines a vertex algebra map. The identity $r_a r_b = r_{a+b}$ proves associativity. Merges preserve these shifts and inclusions, giving naturality.

Finally, shift the two images of j successively. This gives the displayed U_i and ghosts. For $i < j$, the $\kappa\lambda$ contribution from their common J cancels the pairing of $-\kappa T t_i$ with p_i. The same cancellation proves $[U_{i\,\lambda} K_b] = 0$. Their self-brackets retain $\kappa\lambda$. □

Theorem 20.18.9 *(A factorizing cochain monoid and its action).* The coalgebra $C_{\mathcal{Z}_\kappa}$ has a unital transverse monoid structure and a transverse action on C_{V_κ}. The b-fold product is represented by

$$\mathcal{Z}_\kappa^{\otimes b} \longrightarrow \mathcal{Z}^{(b)} \xleftarrow{\sim} \mathcal{Z}^{(1)} \xleftarrow[j]{\sim} \mathcal{Z}_\kappa.$$

The action is the quartet roof of Theorem 20.18.4. It restricts along $C_R \to C_{\mathcal{Z}_\kappa}$ to the pointed ghost action, and does not factor through J.

Proof. The free-field tensor comparison transports the preceding strict products and action to factorizing coalgebras. Let $\mathcal{P}$ be the category of nonempty finite ordered sets and order-preserving surjections. The two towers are functors on $\mathcal{P}^{\mathrm{op}}$, with lax multiplication given by concatenation. They take every arrow to an equivalence.

Their coherent descent can be seen in the operad for a nonunital algebra and a left module. The symmetric monoidal envelope of the pair of towers has fibers that are finite products of $\mathcal{P}^{\mathrm{op}}$. Each is contractible, since the singleton is final in $\mathcal{P}$. Localizing at the fiber arrows therefore gives the envelope of the algebra-module operad. The strict tower data descend through this localization. This proves associativity with all coherences, and gives the product roofs in the statement.

The vacuum is a quasi-unit. Right multiplication is the inclusion into the two-quartet term. Left multiplication is the shift r_1. On the image of j, the inclusion agrees with the merge. Two polynomial homotopies join the merge to the shift:

	J	c
	$J - \kappa T((1-s)t_1 + st_2)$	$-(1-s)\eta_1 - s\eta_2 - ds(t_2 - t_1)$
	$J + sp_1 + ds\,\iota_1 - \kappa T t_2$	$-\eta_2.$

They preserve brackets, differential, and commutation with K_2.

The vacuum action on the module is also an equivalence, since $r_1 i_1 = i_2$. The quasi-unit theorems (*Higher Algebra*, Theorem 5.4.3.5 and Proposition 5.4.3.14) refine both structures to unital ones, uniquely up to contractible choice.

Transport along j and i_1 gives the stated objects. Let $m : W_1 \to W_2$ be the merge map. The identity

$$\mu_{1,1}(j(z) \otimes i_1(v)) =: j(z) i_2(v) := m\big(: j(z) i_1(v) :\big)$$

identifies the action roof. Its restriction has $c \mapsto -\eta_1$ and $J \mapsto J + p_1$. Proposition 20.18.6 excludes factorization through J. □

The action at one position is the full evaluation of the moving-vacuum internal Hom. Indeed, its adjoint is $z \mapsto j(z)$ into the resolved invariants. In their continuous cochains, compare

$$f_0 : (J, c) \mapsto (J + p, c), \qquad f_1 : (J, c) \mapsto (J - \kappa T t, -\eta).$$

They are joined through $(J, c) \mapsto (J, c)$ by

$$(J + s p + ds\, \iota, c), \qquad (J - s\kappa T t, (1 - s)c - s\eta - ds\, t).$$

Here the total cochain differential has $Dt = \eta + c$.

Integrating the ds coefficient gives a chain homotopy commuting with translation. Thus the adjoint is the identity of $\mathcal{Z}^{\ell}$, and evaluation induces

$$R\operatorname{Hom}_{D_X}(N, \mathcal{Z}^{\ell}) \simeq R\operatorname{Hom}_{\mathrm{mov}}(N \otimes_{O_X} \mathcal{V}, \mathcal{V})$$

for every complex N. This universal property at one position does not establish finality of the factorizing actor on all configurations.

The order of the coherent product can also be checked on a common resolution. Put $\mathcal{T} = C^{\bullet}_{\mathrm{sm}}(W_2) = W_2 \otimes \Lambda[c]$. Its differential satisfies

$$DJ = \kappa T c, \quad Dt_l = \eta_l + c, \quad D\iota_l = p_l, \quad D p_l = D\eta_l = Dc = 0.$$

The tower roof and the exchanged binary roof map into $\mathcal{T}$ through quasi-isomorphisms. Their unit maps are joined by the two homotopies used above.

A family of two-input maps is given by

$$J^{(i)} \longmapsto J + \sum_l \big(\beta_l^{(i)} p_l + \kappa \epsilon_l^{(i)} T t_l + ds\, \partial_s \beta_l^{(i)} \iota_l\big),$$
$$c^{(i)} \longmapsto (1 + \epsilon_1^{(i)} + \epsilon_2^{(i)})c + \sum_l \big(\epsilon_l^{(i)} \eta_l + ds\, \partial_s \epsilon_l^{(i)} t_l\big).$$

It preserves brackets precisely when

$$\beta^{(i)} \cdot \epsilon^{(i)} = 0, \qquad \beta^{(1)} \cdot \epsilon^{(2)} + \beta^{(2)} \cdot \epsilon^{(1)} = -1,$$

and every cross pairing is constant in s.

The tower starts at

$$(\beta^{(1)}, \epsilon^{(1)}, \beta^{(2)}, \epsilon^{(2)}) = ((0, 0), (-1, 0), (1, 0), (0, -1)).$$

Change successively

$$\epsilon^{(2)} = (0, s - 1), \quad \beta^{(2)} = (1, 2s), \quad \epsilon^{(1)} = (-1 + 2s, -s), \quad \beta^{(1)} = (s, s),$$

keeping the other three vectors at their current values. Each segment satisfies the bracket conditions. The endpoint is the exchanged binary map. Thus the tower product equals the opposite binary product in the localization at quasi-isomorphisms. Its induced cohomology product remains the exterior product.

A coherent loop that prevents finality

The cochain monoid has the expected moving-vacuum evaluation. A local center must also represent the homotopies of actions on separated configurations. An actor in degree two detects a homotopy that the cochain monoid misses.

Let

$$N = k[t_0, t_1, \ldots], \qquad |t_n| = 2, \qquad T t_n = t_{n+1}, \qquad d = 0,$$

with zero vertex brackets. Its augmentation ϵ kills the t_n. The coalgebra $F_2 = C_N$ is a commutative transverse monoid. Its lattice on X^I is $\mathrm{Sym}_{\mathcal{O}_{X^I}}(H_I[-2])$. It is K-flat by the same finite-jet argument as for the ghost, and gives natural equivalences

$$F_2^{\otimes^! p} \otimes^! C \simeq C_{N^{\otimes p} \otimes V_\kappa}.$$

Let α_0 be the augmentation action and $g_0 : F_2 \to J \to C_{\mathcal{Z}_\kappa}$ its factorization through the unit.

Put $\mathfrak{h}_N = L_{N \otimes V_\kappa}$ and $\mathfrak{g} = L_{V_\kappa}$. The derived deformation complex at α_0 is the relative convolution complex

$$\mathcal{T}_{\mathrm{rel}} = \mathrm{Hom}^{\mathrm{der}}\big(\overline{C^{\mathrm{CE}}_\star(\mathfrak{h}_N)}, U_\star\mathfrak{g}\big)_{\mathrm{rel}}, \qquad d_{\tau_0} = d + [\tau_0, -].$$

Here *relative* means vanishing on $C^{\mathrm{CE}}_\star(\mathfrak{g})$, and all coefficient Homs remain derived. Completion is by products over the total polynomial degree G in the t_n. The base twisting cochain τ_0 is the augmentation on singleton inputs.

This filtration is complete, starts at $G = 1$, and is added by convolution. Thus the complex is a pronilpotent differential graded Lie algebra. Derived bar–cobar identifies

$$\pi_1\Phi_C(F_2, u) = \big(H^0\mathcal{T}_{\mathrm{rel}}, \mathrm{BCH}\big), \qquad \pi_n\Phi_C(F_2, u) = H^{1-n}\mathcal{T}_{\mathrm{rel}} \quad (n \geq 2)$$

at the augmentation. A closed degree-zero cochain h gives the loop $\tau_0 + ds\, h$, with class $\exp[h]$.

Because τ_0 is Lie-valued, PBW output degree is preserved. In output degree a, a component has a partition into a blocks, determined on their distinct locus. Its differential acts inside each block. This assertion uses support and localization, rather than a factorization of Hom for infinite-dimensional coefficient modules.

Lemma 20.18.10 *(The degree bound).* In total t-degree G and output degree a, the complex is concentrated in degrees at least $a - 2G$. For $G = 1$, $a = 2$, closed degree-zero cochains have ordinary binary coefficients, and no degree-zero boundaries occur.

Proof. With n inputs and coefficient extension degree e, suspension changes the input degree from $2G$ to $2G - n$. The cochain degree is therefore $e + n - 2G$. The underlying coefficient modules admit derived Hom in degrees $e \geq 0$. Support forces $n \geq a$: a source on at most n blocks restricts to zero on an a-point locus when $n < a$. Derived adjunction gives the same vanishing.

At each finite configuration the number of blocks is finite. Products and the configuration limit preserve the bound. For $G = 1$, $a = 2$, degree zero forces $n = 2$, $e = 0$, and degree minus one does not occur. □

Define the augmentation derivation $\ell : N \to k$ by $\ell(t_n) = \delta_{n0}$, vanishing on other polynomial degrees. It obeys

$$\ell(Ta) = 0, \qquad \ell(ab) = \ell(a)\epsilon(b) + \epsilon(a)\ell(b).$$

The corresponding singleton cochain is

$$\kappa_1\big(s(t_n \otimes v)\big) = \delta_{n0} v.$$

It has degree -1 and is closed.

Indeed, $t_0 \mapsto u$, $t_{n>0} \mapsto 0$ defines the first-order vertex map with $|u| = 2$, $u^2 = 0$. The coefficient of u in its Maurer–Cartan equation is $d_{\tau_0}\kappa_1 = 0$. The degree bound excludes boundaries below it, and its value on $s(t_0 \otimes \mathbf{1})$ is nonzero.

On the vacuum, $J_1 = \kappa \partial_{x_1}$ commutes with T and is a derivation of every vertex operation. It kills $\mathbf{1}$ and sends J to $\kappa\mathbf{1}$. Define the two-output cochain

$$h = \kappa_1 \boxtimes J_1 = -\big(\kappa_1 * (J_1\tau_0)\big)^{(2)}.$$

On two separated singleton blocks its value is

$$h\big(s(t_n \otimes v), s(\mathbf{1} \otimes w)\big) = \delta_{n0}\, v \boxtimes J_1 w.$$

The negative convolution sign cancels the sign from passing the degree-one second cochain across the degree-one first input. Both factors are closed, so h is closed of degree zero.

LEMMA 20.18.11 *(The separated vacuum coefficient).* There is a degree-minus-one chain map $\mathsf{P} : \mathcal{T}_{\mathrm{rel}}^{(a)} \to \mathcal{T}_{\mathrm{rel}}^{(a-1)}$ with

$$d_{\tau_0}\mathsf{P} + \mathsf{P}d_{\tau_0} = 0, \qquad \mathsf{P}(h) = \kappa\kappa_1.$$

Its value on the degree-zero, $G = 1$, two-output part of every class induced by a pointed map to $C_{\mathcal{Z}_\kappa}$ is zero.

Proof. Insert a separated singleton at z carrying $\mathbf{1} \otimes J$, use test function one there, and apply the vacuum coefficient to its output. Expand the resulting rational function at $z = \infty$ and take its constant term. Place the suspended current first, including its permutation sign. On a degree-r cochain multiply this operation by $(-1)^{r+1}$. This defines P.

The input J is a free translation generator, since it has weight one and TV_+ has no weight-one state. Hence insertion is defined on derived coefficient resolutions. Extraction commutes with the coefficient differential and with derivatives and residues in the remaining variables. A bracket inside the singleton block has no second input. The two products with $\tau_0(J) = J$ cancel on the separated locus. The remaining differential is the one on the other blocks.

Insertion has degree -1. The displayed sign gives the asserted anticommutation. These operations preserve finite normal order and G, so extend to the completion.

For h, the inserted current gives $J_1 J = \kappa\mathbf{1}$, constant in z. The permutation sign cancels the sign in P, leaving $\kappa\kappa_1$.

For the image assertion, use the quartet commutant model of the cochain action. Its transferred twisting cochain is Lie-valued and supported on small diagonals. Its linear term is the weight-preserving contraction of

$$m(\zeta, v) = \zeta_{(-1)} i(v).$$

Here is a transfer retaining these properties. Take the quartet contraction (i, π, H) in coordinates that keep $i(V_\kappa)$ fixed. Then $QH + HQ = 1 - i\pi$, $Hi = \pi H = H^2 = 0$, and $H\mathbf{1} = 0$.

On n suspended factors let K_n be the signed sum of the shifted H, divided by the number of factors of positive quartet degree. Set it to zero when that number is zero. It satisfies

$$d_Q K_n + K_n d_Q = 1 - \mathrm{Sym}^n(i\pi).$$

With $P_1 = s\pi s^{-1}$, define recursively

$$P_n = \left(\frac{1}{2} \sum_{n_1+n_2=n} \beta_V (P_{n_1} \otimes P_{n_2})\Delta_{n_1,n_2} - P_{n-1}\delta_W\right) K_n.$$

Here β_V is the suspended bracket, ∂_W the Chevalley bracket differential, and Δ the unshuffle coproduct.

The expression in parentheses is a cycle and vanishes on $\mathrm{Sym}^n(i)$. The contraction identity therefore proves the coalgebra-map equation inductively. It gives $P\,\mathrm{CE}(i) = 1$. Each component is a finite sum of bracket and contraction composites, with values in the Lie object.

The higher components vanish on a vacuum input. Indeed, the vacuum has quartet degree zero, and its bracket with the output equals the sum of its brackets with the inputs. This is the partial-fraction residue identity around those inputs. The two remaining terms in the recursion cancel, with the suspended vacuum sign. Thus $\sigma = \vartheta_V P\,\mathrm{CE}(m)$ is the required normalized twisting cochain, where ϑ_V is the canonical Lie-valued twisting cochain.

Free localized normal resolutions have surjective normal derivative. Their inverse limits and products preserve this comparison. Its derivatives retain the normalization.

Differentiate composition at the augmentation. At a separated input carrying $\mathbf{1} \otimes J$, either the base point supplies J, or the variable block supplies $\zeta_{(-1)}(J + p)$ before contraction. Both have positive conformal weight. Their vacuum coefficient vanishes, since the resolution has nonnegative weights and the contraction preserves weight.

This is also a derived vanishing: the map factors through the subcomplex of positive weights before applying coefficient resolutions. By the degree bound, its closed degree-zero two-output representative is ordinary. Its vacuum coefficient is already zero before taking the constant term at infinity. This proves the assertion. □

Theorem 20.18.12 *(Failure of finality of the cochain actor).* The mapping space from the augmentation action (F_2, α_0) to the cochain action $(C_{\mathcal{Z}_\kappa}, \alpha_{\mathcal{Z}})$ has at least two connected components. Consequently this cochain actor is not a local center on the full category of factorizing coalgebras.

Proof. The class $[h]$ is missed by the map on pointed-action fundamental groups. Its probe is the nonzero class $\kappa[\kappa_1]$, whereas every image has zero probe. A source loop is represented by $ds\,K'$ with K' closed of degree zero. Only the derivative of composition contributes, since $(ds)^2 = 0$. The exponential identification for the complete Lie algebra therefore shows that $\exp[h]$ is not an image loop.

We must also retain action coherences. For p actor factors put

$$\epsilon_p(a_1, \dots, a_p) = \prod_i \epsilon(a_i), \qquad \ell_p(a_1, \dots, a_p) = \sum_i \ell(a_i) \prod_{j \neq i} \epsilon(a_j).$$

Let κ_p be the resulting singleton cochain and $\tau_0^{(p)}$ the augmentation twisting cochain. Then

$$h_p = -\big(\kappa_p * (J_1 \tau_0^{(p)})\big)^{(2)}$$

is closed. Over a square-zero parameter δ of degree one, $\tau_0^{(p)} + \delta h_p$ is a twisting cochain.

Multiplication faces use the derivation rule for ℓ. Unit faces use $\ell(1) = 0$. Composition uses

$$\ell_{p+q} = \ell_p \otimes \epsilon_q + \epsilon_p \otimes \ell_q.$$

Terms with two copies of δ vanish. On every parenthesized word, the linear term is therefore the same sum over the factor on which ℓ acts.

The free associative bar resolution has constant compatible fillers on all simplices and its usual extra unit degeneracy. It gives all action coherences. Extending $\delta \mapsto ds$ produces a loop of transverse actions based at α_0, whose underlying pointed loop is $\exp[h]$.

The mapping space in the statement is the homotopy fiber over α_0 of

$$\mathrm{Map}_{\mathrm{Alg}}(F_2, C_{\mathcal{Z}_\kappa}) \longrightarrow \mathrm{Act}(F_2, C).$$

It contains g_0. The loop just constructed is not the image of a loop on the left, since forgetting multiplication would contradict the pointed obstruction. The homotopy-fiber sequence therefore gives at least two components. A final action would make this fiber contractible. □

This obstruction concerns the specified cochain actor. It does not exclude every possible local center, or claim that individual actions cannot lift. The missing homotopy changes the external-product identifications at a separated boundary input. Fixing those identifications coherently defines a further representability problem. So does constructing a larger actor that retains their deformations.

20.19 The marked center of the affine E_6 category

A finite tensor category supplies a different central action. Its sectors may change the boundary object. The affine E_6 realization makes that action explicit, including the algebra that recovers the boundary and the fields that implement its junctions.

Work over $\mathbb{C}$ at the unitary embedding of Theorem 16.11.1. Put

$$V = L_{\widehat{\mathfrak{sl}}_2}(10, 0), \qquad \mathcal{D} = \mathrm{Rep}(V).$$

Its simple modules H_j, $0 \le j \le 10$, have lowest weights $h_j = j(j+2)/48$. Retain the connected commutative separable algebra $A = H_0 \oplus H_6$ with its specified multiplication.

Let $\mathcal{M} = \mathcal{D}_A$ be the category of right A-modules. Our balanced tensor gives a right module N the left action

$$\ell_N = r_N c_{A,N}.$$

This convention is part of the center computation.

The even component C has simples 1, g, ρ and

$$g^2 = 1, \qquad g\rho = \rho g = \rho, \qquad \rho^2 = 1 + g + 2\rho.$$

With $d = 1 + \sqrt{3}$, their dimensions are $1, 1, d$, and $\dim C = 6 + 2\sqrt{3}$. The local modules form $\mathcal{E} = \mathrm{Rep}(W)$ for $W = L_{\widehat{\mathfrak{so}}_5}(1, 0)$:

$$W_0 = H_0 \oplus H_6, \quad W_v = H_4 \oplus H_{10}, \quad W_s = H_3 \oplus H_7.$$

Their dimensions are $1, 1, \sqrt{2}$ and their lowest weights are $0, 1/2, 5/16$.

Let $S = L_{\widehat{\mathfrak{so}}_{11}}(1, 0)$. Its three simples S_0, S_v, S_s have the same dimensions and weights $0, 1/2, 11/16$. The affine realization identifies $\mathrm{Rep}(S)$ with $\mathcal{E}^{\mathrm{rev}}$, where reversal means $c^{\mathrm{rev}}_{X,Y} = c^{-1}_{Y,X}$. This is the reversed Ising category in Bischoff's center realization, Corollary 4.7 and Section 5.

Set $T = V \otimes S$ and $\mathcal{T} = \mathcal{D} \boxtimes \mathrm{Rep}(S)$. The invertible object $J_* = H_{10}S_v$ has order two and integral weight three. Choose the unitary commutative algebra $L = 1 \oplus J_*$ with its vacuum unit. Its vertex extension is

$$U = H_0S_0 \oplus H_{10}S_v, \qquad c_U = 8.$$

Here H_jS_a abbreviates the external tensor module $H_j \otimes S_a$. The category tensor is the specified vertex tensor product, not the algebraic tensor of states. The tensor-product and extension theorems apply to these strongly rational affine algebras.

An object of the *Drinfeld center* $Z(C)$ is an object M with a natural half-braiding $\gamma_N : M \otimes_A N \to N \otimes_A M$ satisfying the hexagon. Its forgetful functor retains the object while forgetting this family.

Theorem 20.19.1 *(Ten central sectors).* There is a braided equivalence

$$\Psi : \mathrm{Rep}(U)^{\mathrm{rev}} \xrightarrow{\sim} Z(\mathcal{C}).$$

The central forgetful functor F is obtained before descent from

$$\widetilde{F}(X,Y) = (X \otimes A) \otimes_A Y, \qquad X \in \mathcal{D}, \quad Y \in \mathcal{E}.$$

Its half-braiding with a right A-module N is induced by

$$X \otimes Y \otimes N \xrightarrow{1 \otimes c_{Y,N}} X \otimes N \otimes Y \xrightarrow{c_{N,X}^{-1} \otimes 1} N \otimes X \otimes Y.$$

Associators are inserted between these displayed tensors. Restrict to $\mathcal{C}$ and descend by the trivial character of $\widetilde{F}(L) \simeq \mathbb{C}[\mathbb{Z}/2] \otimes 1$.

The ten simples and their forgetful images are

	restriction to T	F	dim	h mod 1
x_0	$H_0S_0 \oplus H_{10}S_v$	1	1	0
x_2	$H_2S_0 \oplus H_8S_v$	ρ	d	$1/6$
x_4	$H_4S_0 \oplus H_6S_v$	$g + \rho$	$d+1$	$1/2$
x_6	$H_6S_0 \oplus H_4S_v$	$1 + \rho$	$d+1$	0
x_8	$H_8S_0 \oplus H_2S_v$	ρ	d	$2/3$
x_{10}	$H_{10}S_0 \oplus H_0S_v$	g	1	$1/2$
y_1	$(H_1 \oplus H_9)S_s$	ρ	d	$3/4$
y_3	$(H_3 \oplus H_7)S_s$	$1 + g + \rho$	$d+2$	0
z_+	H_5S_s	ρ	d	$5/12$
z_-	H_5S_s	ρ	d	$5/12$.

Sums in this table are direct sums. The twist in $Z(\mathcal{C})$ is $e^{-2\pi i h}$. The universal categorical central action is $(Z, M) \mapsto F(Z) \otimes_A M$ with this half-braiding.

Proof. Apply the center theorem for a connected étale algebra to $\mathcal{D}^{\mathrm{rev}}$. With our module tensor convention, the theorem of Davydov–Müger–Nikshych–Ostrik gives

$$\mathcal{D}^{\mathrm{rev}} \boxtimes \mathcal{E} \simeq Z(\mathcal{M}).$$

Its two crossings give the displayed formula. Locality of Y, expressed by $r_Y c_{A,Y} c_{Y,A} = r_Y$, preserves the balancing relations. The braiding hexagons then give the half-braiding hexagon.

The unit checks the orientation. For $Y = N = A$ the inverse crossing cancels the crossing in the left unit constraint. A positive crossing would leave the double braiding $c_{A,X}c_{X,A}$. On the H_6 channel of $H_2 \boxtimes H_6$ its scalar is

$$e^{2\pi i(h_6 - h_2 - h_6)} = e^{-\pi i/3} \neq 1.$$

It would therefore fail the unit constraint.

The central object $H_{10}S_v$ forgets to $g \otimes_A g = 1$. Its central structure is the nontrivial parity character. The fusion rules force g, ρ to have neutral degree in any grading, while $H_1 \otimes A$ generates the odd part.

Thus the universal grading of $\mathcal{M}$ is $\mathbb{Z}/2$. The center theorem for graded fusion categories (Gelaki–Naidu–Nikshych, Corollary 3.7) identifies the neutral de-equivariantized center with $Z(C)$.

Concretely, an L-action becomes an involution t after applying $\widetilde{F}$. The idempotent $(1+t)/2$ selects its vacuum character. The half-braiding of J_* is trivial on C, so it descends to this image. The vertex extension theorem identifies $\mathcal{T}_L^0$ with $\mathrm{Rep}(U)$ as a braided tensor category. Reversing the ambient braiding reverses the local-module braiding, proving the claimed orientation.

The monodromy of J_* on $H_j S_a$ is $(-1)^j$ for $a = 0, v$, and $(-1)^{j+1}$ for $a = s$. There are seventeen local simples before extension. Eight orbits have size two. The fixed object $H_5 S_s$ has two equivariant structures, producing z_+, z_-. The multiplication of L fixes $t^2 = 1$. Changing the sign of its normalized fixed-point intertwiner exchanges these two labels.

To compute F, let $\widetilde{I}$ be right adjoint to $\widetilde{F}$. Rigidity and induction give

$$\mathrm{Hom}_{\mathcal{M}}(\widetilde{F}(X,Y),1) \simeq \mathrm{Hom}_{\mathcal{D}}(X, \mathrm{Res}\, Y^*).$$

Consequently

$$\widetilde{I}(1) = (H_0 \oplus H_6)S_0 \oplus (H_4 \oplus H_{10})S_v \oplus (H_3 \oplus H_7)S_s.$$

The images of H_0S_0, $H_{10}S_0$, H_2S_0 are $1, g, \rho$. By the projection formula, the multiplicity of one of these images in $\widetilde{F}(Q)$ is the coefficient of its corresponding T-module in $\widetilde{I}(1) \boxtimes Q$. Use

$$H_a \boxtimes H_b = \bigoplus_{\substack{|a-b| \le j \le \min(a+b,20-a-b) \\ j \equiv a+b \ (2)}} H_j$$

and $S_v^2 = S_0$, $S_v S_s = S_s$, $S_s^2 = S_0 + S_v$. This gives the forgetful column. At the fixed point the image is 2ρ. Each resolved summand has dimension d and therefore image ρ.

Dimensions and weights follow by induction. The sum of their squared dimensions is $(6+2\sqrt{3})^2$. Finally, a central tensor functor is exactly a tensor functor with the specified half-braidings. Its factorization through $Z(C)$ gives the universal categorical action. □

This action has actual affine fields. For $p : F(Z) \otimes_A M \to N$, take the intertwining operator associated with

$$\mathrm{Res}\, F(Z) \boxtimes \mathrm{Res}\, M \longrightarrow \mathrm{Res}(F(Z) \otimes_A M) \xrightarrow{\mathrm{Res}\, p} \mathrm{Res}\, N.$$

The first arrow is the balanced quotient defined by the separability idempotent. Vertex tensor associativity transports its identities to every descendant coefficient. The X constituent crosses clockwise and the local Y constituent counterclockwise.

The parameter states are those of $\mathrm{Res}\, F(Z)$. A field with the states of the U-module Z has another domain.

The distinguished algebra and the boundary sectors

Let I be right adjoint to F and put $B = I(1)$. Its multiplication is part of the central data: if $\epsilon : F(B) \to 1$ is the counit, then $\mu_B : B \boxtimes B \to B$ is adjoint to

$$F(B \boxtimes B) \simeq F(B) \otimes_A F(B) \xrightarrow{\epsilon \otimes \epsilon} 1.$$

The unit is adjoint to 1_1. A direct-sum decomposition alone would not specify this algebra.

Proposition 20.19.2 *(The marked algebra).* With the preceding multiplication,

$$B = x_0 \oplus x_6 \oplus y_3, \qquad F(B) = 31 \oplus g \oplus 2\rho.$$

It is connected, commutative, separable, of dimension $6 + 2\sqrt{3}$, and has trivial twist. Using the same positive balancing convention on right B-modules,

$$\mathrm{Rep}(U)_B \simeq \mathcal{C}, \qquad \mathrm{Rep}(U)_B^0 \simeq \mathrm{Vec}\,.$$

Its vertex extension is the holomorphic algebra $L_{\widehat{\mathfrak{e}_8}}(1,0)$.

Proof. Adjunction identifies the multiplicity of Z in $I(1)$ with the multiplicity of 1 in $F(Z)$. The table gives the displayed sum. The adjoint of the central forgetful functor carries its canonical connected commutative separable algebra, with the multiplication just defined. The canonical-algebra theorem recovers $\mathcal{C}$ as its module category.

Commutativity for a braiding also implies commutativity for its reverse. The canonical module tensor uses $c_{N,B}^{-1}$ in the central category. Since that category is $\mathrm{Rep}(U)^{\mathrm{rev}}$, this is the positive crossing $c_{B,N}$ of U-modules. The identity $\dim(B)^2 = \mathrm{Dim}\,\mathrm{Rep}(U)$ makes the local module category trivial. All three summands of B have integral weight.

The vertex extension theorem constructs a simple CFT-type algebra $\mathbb{V}_B$ with multiplication μ_B. Its restriction to T is $\widetilde{I}(1)$. It has a one-dimensional weight-zero space. The other two U-summands begin in weight one.

Apply Creutzig–Kanade–McRae's gluing theorem, Theorem 5.12 and Corollary 5.13, with S as the first factor. Its distinct simple modules pair with the V-modules $\mathrm{Res}\,W_a$, and

$$\dim \mathrm{Hom}_V(V, \mathrm{Res}\,W_a) = \delta_{a0}.$$

It proves strong rationality of this extension.

Every irreducible extension module is grading-restricted. Its restriction to the regular algebra T has finite multiplicities, since each conformal-weight space is finite. The local-module equivalence therefore places it in $\mathrm{Rep}(U)_B^0 = \mathrm{Vec}$. Thus the vacuum is the only irreducible module.

The central charge is eight, so Dong–Mason's classification, Theorem 1, identifies it with $L_{\widehat{\mathfrak{e}_8}}(1,0)$. This constructs the embedding from μ_B. It requires no uniqueness assertion about another embedding into the same holomorphic algebra. □

The other simple right B-modules are determined by the same adjunction:

$$\begin{aligned} I(g) &= x_{10} \oplus x_4 \oplus y_3, \\ I(\rho) &= x_2 \oplus x_4 \oplus x_6 \oplus x_8 \oplus y_1 \oplus y_3 \oplus z_+ \oplus z_-. \end{aligned}$$

Their complete restrictions are

$$\begin{aligned} I(1)|_T &= (H_0 \oplus H_6)S_0 + (H_4 \oplus H_{10})S_v + (H_3 \oplus H_7)S_s, \\ I(g)|_T &= (H_4 \oplus H_{10})S_0 + (H_0 \oplus H_6)S_v + (H_3 \oplus H_7)S_s, \\ I(\rho)|_T &= (H_2 \oplus H_4 \oplus H_6 \oplus H_8)(S_0 \oplus S_v) \\ &\qquad + (H_1 \oplus H_3 \oplus 2H_5 \oplus H_7 \oplus H_9)S_s. \end{aligned}$$

These are full module identities, including descendants. Their S_0-multiplicity spaces are the original three affine sectors. Only $I(1)$ is local. The other two are ordered boundary sectors, rather than ordinary modules of the holomorphic extension.

The extension also realizes fields with full U-module inputs. For $K_M = I(M)$, the projection formula is

$$\kappa_{Z,M} : Z \boxtimes K_M \xrightarrow{\sim} I(F(Z) \otimes_A M).$$

It is adjoint to $1 \otimes \epsilon_M$. Rigidity and adjunction identify, for every Q,

$$\begin{aligned} \mathrm{Hom}(Q, Z \boxtimes I(M)) &\simeq \mathrm{Hom}_C(F(Z)^* \otimes_A F(Q), M) \\ &\simeq \mathrm{Hom}(Q, I(F(Z) \otimes_A M)). \end{aligned}$$

Hence $\kappa_{Z,M}$ is an isomorphism. The counit construction makes it B-linear and compatible with iterated tensor products.

For a junction $p : F(Z) \otimes_A M \to N$, the field is

$$\mathcal{J}_p = \mathcal{Y}_{I(p)\kappa_{Z,M}} : Z \otimes K_M \longrightarrow \overline{K_N}\{u\}.$$

The bar completes the output by conformal weight. The braces allow the prescribed fractional powers. The vertex tensor correspondence gives all descendant coefficients, associativity, and the central crossing. At $Z = U$ this is the ordinary module field Y_{K_M}. It can have singular products.

The mirror states cannot be removed by an operation-preserving vacuum projection. Already on $V \otimes S$, let $P = 1_V \otimes \epsilon_S$ project to the mirror vacuum. For normalized mirror currents a, b,

$$P(a_{(1)}b) = 1_V, \qquad P(a)_{(1)}P(b) = 0.$$

The extension has weight-one dimension $3 + 55 + 7 + 5 \cdot 11 + 4 \cdot 32 = 248$. The mirror currents alone contribute 55 states. The multiplicity-space identification does not delete their vertex operations.

The pointed field action and its obstruction

For a vertex algebra Q, define

$$Z_{\mathrm{vert}}(Q) = \{q : q_{(n)}v = 0 \text{ for every } v \in Q,\ n \geq 0\}.$$

A pointed action of Q on W means a unital vertex map $Q \otimes W \to W$ restricting to the identity on $1_Q \otimes W$. It need not preserve a conformal vector.

PROPOSITION 20.19.3 *(The current double-pole obstruction).* Pointed vertex maps $Q \otimes W \to W$ are in bijection with vertex maps $Q \to \mathbb{C}1$. In particular, there is no pointed map $U \otimes W \to W$. The derived pointed mapping space

$$\mathrm{Map}_{C_W/}(C_U \otimes^! C_W, C_W)$$

is empty.

Proof. If w is central, skewsymmetry makes $Y(v,z)w$ regular. Taking $v = \omega_W$ gives $L_0 w = 0$. Since W is of CFT type, $Z_{\mathrm{vert}}(W) = \mathbb{C}1$.

The image of $q \otimes 1$ under a pointed map must commute with $1 \otimes W$ in every nonnegative product. It therefore lies in this center. Conversely, a vertex map $\varphi : Q \to \mathbb{C}1$ defines the pointed action $q \otimes w \mapsto \varphi(q)_{(-1)}w$. These constructions are inverse.

Take standard currents e, f in $L_{\widehat{\mathfrak{sl}}_2}(10, 0) \subset U$, with $(e, f) = 1$. They satisfy

$$e_{(1)}f = 10\, 1_U.$$

All nonnegative products of scalar vacuum states vanish. A unital map $U \to \mathbb{C}1$ would send this identity to $10 = 0$, which is impossible.

The affine vertex algebras give flat chiral algebras. The heart theorem identifies their pointed factorization mapping space with the discrete space of chiral maps from U to the chiral center of W. The same current relation excludes such a map locally. Thus no higher coherence supplies a missing point. Replacing the entire pointed diagram by equivalent objects preserves this empty mapping space. □

A regular action of a commutative vertex algebra on all three boundary sectors, compatible with their ordered junctions, is consequently scalar. Its restriction to W is a map of commutative differential algebras $\varphi : R^{\ell} \to \mathcal{O}_X$. Inserting the vacuum in the junction $W \otimes_A M \to M$ forces the action on every M to be $r \otimes m \mapsto \varphi(r)m$. If it commutes with translations, φ comes from a vertex map $R \to \mathbb{C}$.

The categorical central action remains valid. It takes a central sector to a tensor functor on boundary objects, often changing the object. Its universal property does not give a pointed field map on the fixed vacuum W. The ordinary transverse endomorphism monoid of C_W also exists by the earlier construction. The extra factorization and pointing conditions determine the obstruction just proved.

Derived current classes

Scalar regular actions do not exhaust derived central cohomology. Let $A_W = \Omega_{\mathrm{cut}} C(W)$ be the word cobar of the ordered residue coalgebra. Its scalar word center uses product totalization in word size and Hochschild length, with algebraic input state spaces.

Proposition 20.19.4 *(Polynomial current derivations).* The scalar word center satisfies

$$H^{i<0} Z_{\mathrm{word}}(A_W) = 0, \qquad H^0 Z_{\mathrm{word}}(A_W) = \mathbb{C}.$$

There is a natural injection of Lie algebras

$$\mathfrak{so}_5[z] \hookrightarrow H^1 Z_{\mathrm{word}}(A_W), \qquad x \otimes f \longmapsto \delta_{x,f}(z) = \sum_{n \geq 0} \frac{f^{(n)}(z)}{n!} x_{(n)}.$$

On a current state a,

$$\delta_{x,f}(a) = f(z)[x, a] + f'(z)(x, a)\mathbf{1}.$$

The invariant form gives long roots squared length two. Constant conformal-weight-preserving vertex derivations form the ten-dimensional subspace of constant currents.

Proof. The negative and degree-zero assertions are the general word-center calculation above. The translation relation gives

$$\partial_z \delta_{x,f} + [T, \delta_{x,f}] = 0.$$

The current commutator formula and Taylor expansion give

$$[\delta_{x,f}(z), Y(a, u)] = Y(\delta_{x,f}(z + u)a, u).$$

These are precisely the chiral derivation equations. Summing the operator over state blocks commutes with all mergers, cuts, and normal derivatives. The all-word derivation identification therefore gives the class, with no inner-derivation quotient.

The affine relation at level one gives its value on a. If a polynomial combination vanishes, its weight-one part commutes with every element of $\mathfrak{so}_5$. The Lie center of $\mathfrak{so}_5[z]$ is zero, proving injectivity. For nonnegative modes the central term of their commutator vanishes. The derivative Leibniz rule yields

$$[\partial_{x,f}, \partial_{y,g}] = \partial_{[x,y],fg}.$$

A constant weight-preserving derivation restricts to a derivation of the simple Lie algebra W_1. It is inner there and extends uniquely, because the currents generate W. Thus it is $a_{(0)}$ for a unique $a \in \mathfrak{so}_5$. □

The same construction with $\mathfrak{sl}_2[z]$ acts on every affine boundary summand H_j. For a junction intertwiner $\mathcal{Y}_p$, its Jacobi identity reads

$$\partial^N_{x,f}(z)\mathcal{Y}_p(m,u) - \mathcal{Y}_p(m,u)\partial^M_{x,f}(z) = \mathcal{Y}_p(\partial^{F(Z)}_{x,f}(z+u)m, u).$$

The balancing maps are affine module maps, so these identities respect their composites and central crossing. On the level-ten currents the scalar term is $10f'(z)(x,a)\mathbf{1}$. It retains the level in the field operations. It does not prove that these classes survive a different endomorphism complex for the full marked transverse center.

The remaining comparison must retain the root, full collision atlas, and distinguished algebra $I(1)$ with its multiplication. It also requires a passage to rational boundary sectors. The center equivalence supplies the categorical action and its intertwiners. The double-pole calculation excludes replacing this passage by a pointed action of C_U on the original vacuum.

20.20 Representation tensors from specified fields

A field exchange becomes a representation intertwiner only after the tensor action has been specified. Central contractions give a model in which both the positive construction and the possible mismatch can be computed on all modes.

Let $P = k[x_0, x_1, \dots]$, with $Tx_i = x_{i+1}$ and $\mathrm{wt}(x_i) = i + 1$. Introduce a formal parameter $\hbar$ and a central state κ with $T\kappa = d\kappa = 0$. For a Laurent kernel $K(z)$, prescribe

$$Y_K(x_0, z)x_0 = (e^{zT}x_0)x_0 + \hbar\kappa K(z).$$

The simple pole $K = z^{-1}$ is nonlocal. The symmetric double pole $K = z^{-2}$ gives the usual central local current bracket.

We retain a resolution of this polynomial algebra. Let $A_{\mathrm{ext}} = \Lambda(\theta_i : i \geq 0)$, where $|\theta_i| = 1$ and $\mathrm{wt}(\theta_i) = i + 1$. The weight-restricted dual

$$E = (B_{\mathrm{alg}} A_{\mathrm{ext}})^\circ$$

is freely associative on y_I for nonempty increasing finite subsets I of $\mathbb{N}$. Its differential is

$$|y_I| = 1 - |I|, \qquad dy_I = \sum_{I = A \sqcup B} (-1)^{|A|+1} \epsilon(A,B)\, y_A y_B.$$

The sum uses ordered nonempty parts, and $\epsilon(A,B)$ is their exterior permutation sign. Thus $x_i = y_{\{i\}}$ and $dy_{ij} = x_i x_j - x_j x_i$.

Lemma 20.20.1 *(The finite-weight resolution).* Sending singleton generators to x_i and higher generators to zero gives a quasi-isomorphism $\pi : E \to P$. It uses a direct sum of finite weight duals.

Proof. Let $\mathrm{Sym}^c(\bigoplus_i k t_i)$ have primitive degree-zero generators of weights $i+1$. The map to the bar is

$$j(t_{i_1}\cdots t_{i_r}) = \sum_{\sigma\in S_r} [s\theta_{i_{\sigma(1)}}|\cdots|s\theta_{i_{\sigma(r)}}].$$

Adjacent interior products cancel in pairs, since the θ_i are odd. Deconcatenation matches the unshuffle coproduct, including repeated-index multiplicities.

The free A_{ext}-module complex $A_{\mathrm{ext}}\otimes k[t_i]$, with $dt_i = \theta_i$, resolves k. Its contraction on positive total generator degree N is $N^{-1}\sum_i t_i\partial_{\theta_i}$. The normalized bar is another semifree resolution. The map $1\otimes j$ intertwines their differentials, including the endpoint term $\sum_i \theta_i\partial_{t_i}$, and lifts the identity on k. Lifting through the free filtrations gives a homotopy inverse, weight by weight.

Every weight is finite-dimensional. Dualize there with $\langle x^\alpha, t^\beta\rangle = \alpha!\delta_{\alpha\beta}$, which converts the unshuffle coproduct into polynomial multiplication. The dual is π. Taking the direct sum of the weight comparisons proves the assertion. □

Extend translation to E by raising each index of y_I in turn, with a repeated index giving zero and exterior reordering carrying its sign. Let $\partial_m(y_I) = 1$ for $I = \{m\}$ and zero otherwise. These graded derivations satisfy

$$[d,T] = [d,\partial_m] = 0, \qquad [T,\partial_m] = -\partial_{m-1}, \qquad [\partial_m,\partial_n] = 0, \qquad \partial_{-1} = 0.$$

On the bar, the transposed operators lower an exterior index and insert $s\theta_m$ in every gap. Those operations commute with its differential, proving the identities. The map π intertwines them.

Put

$$K_{mn}(z) = \partial_z^m(-\partial_z)^n K(z), \qquad C_K(z) = \hbar\kappa \sum_{m,n\ge 0} K_{mn}(z)\partial_m\otimes\partial_n.$$

With the ordered coefficient multiplication μ_E, define

$$Y_K(a,z)b = \mu_E(e^{zT}\otimes 1)e^{C_K(z)}(a\otimes b).$$

Every contraction lowers polynomial degree in both inputs, so the exponential is finite on polynomial states. The same formula with μ_P defines the polynomial fields.

All parenthesized ordered products expand the common expression

$$\mu_r\left(\bigotimes_i e^{z_i T}\right)\exp\left(\sum_{i<j} C_K^{ij}(z_i - z_j)\right).$$

The pair contractions commute, and their derivation rule gives the product and iterate identities. Thus both carriers are differential nonlocal vertex algebras, and π preserves every field mode. The completion is $(E\otimes k[\kappa])[[\hbar]]$: each parameter coefficient has finite polynomial and energy support. There is no unrestricted energy product.

For inputs of energies a, b, a term with q contractions and a kernel of pole order p has pole order at most $a + b + (p-2)q$. Modulo $\hbar^N$, also $q \le \min(a, b, N-1)$. This proves the required Laurent bounds at each precision.

The regular action is faithful, since $Y_E(a,z)1 = e^{zT}a$ has constant term a. Its operator-field multiplication uses regularized substitution $w_1 = w + u$ after multiplying by a sufficient power of $w_1 - w$. The common Wick expression proves

$$\mathcal{Y}(Y_E(a,w),u)Y_E(b,w) = Y_E(Y_E(a,u)b,w).$$

This retains the full substitution, not only a principal part.

The universal level and additive module tensor

The coproduct is over $k[[\hbar]]$, with κ a state:

$$\Delta\kappa = \kappa\otimes 1 + 1\otimes\kappa, \qquad \Delta y_I = y_I\otimes 1 + 1\otimes y_I.$$

Its target has independent level states κ_L, κ_R. The counit kills them and all y_I.

PROPOSITION 20.20.2 *(The universal vertex bialgebra).* These formulas make $(E\otimes k[\kappa])[[\hbar]]$ a counital differential nonlocal vertex bialgebra. The map π is a coalgebra map and an all-mode field quasi-isomorphism. The induced module tensor adds levels.

Proof. Each dy_I is a sum of graded commutators of primitive generators, so Δ is a chain map. Coassociativity and the coefficient counit hold on generators. For each m,

$$(\partial_m\otimes 1)\Delta = \Delta\partial_m = (1\otimes\partial_m)\Delta.$$

Each outer derivative separately gives this identity. Their sum would double it.

The target contractions therefore contribute $\hbar(\kappa_L+\kappa_R)K_{mn}$, exactly the image of the source contraction. Exponentiation proves

$$\Delta Y_K = (Y_K\otimes Y_K)(1\otimes\tau\otimes 1)(\Delta\otimes\Delta).$$

Every contracted term contains κ, so the counit kills it. The uncontracted term is its ordinary augmentation. Equivariance of π proves the remaining claims. □

A nonzero fixed-level ideal $(\kappa - c)$ is not a coideal: its image is $\kappa_L + \kappa_R - c$, while setting both target levels to c gives c. This does not prevent maps from level $c_1 + c_2$ to the tensor of levels c_1, c_2.

An admissible module here is topologically free, $M = M_0[[\hbar]]$, with continuous fields lower truncated on each input modulo every $\hbar^N$. For two such modules define $M\widehat{\boxtimes}N = (M_0\otimes_k N_0)[[\hbar]]$ and

$$Y_{M\widehat{\boxtimes}N}(a,z)(m\otimes n) = \sum_{(a)}(-1)^{|a_{(2)}||m|}Y_M(a_{(1)},z)m\otimes Y_N(a_{(2)},z)n.$$

At each precision only finitely many coproduct terms occur, and two lower-bounded Laurent series have finite coefficient convolution. The bialgebra identity proves module associativity. Coassociativity proves the pentagon.

A derived version uses K-flat models and the specified completed derived tensor. This is an additive-level module tensor, with its stated carrier.

Normal-ordering transport

Let $H(z) \in k[[z]]$ be even and put

$$H_{mn} = (-1)^n H^{(m+n)}(0), \qquad D_H = \frac{1}{2}\sum_{m,n} H_{mn}\partial_m\partial_n, \qquad W_H = e^{\hbar\kappa D_H}.$$

The matrix is symmetric and $H_{m+1,n} + H_{m,n+1} = 0$.

Proposition 20.20.3 *(Fields, tensors, and formal states).* The map W_H is invertible, preserves the vacuum, differential, and translation, and satisfies

$$\begin{aligned} W_H Y_K(a,z)b &= Y_{K+H}(W_H a, z) W_H b, \\ \Delta W_H &= (W_H \otimes W_H)\Delta, \qquad \pi W_H = W_H \pi, \\ W_{H_2} W_{H_1} &= W_{H_1+H_2}, \qquad W_H^{-1} = W_{-H}. \end{aligned}$$

Define a coefficient-valued functional independently by zero odd moments and

$$\lambda_H(x_{i_1}\cdots x_{i_{2r}}) = (-\hbar\kappa)^r \sum_{\text{pairings}} \prod_{\{a,b\}} H_{i_a i_b}, \qquad \lambda_H(1) = 1.$$

Then $\lambda_H = \lambda_0 W_H^{-1}$, where λ_0 sets currents to zero while retaining κ.

Proof. All contractions commute with d. The recurrence for H_{mn} makes $[T, D_H] = 0$. The second-order Leibniz rule gives

$$D_H \mu_E = \mu_E\left(D_H \otimes 1 + 1 \otimes D_H + \sum_{m,n} H_{mn}\partial_m \otimes \partial_n\right).$$

Exponentiate and move the cross term past e^{zT}. Its Taylor series is $K_{mn}(z) + \partial_z^m(-\partial_z)^n H(z)$, proving the field identity.

For the coproduct, each outer D_H equals ΔD_H after Δ. The source level splits as $\kappa_L + \kappa_R$, giving precisely the two target normal-ordering operators. Their commutation proves the composition and inverse formulas.

Finally, the constant term of $D_H^r/r!$ counts complete pairings. The factor $1/2$ removes their two orientations and $r!$ removes their order. This proves the stated moment formula, including repeated indices. □

The formal state has a separate bar realization. Let I_m insert $s\theta_m$ into every bar gap. Adjacent exterior products cancel, so I_m commutes with the bar differential. Insertion operators commute. The vector

$$\nu_H = \exp\left(-\frac{\hbar\kappa}{2}\sum_{m,n} H_{mn} I_m I_n\right)1$$

lies in the product over output weights, with a finite formula at each weight and parameter order.

Its pairing against weight-restricted dual observables is a continuous chain functional. The identity $I_m j(f) = j(t_m f)$ and the factorial pairing give $\langle -, \nu_H\rangle = \lambda_H \pi$. Thus this comparison follows from two specified constructions of the state.

These functionals are formal and coefficient-valued. They retain κ and detect contractions, unlike the bialgebra counit. For example,

$$\lambda_H(x_0^2) = -\hbar\kappa H(0), \qquad \lambda_H(Y_{K+H}(x_0, z)x_0) = \hbar\kappa K(z).$$

The second identity cancels the new regular contraction.

On a curve chart, a regular symmetric kernel $H(z, w)$ has diagonal jets $H_{mn}(s)$ satisfying $\partial_s H_{mn} = H_{m+1,n} + H_{m,n+1}$. Hence $[\partial_s + T, D_H(s)] = 0$. For supplied kernels whose differences are $H_{\alpha\beta}$, the identity

$$W_{H_{\beta\gamma}} W_{H_{\alpha\beta}} = W_{H_{\alpha\gamma}}$$

gives horizontal gluing of fields and comparisons. It assumes the kernels and their coordinate identifications. A projective connection alone does not supply a global bidifferential or state. A regular symmetric change leaves the exchange-antisymmetric part of the kernel unchanged.

Changing the tensor action

At unit level and $K(z) = z^{-1}$, the polynomial state-exchange operator is

$$\mathcal{S}(z) = \exp\left(-2\hbar \sum_{m,n} K_{mn}(z)\, \partial_m \otimes \partial_n\right).$$

The additive current acts by $J_{-1}^{\mathrm{tot}} = M_{x_0} \otimes 1 + 1 \otimes M_{x_0}$. They do not commute:

$$[\mathcal{S}(z), J_{-1}^{\mathrm{tot}}](x_0 \otimes 1) = -\frac{2\hbar}{z}\, 1 \otimes 1.$$

The ordinary flip does intertwine the cocommutative additive action. Thus field exchange and the displayed module tensor have different intertwiners.

A change of action gives a positive comparison. Decorate each admissible module by commuting even chain operators D_m lowering an exhaustive nonnegative energy filtration by $m + 1$. Each algebraic state has bounded energy. Morphisms preserve these operators and the field action.

For a finite set of spectral slots I, set

$$R_I = k[z_i : i \in I][(z_i - z_j)^{-1} : i \neq j], \qquad M_I = (R_I \otimes_k \bigotimes_i M_{i,0})[[\hbar]].$$

The field variable w is independent of the z_i. For an order σ define

$$C_{ij} = \hbar \sum_{m,n} K_{mn}(z_i - z_j) D_m^{(i)} D_n^{(j)}, \qquad F_\sigma = \exp\left(\sum_{i \prec_\sigma j} C_{ij}\right), \qquad \rho_\sigma(a, w) = F_\sigma \rho_0(a, w) F_\sigma^{-1}.$$

The coefficient $\hbar$ is specified tensor data. It is not forced by an arbitrary coproduct.

A term with q contractions consumes at least $\sum(m + n + 2)$ units of energy and has pole order $\sum(m + n + 1)$. Its pole order is at most $\sum_i a_i - q$ on inputs of energies a_i. Also $q < N$ modulo $\hbar^N$. These bounds make $F_\sigma^{\pm 1}$ continuous on the stated carrier and preserve each lower Laurent bound in w.

THEOREM 20.20.4 *(Coherent tensor transport on separated slots).* For ordered blocks B, D, the maps $F_{B,D} = \exp(\sum_{i \in B, j \in D} C_{ij})$ give a monoidal equivalence between the original decorated tensor actions and ρ_σ. If $P_{\tau\sigma}$ is the graded permutation of carriers, then

$$c_{\tau\sigma} = F_\tau P_{\tau\sigma} F_\sigma^{-1}$$

intertwines every field mode and satisfies all block hexagons and braid identities. On two slots it is

$$c^{F}_{M,N}(z) = \tau \exp\left(-2\hbar \sum_{m,n} K_{mn}(z) D_m \otimes D_n\right).$$

Proof. All pair contractions commute, including those sharing a slot. For three blocks, both parenthesizations give

$$\exp(C_{B,D} + C_{B,H} + C_{D,H}).$$

Every higher parenthesization counts each pair once. This proves the pentagon. Empty pair sets give the unit.

The original permutation intertwines ρ_0. Conjugating this identity proves the new intertwining relation on every mode. Consecutive order changes telescope, while splitting blocks partitions the same pair set. These facts prove the braid and hexagon identities. Finally $K_{nm}(-z) = -K_{mn}(z)$ gives the two-slot formula. The energy and parameter bounds justify every exponential. □

This transported category is monoidally equivalent to the original symmetric category. Its nonidentity formula does not by itself construct an inequivalent representation category.

For two regular polynomial factors put $M = M_{x_0^{(1)} + x_0^{(2)}}$ and $C = C_{12}$. Then

$$[C, M] = \hbar A(z), \qquad [C, A(z)] = 0,$$

where $A(z) = \sum_m K_{m0}(z) D_m^{(1)} + \sum_n K_{0n}(z) D_n^{(2)}$. The transported creation modes are

$$J^{\pm}_{-1} = M \pm \hbar A(z), \qquad e^{-2C} J^{+}_{-1} = J^{-}_{-1} e^{-2C}.$$

On polynomials in the two lowest generators this reads $x + y \pm \hbar z^{-1}(\partial_x + \partial_y)$.

For the full current,

$$J^{\pm}(w) = J^{0}(w) \pm \hbar \sum_{n \geq 0} \big(K_{n0}(z - w) D_n^{(1)} + K_{0n}(z + w) D_n^{(2)}\big),$$

expanded in nonnegative powers of w. The first commutator gives the correction and the second vanishes. The fields of the higher y_I are unchanged: the decorations kill those generators and their translates. The negative-degree resolution cells are retained.

Equivariance of π gives a quasi-isomorphism $\Pi_I = \pi^{\widehat{\otimes} I}$ intertwining all transported fields, tensorators, and exchanges. The finite-weight contraction extends coefficientwise to the parameter completion.

There are compatible formal states as well. Define λ_σ by complete matchings between distinct slots, assigning $-\hbar K_{mn}(z_i - z_j)$ to a paired occurrence $x_m^{(i)}, x_n^{(j)}$ with $i \prec_\sigma j$. The bar-side definition uses

$$\nu_\sigma = \exp\left(-\hbar \sum_{i \prec_\sigma j} \sum_{m,n} K_{mn}(z_i - z_j) I_m^{(i)} I_n^{(j)}\right) 1^{\otimes I}.$$

The pairing-count argument proves

$$\lambda_\sigma = \lambda_0^{\otimes I} F_\sigma^{-1}, \qquad \lambda_\sigma^{E} = \lambda_\sigma \Pi_I, \qquad \lambda_\tau c_{\tau\sigma} = \lambda_\sigma.$$

For four lowest currents,

$$\lambda_{1234}(x_0^{\otimes 4}) = \hbar^2 \left(\frac{1}{z_{12} z_{34}} + \frac{1}{z_{13} z_{24}} + \frac{1}{z_{14} z_{23}}\right).$$

At $(1,3,7,13)$ it is $29\hbar^2/240$. These are normalized formal functionals on the separated tensor spaces, with no positivity assertion.

On the actual order-chart overlap, in one fixed tensor order,

$$G_{\tau\sigma} = F_\tau F_\sigma^{-1}.$$

Only pairs whose orders differ occur in its exponent. Their differences are precisely the ones inverted on that overlap. On regular E, P coefficients the connection is $\nabla_i = \partial_{z_i} + T_i$. The kernel recurrence gives $[T_i, C_{ij}] = -\partial_{z_i} C_{ij}$, so $G_{\tau\sigma}$ is horizontal. Cancellation gives its cocycle identity.

These maps glue differential modules, but they do not supply the unchanged tensor-power collision equivalence. Modulo $\hbar$, diagonal restriction of the free two-point module leaves $P \otimes P$. Its energy-one piece has dimension two, whereas that of P has dimension one. The normal Koszul complex adds no differential that changes these ranks. Thus an energy-preserving collision equivalence with singleton P is impossible on this carrier. Additional collision relations or coefficients are needed.

An actual spectral symmetry Hopf algebra

Let $\mathfrak{t}$ have generators T, p_m, $m \geq 0$, with

$$[p_m, p_n] = 0, \qquad [T, p_m] = -p_{m-1}, \qquad p_{-1} = 0.$$

Give $\mathscr{H} = U(\mathfrak{t})[[\hbar]]$ the primitive coproduct. On modules with T raising energy and p_m lowering it by $m+1$, define

$$\mathcal{R}(z) = \exp\left(-2\hbar \sum_{m,n} K_{mn}(z)\, p_m \otimes p_n\right).$$

This is an operator in the completion defined by these modules. It need not be a finite tensor in $\mathscr{H}^{\otimes 2}$.

The exponent commutes with each Δp_m. Its two commutators with T are opposite z-derivatives, so it also commutes with ΔT. Therefore $\tau\mathcal{R}(z)$ is a module intertwiner. Applying the primitive coproduct splits its exponent, proving both hexagons. The pair exponents commute, giving Yang–Baxter at arguments u, $u+v$, v and

$$\mathcal{R}^{21}(-z)\mathcal{R}(z) = 1.$$

For E, P, take $p_m = \partial_m$. The field has shifted equivariance

$$hY_E(a,z)b = \sum Y_E\big((e^{-z\,\mathrm{ad}\,T} h_{(1)})a, z\big) h_{(2)} b.$$

This follows by moving $h_{(1)}$ through e^{zT}. The shifted coproduct commutes with the contractions. It identifies the symmetry acting in this model. The earlier creation-mode defect prevents identifying that symmetry with an arbitrary vertex-module tensor action.

Noncommuting contractions and the singlet order

Permutation operators give a precise limit of the commuting-contraction argument. On $(k^2)^{\otimes 3}$, scalar normalization of $e^{\hbar P/u}$ gives $1 + f(u)P$ with $f(u) = \tanh(\hbar/u)$. Direct multiplication yields

$$\begin{aligned}
&(1 + aP_{12})(1 + bP_{13})(1 + cP_{23}) \\
&\quad - (1 + cP_{23})(1 + bP_{13})(1 + aP_{12}) \\
&= (ac - b(a+c))(P_{12}P_{23} - P_{23}P_{12}).
\end{aligned}$$

For $a = f(u)$, $b = f(u+v)$, $c = f(v)$, the first scalar defect is

$$-\frac{\hbar^4(u^2+uv+v^2)}{3u^2v^2(u+v)^2} + O(\hbar^6).$$

The commutator matrix has rank four. At $u = v = 1$ its order-four coefficient is $-1/4$. A scalar prefactor multiplies both Yang–Baxter sides by the same factor and cannot remove this defect.

By contrast, $f(u) = \hbar/u$ satisfies $ac = b(a+c)$. Hence

$$R_{\mathrm{rat}}(u) = \frac{u\,1 + \hbar P}{u+\hbar}$$

satisfies Yang–Baxter and $R^{21}_{\mathrm{rat}}(-u)R_{\mathrm{rat}}(u) = 1$. The integral RTT Hopf algebra and the specified Bethe-algebra representation of Section 18.33 retain this positive algebraic domain. Neither existence nor nonexistence of an arithmetic realization follows from the absence of a subtraction operation between local fields.

Likewise, the quadratic Hecke relation $(\check R - q)(\check R + q^{-1}) = 0$ gives

$$\check R - \check R^{-1} = (q - q^{-1})1.$$

For $C(z) = z\check R - z^{-1}\check R^{-1}$ it implies

$$C(z^{-1})C(z) = (q^2 + q^{-2} - z^2 - z^{-2})1.$$

This calculation remains valid at repeated roots. Yang–Baxter additionally requires a Hecke braid representation. The involution $\mathrm{diag}(1,1,1,-1)$ at $q = 1$ satisfies the quadratic relation and fails the adjacent braid relation.

For the singlet, let

$$j(v) = (e_0 \otimes e_1 - e_1 \otimes e_0) \otimes v, \qquad \pi = \tfrac{1}{2} j^{\mathrm{t}}, \qquad R(u) = 1 + \hbar P/u.$$

Then

$$R_{23}(u+\hbar)R_{13}(u)\,j = \frac{u+2\hbar}{u+\hbar}\,j, \qquad \pi R_{13}(u)R_{23}(u+\hbar) = \frac{u+2\hbar}{u+\hbar}\,\pi.$$

Indeed, for $A = P_{13}$, $B = P_{23}$, $(A+B)\,j = j$ and $BAj = -Aj$. With $a = \hbar/u$, $b = \hbar/(u+\hbar)$, the unwanted coefficient is $a - b - ab = 0$. In the reverse order it is $a - b + ab \neq 0$.

The normalization preserving this cup and cap therefore obeys

$$f(u)f(u+\hbar) = \frac{u+\hbar}{u+2\hbar}.$$

It has a unique solution with constant term one at infinity: each coefficient is twice the new unknown plus earlier terms. Writing $t = \hbar/u$ gives

$$F(t) = 1 - \tfrac{1}{2}t + \tfrac{5}{8}t^2 - \tfrac{11}{16}t^3 + \cdots, \qquad F(t)F(-t) = \frac{1}{1-t^2}.$$

For the last identity, put $G(t) = F(t)F(-t)$. The shift equation implies $G(t)G(t/(1+t)) = (1+t)/((1-t)(1+2t))$. Both G and $(1-t^2)^{-1}$ solve it with constant term one. The same triangular uniqueness proves equality. Thus the normalized exchange is formally unitary.

For fixed $\hbar \neq 0$, there is no rational solution. If d_n is its order at $-2\hbar + n\hbar$, the equation requires $d_n + d_{n+1}$ to be -1 at $n = 0, 1$ at $n = 1$, and zero elsewhere. Finite support forces its largest nonzero index into $\{0,1\}$ and its smallest into $\{1,2\}$. Only d_1 could remain, but it would have to equal both -1 and 1. Meromorphic normalizations require separate analytic choices. The algebraic cup calculation also leaves the comparison with a chosen Yangian evaluation-module duality to its specified coproduct and parameter conventions.

20.21 HALF-BRAIDINGS AND THEIR PROBES

The objects against which a half-braiding is tested are part of its definition. For geometric words, the allowed maps of the labeled base matter as well.

Let X be smooth and separated of finite type, with arbitrarily many distinct closed k-points. Use word objects with monotone collision equivalences, the prefix/suffix cut tensor, and its isolated empty unit. Require comparison maps over the fixed labeled base. For a point x, let P_x have zero empty coefficient and positive coefficient $(x, \dots, x)_* k$.

PROPOSITION 20.21.1 *(The absolute point probes).* If $F \star P_x \simeq P_x \star F$ for every closed point x, then every positive coefficient of F vanishes.

Proof. Choose the least positive n with $F_n \neq 0$. In arity $n+1$, restrict to $(X \setminus \{x\})^n \times \{x\}$. On the left, the cut after n contributes $F_n|_{(X\setminus\{x\})^n}$. All smaller positive cuts vanish by minimality. The empty term has constant support and also vanishes.

On the right the remaining positive cut requires the first coordinate to be x, so it vanishes too. Thus F_n restricts to zero on each $(X \setminus \{x\})^n$.

Choose $n+1$ distinct points. Every n-tuple omits at least one, so these opens form a finite cover of X^n. Descent gives $F_n = 0$, a contradiction. □

This result uses the cut tensor, all point probes, and the fixed labeled base. It does not apply to the symmetric convolution using all ordered decompositions.

Restricting to one point gives a positive alternative. Objects supported at the constant tuple x correspond to pairs of complexes (V_0, V_1), because the positive collision diagram has terminal singleton. Their tensor is

$$(V_0, V_1) \star (W_0, W_1) = (V_0 \otimes W_0,\ V_0 \otimes W_1 \oplus V_1 \otimes W_0).$$

Two positive factors give zero on the cut-disjoint open. Every nonzero iterated term therefore has at most one positive factor. The Koszul flip on these terms supplies a symmetry and all its coherences. Nonzero positive objects have half-braidings in this relative probe category.

Charge categories and excess central objects

Even a braided category can have central objects outside its canonical central image. For finite-dimensional $\mathbb{Z}$-graded vector spaces, choose any bicharacter braiding. On the unit, the scalars T^n on charge n define a half-braiding for every $T \in \mathbb{C}^\times$. Its hexagon is $T^{n+m} = T^n T^m$. The canonical central image with underlying unit has trivial half-braiding, so the examples with $T \neq 1$ are additional central objects. A fixed-level Heisenberg realization would require its own fusion tensor and monoidal comparison.

There is a finite modular example with all coherences visible. Let $\ell > 0$ be even and $G = \mathbb{Z}/\ell\mathbb{Z}$. For representatives $0 \le a, b < \ell$, define

$$c(a,b) = \left\lfloor \frac{a+b}{\ell} \right\rfloor, \qquad [a+b] = a + b - \ell c(a,b).$$

On finite-dimensional G-graded vector spaces set

$$\omega(a,b,c) = (-1)^{ac(b,c)}, \qquad R(a,b) = e^{\pi i ab/\ell}, \qquad \theta(a) = e^{\pi i a^2/\ell}.$$

The first scalar is the associator from left to right parenthesization, the second multiplies the interchange, and the third is the twist.

Proposition 20.21.2 *(The finite cyclic center).* These data define a modular ribbon category $\mathcal{C}_\ell$. Its simple objects have dimension one. The center has ℓ^2 simples, indexed by $(a, j) \in G^2$, with canonical central image $(a, 0)$. The braided functor

$$\mathcal{C}_\ell \boxtimes \mathcal{C}_\ell^{\mathrm{rev}} \longrightarrow \mathcal{Z}(\mathcal{C}_\ell)$$

is an equivalence and sends (a, b) to $([a + b], -b)$.

Proof. The carry identity

$$c(b, c) + c([b + c], d) = c(c, d) + c(b, [c + d])$$

expresses the quotient and remainder of $b + c + d$. The pentagon exponent discrepancy is $\ell c(a, b)c(c, d)$, which is even. The two hexagons are

$$R(a, [b + c]) = \frac{\omega(b, a, c)}{\omega(a, b, c)\omega(b, c, a)} R(a, b)R(a, c),$$
$$R([a + b], c) = \frac{\omega(a, b, c)\omega(c, a, b)}{\omega(a, c, b)} R(a, c)R(b, c).$$

Symmetry of the carry cancels two factors in each ratio. The remaining sign is exactly the phase from reducing the sum modulo ℓ. Without the associator, the first hexagon already fails at $\ell = 2, a = b = c = 1$.

Balancing follows from

$$\theta([a + b]) = R(a, b)R(b, a)\theta(a)\theta(b).$$

The exponent discrepancy is $\pi i[-2c(a, b)(a + b) + \ell c(a, b)^2]$. Choose dual $[-a]$, evaluation one, and coevaluation $\omega(a, [-a], a)^{-1}$. The carry identities prove both triangles, and $\theta([-a]) = \theta(a)$ gives dual compatibility. The ribbon dimension is

$$\theta(a)R(a, [-a])\omega(a, [-a], a)^{-1} = 1.$$

Double braiding is the Fourier matrix $e^{2\pi i ab/\ell}$, with inverse $\ell^{-1}e^{-2\pi i ab/\ell}$, proving nondegeneracy.

For a central object of degree a, divide its half-braiding with degree b by $R(a, b)$. The hexagon makes the remaining operators a representation of G. It splits into characters $e^{2\pi i jb/\ell}$, giving the stated simple labels. The canonical image has $j = 0$.

Using the original crossing on the first tensor factor and the inverse crossing on the second gives $([a + b], -b)$. The associator factors are those just checked. The mixed double braiding cancels, so this is braided. It is bijective on simples and their scalar Hom spaces, hence is an equivalence of semisimple categories. □

The even-level condition has an integral normalization. With minimum electric charge one and $F/(2\pi)$ representing c_1, the action $\ell(4\pi)^{-1}\int A \wedge dA$ changes under a four-dimensional extension by

$$\exp\left(2\pi i\,\frac{\ell}{2}\int (F/(2\pi))^2\right).$$

Even ℓ makes this one on every oriented extension. The hyperplane line bundle on $\mathbb{CP}^2$ proves necessity. In this bosonic convention the class is $(\ell/2)c_1^2 \in H^4(BU(1); \mathbb{Z})$. The cell structure of $\mathbb{CP}^\infty$ gives $H^*(BU(1); \mathbb{Z}) = \mathbb{Z}[c_1]$ and $H^3 = 0$.

For the marked boundary current with $J(z)J(w) \sim \ell(z - w)^{-2}$, the stress tensor $(2\ell)^{-1} : JJ :$ has double-contraction coefficient $2\ell^2/(4\ell^2) = 1/2$, hence Virasoro central charge one. The current commutator, integral charge lattice, and quadratic form still retain ℓ. An unmarked rescaling does not preserve these data.

20.22 ARITHMETIC CENTERS AND GEOMETRIC COMPARISONS

The arithmetic constructions require the same distinctions. An ordinary center acts by natural endomorphisms. A scalar Hochschild center is a complex with its higher operations. A categorical center is itself a category. An identity trace is a class in a trace recipient. A comparison must specify which of these objects it carries.

For a stable presentable k-linear monoidal category C, with tensor preserving colimits separately, put

$$Z_{\mathrm{cat}}(C) = \mathrm{Fun}^{\mathrm{L}}_{C\otimes C^{\mathrm{op}}}(C, C),$$
$$\mathrm{Tr}_{\mathrm{cat}}(C) = C \otimes_{C\otimes C^{\mathrm{op}}} C.$$

The tensor and functors are in presentable k-linear categories. The first has a braided tensor structure. The second carries a circle action. For an ordinary algebra A, the scalar complexes $R\,\mathrm{Hom}_{A^e}(A, A)$ and $A \otimes^{\mathbf{L}}_{A^e} A$ occur one categorical level lower. They are not identified by their shared name Hochschild.

The precise positive geometric comparisons of Section 18.29 apply here. For a perfect derived stack X,

$$Z_{\mathrm{cat}}(\mathrm{QCoh}(X)) \simeq \mathrm{QCoh}(\mathcal{L}X) \simeq \mathrm{Tr}_{\mathrm{cat}}(\mathrm{QCoh}(X)).$$

For the complex reductive Hecke category $D(B\backslash G/B)$, the center and trace identify with the character category generated by the Harish–Chandra transform. The same holds for its specified unipotently monodromic version. These are the theorems of Ben-Zvi–Francis–Nadler and Ben-Zvi–Nadler on their respective geometric carriers. They do not identify a category with a ring of functions on an unspecified arithmetic parameter space.

Even a smooth affine line has derived loops:

$$O(\mathcal{L}\mathbb{A}^1) = k[x] \otimes^{\mathbf{L}}_{k[x_1,x_2]} k[x] \simeq k[x, \eta], \qquad |\eta| = -1, \quad d = 0.$$

The diagonal Koszul resolution gives this formula. Thus smoothness of X does not make its derived loop space classical.

For finite cyclic loops of $B\mathbb{G}_m$, the complex points instead have μ_n components, each with stabilizer $\mathbb{C}^\times$. A quotient of finite cyclic groups reverses the induced mapping-stack arrow. These constructions do not form formal neighborhoods of the identity by notation alone. An arithmetic loop comparison must specify its source topology and retain the actual Weil and inertia data.

Scalar actions and the full categorical center

Assume characteristic zero, with coefficient prime different from the residue prime. The stated GL_2 Bernstein theorem identifies the ordinary Bernstein center with functions on its continuous Weil parameter stack. Its normalization retains inertia and Frobenius. The fixed-character and coefficient-prime comparisons are different theorems.

For the latter, the ring

$$E_{\mathcal{B}} = \mathrm{End}(P_{\mathcal{B}}) = \mathrm{End}_G(J_{\mathcal{B}})^{\mathrm{op}}$$

of Section 18.7.3 is pseudocompact and finite over its pseudodeformation center. In the generic reducible case its full algebra retains the two opposite extension representations. The center does not replace that algebra.

A scalar action on a spectral category need not exhaust its center. For example, objects of $\mathrm{QCoh}(B\mathbb{G}_m)$ decompose into integer weights. Each sequence $(a_n)_{n\in\mathbb{Z}}$ acts naturally by a_n on weight n. The weight-zero projector is a central operation that is not multiplication by a scalar function on $B\mathbb{G}_m$, whose global

functions are k. In the scalar stabilizer of a GL_2 parameter, a determinant twist changes weight by two. It cannot identify every weight sector or eliminate these projectors.

Similarly, a matrix-algebra description on a generic locus gives a Morita equivalence there, with its center. It does not extend across a singular locus without a compatible functor and its inverse. A regular ring alone does not make extensions vanish at every point: for $A = k[t]$,

$$\operatorname{Ext}^1_A(k,k) = k.$$

Localization to $k(t)$ kills this supported module. The generic and supported categories retain different information.

Gluing central actions

Formal patching supplies a positive ordinary-center calculation with actual overlap maps. For

$$A = k[t], \quad B = k[[t]], \quad C = k[t,t^{-1}], \quad D = k((t)),$$

the equivalence of finitely generated module categories in Theorem 18.28.3 uses triples (P, Q, η) with an isomorphism over D. The ordinary center is

$$Z(\operatorname{mod}_{\mathrm{fg}} A) \simeq B \times_D C = A.$$

Indeed, a natural endomorphism on finitely generated R-modules is multiplication by its value on $1 \in R$. The identity $B \cap C = A$ inside D then gives the formula.

The punctured formal disk is an actual overlap. It is not the empty intersection of a closed point with its complementary open.

Higher centers need more than this scalar equalizer. An equivalence of categories with effective descent transports central operations together with their coherences. An isomorphism of rings of parameters does not supply the categorical descent equivalence. For a derived external product followed by pullback, ordinary formulas also need two Tor-independence conditions, one for each step. Already

$$k \otimes^{\mathbf{L}}_{k[[t]]} k \simeq k \oplus k[1]$$

has an extra term although both factors are perfect. An identity pullback preserves it.

For quasi-smooth characteristic-zero charts, singular support is a cone in

$$\operatorname{Sing}(X) = \operatorname{Spec}_{X^{\mathrm{cl}}} \operatorname{Sym} H^1(T_X).$$

Its linear functions act in Hochschild degree two. It is not an unspecified closed locus in X itself. An arithmetic category with this support therefore needs the derived charts, their coefficient theory, and the compatible cone. The finite-stratum generator argument also needs extension functors preserving compactness and the actual gluing morphisms. The localization and recollement constructions of Chapter 18 retain those extensions.

The restricted tensor theorem of Section 18.30 gives another positive assembly. Its finite-stage insertion maps preserve the specified operadic structures, including units. The filtered colimit transports that structure. Local endofunctors act on cofinal diagrams containing their places and commute through tensor interchange. Neither scalar commutativity nor these separate-place actions creates collision maps or raises an E_1 structure to E_2.

The operad of little intervals has an integral associative comparison. Each ordering component is a nonempty convex region of endpoints. Its chains therefore augment quasi-isomorphically to $R[S_n]$ in every arity. Substitution respects orderings.

Rectification of an algebra along this comparison, when available, does not make the algebra formal. The cubic example of (3) retains its nonzero triple Massey product in a strict associative model. For centers, the chain-level E_2 operations, coefficient base, and comparison maps must likewise be retained. A rational operadic comparison alone supplies no integral replacement or arithmetic geometric action.

20.23 The marked arithmetic comparison

Let C_I be the arithmetic fusion category of Chapter 15, over its specified field F_I. Write

$$U_I : Z(C_I) \longrightarrow C_I, \qquad U_I \dashv R_I, \qquad B_I = R_I(\mathbf{1}).$$

The distinguished algebra B_I is defined by adjunction: its multiplication is adjoint to

$$U_I(B_I \otimes B_I) \simeq U_I(B_I) \otimes U_I(B_I) \xrightarrow{\epsilon\otimes\epsilon} \mathbf{1},$$

and its unit is adjoint to $\imath_{\mathbf{1}}$. Its module category reconstructs the boundary category. Consequently the comparison object is the pair $(Z(C_I), B_I)$ with this multiplication and its forgetful action.

Suppose an independently defined boundary or bulk construction provides a braided category $\mathcal{B}_I$ and an algebra $\mathfrak{b}_I$ in it. A marked comparison consists of a braided equivalence

$$\Xi_I : Z(C_I) \xrightarrow{\sim} \mathcal{B}_I$$

and an algebra isomorphism $\xi_I : \Xi_I(B_I) \xrightarrow{\sim} \mathfrak{b}_I$. Using the tensor comparison of Ξ_I, it must satisfy

$$\xi_I \circ \Xi_I(\mu_{B_I}) = \mu_{\mathfrak{b}_I} \circ (\xi_I \otimes \xi_I), \qquad \xi_I \circ \Xi_I(\eta_{B_I}) = \eta_{\mathfrak{b}_I}.$$

The induced module-category comparison must intertwine the central action on the specified boundary objects. An unmarked braided equivalence does not provide these additional identifications.

The arithmetic marking also has semilinear transport. For an ideal $\mathfrak{a}$ in the domain of (15.6), put $\sigma = \mathrm{Art}(\mathfrak{a})$ and $I' = \mathfrak{a}^{-1}I$. The normalized network coefficients satisfy $\sigma(e_{I,g}) = e_{I',g}$, with the stated label transport.

A tensor transport lifting this law must be σ-semilinear on morphisms and preserve the marked junctions and duality. Denote such a transport by $\mathsf{A}_{\mathfrak{a}} : C_I \to C_{I'}$. It induces a center transport and, by the adjunction, a marked algebra isomorphism

$$Z(\mathsf{A}_{\mathfrak{a}})(B_I) \simeq B_{I'}.$$

Its multiplication compatibility follows by transporting the counit definition above.

The boundary or bulk construction must supply its own semilinear transport $\mathsf{T}_{\mathfrak{a}} : \mathcal{B}_I \to \mathcal{B}_{I'}$. The required square is a coherent braided isomorphism

$$\mathsf{T}_{\mathfrak{a}}\Xi_I \simeq \Xi_{I'} Z(\mathsf{A}_{\mathfrak{a}}),$$

compatible with the algebra maps ξ_I, $\xi_{I'}$, the units, and composition of Artin transports. If these tensor functors have not been constructed, the scalar reciprocity identity is only their necessary coefficient condition.

Question 20.23.1 *(The marked center comparison).* Construct the independently specified boundary or bulk center, its distinguished algebra and central action, and the equivalences Ξ_I, ξ_I with their semilinear transport compatibilities. On a field realization, retain the root and full collision diagrams. Construct the separated products and action, and identify the passage to the rational boundary sectors.

The affine E_6 theorem solves the tensor-category center problem in that realization and identifies its distinguished algebra and mirror extension. The pointed obstruction shows why the corresponding U-state algebra cannot simply act on the original vacuum in the required pointed manner. The derived Heisenberg example independently shows that even the correct one-position endomorphism object may miss action homotopies on separated configurations. Both results constrain the comparison without replacing its original domain.

A solution must therefore provide the stated maps, or an invariant incompatible with every permitted marked comparison. Equality of fusion rules, characters, scalar networks, or ordinary centers does not decide it. The trace comparison, the sewing of higher-genus amplitudes, and physical bulk reconstruction require their own operation-preserving maps as well.

Chapter 21

Enhanced traces and sewing

A matrix trace annihilates commutators. The trace of a category can retain an entire complex and a circle action. An arithmetic comparison must specify which of these objects it uses, which class it evaluates, and how the evaluation reaches a scalar partition function. Sewing requires compatible gluing maps as well.

Two elementary examples distinguish these data. In a matrix algebra, the identity need not generate degree-zero Hochschild homology. In a Frobenius algebra, changing the functional can change the sphere value without changing multiplication. Both phenomena matter when a local vacuum or a distinguished arithmetic class is part of the comparison.

We begin with ordinary algebras over a field. Tensor products in the first constructions are algebraic. The later categorical, completed, and Hilbert constructions will have their own coefficients and domains. The centers and actions of Chapter 20 act on specified objects. Passing to their traces is a further operation.

21.1 A trace and the class it evaluates

Let k be a field and A a nonzero unital associative k-algebra. Write $[A, A]$ for the k-linear span of commutators $ab - ba$. Define

$$HH_0(A) = A/[A, A].$$

This quotient is a vector space. In general $[A, A]$ is not an ideal, so the quotient has no multiplication induced by A.

A *cyclic functional* on A is a k-linear map $\tau : A \to k$ satisfying $\tau(ab) = \tau(ba)$ for every a, b. It is equivalent to a linear functional on $HH_0(A)$. The class $[1_A]$ and the value $\tau(1_A)$ are separate data. A normalized cyclic functional has $\tau(1_A) = 1$.

Proposition 21.1.1 *(Matrix trace and the regular object).* For every integer $d \geq 1$, matrix trace induces an isomorphism

$$HH_0(M_d(A)) \longrightarrow HH_0(A), \qquad [X] \longmapsto \left[\sum_i X_{ii}\right].$$

Its inverse sends $[a]$ to $[aE_{11}]$. Under this isomorphism,

$$[1_{M_d(A)}] \longmapsto d[1_A].$$

Here E_{ij} is the matrix with entry one in position (i, j) and zero elsewhere.

Proof. The trace of a matrix commutator is a sum of commutators in A:

$$\operatorname{Tr}(XY - YX) = \sum_{i,j} [X_{ij}, Y_{ji}].$$

Thus trace descends to the quotient.

Conversely, $[a, b]E_{11} = [aE_{11}, bE_{11}]$, so the proposed inverse is well defined. For $i \neq j$,

$$aE_{ij} = [aE_{ij}, E_{jj}],$$

and for $i \neq 1$,

$$aE_{ii} - aE_{11} = [aE_{i1}, E_{1i}].$$

Every matrix class therefore equals the class of its trace placed in the $(1,1)$ entry. The two maps are inverse. The formula for the identity follows by adding its d diagonal entries. □

For $A = k$ of characteristic two and $d = 2$, the space $HH_0(M_2(k))$ is one dimensional, but its identity class is zero. Consequently no cyclic functional on this algebra has value one on the identity. Over a field in which d is invertible, the normalized matrix functional $d^{-1}\operatorname{Tr}$ does have that value. The division by d is part of its normalization.

The matrix comparison has an object-theoretic interpretation. The usual equivalence between perfect $M_d(A)$-modules and perfect A-modules carries the regular matrix module to $A^{\oplus d}$. Its identity class accordingly becomes $d[1_A]$. An equivalence of categories does not require these two regular objects to correspond. An additional object marking can impose that requirement.

21.2 Chains, cyclic rotation, and completion

Put $\overline{A} = A/k1$. The normalized Hochschild chains are

$$C_n(A) = A \otimes_k \overline{A}^{\otimes n} \quad (n \geq 0), \qquad C_n(A) = 0 \quad (n < 0).$$

Write an elementary tensor as $a_0[a_1|\cdots|a_n]$. An entry equal to 1 inside the brackets is zero. The differential lowers degree and is

$$\begin{aligned} b\big(a_0[a_1|\cdots|a_n]\big) = {} & a_0a_1[a_2|\cdots|a_n] \\ & + \sum_{i=1}^{n-1}(-1)^i a_0[a_1|\cdots|a_ia_{i+1}|\cdots|a_n] \\ & + (-1)^n a_n a_0[a_1|\cdots|a_{n-1}]. \end{aligned}$$

The formula in positive degree descends from the unnormalized chains $A^{\otimes(n+1)}$ by quotienting the tensors with a unit in a bracket position. Set $b = 0$ on degree zero.

Definition 21.2.1 *(The regular Hochschild trace).* The *Hochschild chain complex with regular coefficients* is $(C_\bullet(A), b)$. Its homology is $HH_\bullet(A)$. The coefficient bimodule is A itself, with left and right multiplication. Replacing that bimodule changes the trace complex.

Associativity proves $b^2 = 0$. In the unnormalized complex, composing two multiplication faces in either order gives the same result after renumbering the later face. Their alternating signs are opposite. This includes the face multiplying the last entry into the first. In degree zero the resulting homology is exactly $A/[A, A]$.

The circle operation is already visible on these chains. Define Connes' operator $B : C_n(A) \to C_{n+1}(A)$ by

$$B\big(a_0[a_1|\cdots|a_n]\big) = \sum_{i=0}^{n}(-1)^{ni}1[a_i|\cdots|a_n|a_0|\cdots|a_{i-1}]. \tag{21.1}$$

For $i = 0$, the bracket is $[a_0|a_1|\cdots|a_n]$. Thus

$$B(a) = 1[a], \qquad B(a_0[a_1]) = 1[a_0|a_1] - 1[a_1|a_0].$$

Proposition 21.2.2 *(The mixed complex).* The operators satisfy

$$b^2 = 0, \qquad B^2 = 0, \qquad bB + Bb = 0.$$

In particular the pair of differentials (b, B) contains more information than $HH_\bullet(A)$ as a graded vector space.

Proof. The multiplication-face cancellation proves the first identity. Every term of B has leading coefficient one. Applying B again places that coefficient inside the bracket, so every resulting term is degenerate. This proves $B^2 = 0$.

For the remaining identity, expand the boundary of each cyclic rotation in (21.1). Its two outer faces cancel the corresponding outer faces from the adjacent rotation. Each interior multiplication then occurs once in bB and once in Bb. Moving the multiplication past the cyclic starting point changes its face index by one, with the rotation sign $(-1)^{ni}$ accounting for the wrap. The signs of these two terms are opposite. All terms cancel, proving $bB = -Bb$. □

More generally, a *mixed complex* over k is a homologically graded vector space C with two operators. They have degrees $|b| = -1$, $|B| = 1$ and satisfy these three identities. This definition also applies to the cyclic complexes of differential graded categories. Their internal differentials and permutations carry the Koszul signs of their graded morphisms.

For a mixed complex, let u have degree -2. Define its negative cyclic complex by

$$CC^-_m(C) = \prod_{j\geq 0} C_{m+2j}u^j, \qquad d = b + uB.$$

The mixed identities give $d^2 = 0$. The product in this formula is part of the definition.

Its periodic cyclic complex is $CC^{\mathrm{per}}(C) = CC^-(C)[u^{-1}]$, with the same differential. Inverting u is a filtered colimit after forming the displayed product. These two limiting operations must be respected by any comparison involving these complexes.

Example 21.2.3 *(A product created by negative cyclic completion).* For $i \geq 0$, let $C^{(i)}$ be one copy of k in homological degree $2i$, with $b = B = 0$. Then

$$CC^-_0\left(\bigoplus_{i\geq 0} C^{(i)}\right) = \prod_{i\geq 0} k, \qquad \left(\bigoplus_{i\geq 0} CC^-(C^{(i)})\right)_0 = \bigoplus_{i\geq 0} k.$$

The natural map is the inclusion of finite-support sequences and is not surjective. All differentials vanish, so the discrepancy also occurs in homology. An equivariant direct-sum decomposition of Hochschild chains therefore does not, by itself, give a direct-sum decomposition after negative cyclic completion.

A cyclic functional $\tau : A \to k$ is a map of mixed complexes from $C_\bullet(A)$ to k in degree zero, with zero B on the target. The chain condition is $\tau b(a_0[a_1]) = 0$. All other degrees give zero, and the compatibility with B follows from the degrees. This functional is an evaluation of the mixed complex, rather than the complex itself.

Categorical trace and Morita comparison

For a dg algebra A over a commutative ring k, the derived regular trace is $A \otimes^{\mathrm{L}}_{A^e} A$. Choose a dg model with K-flat morphism complexes over k: tensoring with each complex must preserve quasi-isomorphisms. A cofibrant replacement provides such a model for the bar tensors.

This is the Hochschild trace of the identity of its perfect-module category. The complex, with its circle action, is distinct from a single class associated to an object. For example a perfect object has its Hochschild Chern character, giving the additive map $K_0(\mathrm{Perf}\ A) \to HH_0(A)$. For the regular object A, this class is $[1_A]$.

The derived mixed complex is invariant under dg Morita equivalence. More precisely, Keller's Theorem 5.2 in *On differential graded categories* makes the mixed-complex construction a functor on the Morita category and identifies $C(A)$ with $C(\mathrm{Perf}_{\mathrm{dg}}\ A)$. This theorem concerns the enhanced dg categories and their derived equivalences. An equivalence of lists of simple objects does not meet its hypotheses.

For matrix algebras the comparison has an explicit cyclic-chain formula. On unnormalized degree-n chains, set

$$\mathrm{tr}_{\mathrm{cyc}}(X_0 \otimes \cdots \otimes X_n) = \sum_{i_0,\ldots,i_n} (X_0)_{i_0 i_1} \otimes (X_1)_{i_1 i_2} \otimes \cdots \otimes (X_n)_{i_n i_0}.$$

Matrix multiplication proves compatibility with every face, including the cyclic last face. Inserting an identity matrix collapses an adjacent index and gives the scalar-unit degeneracy. Rotating the indices proves compatibility with cyclic rotation. Thus it descends to a map of mixed complexes. In degree zero it is precisely Proposition 21.1.1.

The corner inclusion used there gives an inverse on HH_0. It is not a unital cyclic inverse on normalized chains. It sends 1_A to E_{11}, whereas the matrix-algebra unit is $\sum_i E_{ii}$. The enhanced Morita comparison accounts for the full units and their homotopies. It preserves the derived trace while transporting each chosen object marking to the object actually corresponding under the equivalence.

21.3 A functional that supplies sewing

To contract two boundary entries, a functional needs a nondegenerate pairing. This condition can be imposed and calculated in finite dimension before asking for an arithmetic or analytic realization.

Definition 21.3.1 *(Commutative Frobenius algebra).* A *commutative Frobenius algebra* over k is a finite-dimensional commutative unital k-algebra A with a linear functional $\varepsilon : A \to k$ such that

$$(a, b)_\varepsilon = \varepsilon(ab)$$

is nondegenerate. Choose dual bases e_i, f_i for this pairing and put

$$c = \sum_i e_i \otimes f_i, \qquad E = \sum_i e_i f_i.$$

The tensor c is the inverse pairing, and E is the *handle element*. Both are independent of the chosen dual bases.

The multiplication m joins two inputs. The pairing contracts two entries, and c supplies the reverse contraction. Define

$$\Delta(a) = (a \otimes 1)c.$$

This is the linear map adjoint to multiplication for the Frobenius pairing. In particular its normalization is determined by ε, not by multiplication alone.

PROPOSITION 21.3.2 *(Finite sewing identities).* The maps m, Δ, the algebra unit and ε satisfy the unit and counit identities, associativity and coassociativity, and

$$\Delta(ab) = (a \otimes 1)\Delta(b) = (1 \otimes b)\Delta(a).$$

Furthermore,

$$m\Delta(a) = aE.$$

The closed contraction formed from one unit, g successive handles and one counit is

$$Z_g = \varepsilon(E^g) \qquad (g \geq 0).$$

Proof. The inverse-pairing identity is $\sum_i \varepsilon(af_i)e_i = a$. It proves the counit identity and shows that the adjoint of m is the displayed Δ. Taking adjoints of associativity proves coassociativity, since the tensor-product pairing is nondegenerate.

The inverse tensor obeys $(a \otimes 1)c = (1 \otimes a)c$. To verify this equality, pair both tensors with $x \otimes y$. Each value is $\varepsilon(axy)$. Nondegeneracy proves the equality, and then proves both Frobenius identities for $\Delta(ab)$. Multiplying the two factors of $\Delta(a)$ gives aE. Iterating this handle map on 1 and applying ε gives the formula for Z_g. □

Example 21.3.3 *(Semisimple weights).* Let $A = k^r$, with orthogonal primitive idempotents e_i. Choose nonzero $w_i \in k$ and set $\varepsilon(e_i) = w_i$. The dual basis is $w_i^{-1}e_i$, so

$$\Delta(e_i) = w_i^{-1}e_i \otimes e_i, \qquad E = \sum_i w_i^{-1}e_i, \qquad Z_g = \sum_i w_i^{1-g}.$$

In particular $Z_0 = \sum_i w_i$ and $Z_1 = r$ in k. The algebra does not determine the weights. The counit and the inverse pairing retain them through every contraction.

Example 21.3.4 *(A nilpotent algebra with a nondegenerate pairing).* Let $A = k[\epsilon]/(\epsilon^2)$ and choose $\varepsilon(1) = a$, $\varepsilon(\epsilon) = 1$. Its Gram matrix in the basis $(1, \epsilon)$ is

$$\begin{pmatrix} a & 1 \\ 1 & 0 \end{pmatrix},$$

whose determinant is -1 in every characteristic. The dual basis is $(\epsilon, 1 - a\epsilon)$. Consequently

$$E = 2\epsilon, \qquad Z_0 = a, \qquad Z_1 = 2, \qquad Z_g = 0 \quad (g \geq 2).$$

These are algebraic contractions. Over $\mathbb{R}$, the displayed Gram matrix is indefinite. Nondegeneracy supplies sewing, but does not assert positivity of a Hilbert-space pairing.

The finite identities specify what must be transported in a larger comparison: the functional, inverse pairing, unit, and gluing maps. An equality of closed scalar values cannot recover all these maps. For infinite-dimensional or completed objects, defining the inverse pairing and proving convergence of its contractions are additional parts of the construction.

21.4 Spherical traces and marked closures

A spherical category supplies a trace by its duality maps. It need not supply a cyclic functional on an algebra used to present its objects. The arithmetic fusion example makes this distinction explicit.

Let C be a split spherical fusion category over a characteristic-zero field k. Thus C is a rigid semisimple k-linear tensor category with finitely many simple objects, finite-dimensional morphism spaces, and simple unit. Splitness means $\mathrm{End}(S) = k$ for each simple S. Its chosen pivotal duality identifies left and right categorical traces. Write S_i for its simple representatives and

$$d_i = \mathrm{tr}_{S_i}(1_{S_i})$$

for their spherical dimensions. For an object $X \simeq \bigoplus_i S_i^{\oplus m_i}$, an endomorphism has multiplicity matrices $f_i \in M_{m_i}(k)$.

Proposition 21.4.1 *(Trace on multiplicity spaces).* The categorical trace is

$$\mathrm{tr}_X(f) = \sum_i d_i \,\mathrm{Tr}_k(f_i).$$

In particular it is a cyclic functional on $\mathrm{End}(X)$. The coefficients d_i are determined by the chosen duality.

Proof. Choose inclusions $u_{i\alpha} : S_i \to X$ and projections $v_{i\alpha} : X \to S_i$ with

$$v_{i\alpha} u_{j\beta} = \delta_{ij}\delta_{\alpha\beta} 1_{S_i}, \qquad \sum_{i,\alpha} u_{i\alpha} v_{i\alpha} = 1_X.$$

Expand f using these splittings. Cyclicity of the spherical trace gives $\mathrm{tr}_X(u_{i\alpha}v_{i\beta}) = \mathrm{tr}_{S_i}(v_{i\beta}u_{i\alpha}) = \delta_{\alpha\beta} d_i$. The diagonal matrix entries therefore give the displayed sum. Ordinary matrix trace is cyclic, proving the last assertion. □

For the order-two arithmetic category of Chapter 15, the fusion rules are

$$g^2 = 1, \qquad g\rho = \rho g = \rho, \qquad \rho^2 = 1 + g + 2\rho.$$

The constructed spherical structures have $d_1 = d_g = 1$ and

$$d_\rho = 1 - \sqrt{3} \quad \text{or} \quad d_\rho = 1 + \sqrt{3}$$

at the two indicated embeddings of the coefficient field. Indeed multiplicativity and additivity of dimension require $d_\rho^2 = 2 + 2d_\rho$. Their global dimensions and traces on the sum of the simples are respectively

$$\sum_i d_i^2 = 6 \mp 2\sqrt{3}, \qquad \mathrm{tr}_{1\oplus g\oplus\rho}(1) = 3 \mp \sqrt{3}.$$

These are different contractions. The unitary realization in Chapter 20 uses $1 + \sqrt{3}$. The original arithmetic embedding retains $1 - \sqrt{3}$ and the nonunitary realization of Chapter 16.

One cannot change the sign of a single dimension while keeping that category and its pivotal structure. More precisely, any tensor automorphism of the identity functor acts on the three simples by scalars $\eta_1 = 1, \eta_g, \eta_\rho$. The unit and ρ summands of ρ^2 require

$$\eta_\rho^2 = 1, \qquad \eta_\rho^2 = \eta_\rho.$$

Hence $\eta_\rho = 1$, and the g summand gives $\eta_g = 1$. Two pivotal structures differ by such an automorphism, so the existing pivotal structure is unique. Passing to the other field embedding changes the coefficient data of the category.

The algebra $\mathrm{End}(\bigoplus_i S_i)$ is k^r. When every d_i is nonzero, its spherical trace makes this commutative algebra a Frobenius algebra with weights $w_i = d_i$. Example 21.3.3 then gives its finite contractions. This construction records a trace on the sum of the simples. Recovering the fusion tensor, its associator or its geometric sewing requires those maps as additional data.

The scalar unit of a Leavitt algebra

Let L_r be the unital algebra with generators $s_1, \dots, s_r, t_1, \dots, t_r$ and relations

$$t_i s_j = \delta_{ij} 1, \qquad \sum_i s_i t_i = 1.$$

The t_i are algebraic dual generators. No complex conjugation is part of this notation.

Proposition 21.4.2 *(A vanishing unit class).* If $r - 1$ is invertible in k, then $[1] = 0$ in $HH_0(L_r)$. Consequently every cyclic functional on L_r vanishes at 1.

Proof. The defining relations give the literal commutator identity

$$\sum_{i=1}^{r} [t_i, s_i] = r1 - \sum_i s_i t_i = (r-1)1.$$

Divide by $r - 1$ and pass to $L_r/[L_r, L_r]$. □

This argument concerns one class. It does not assert that $HH_0(L_r)$ is zero. It also has the stated coefficient restriction. If $r = 1$, the algebra is $k[s, s^{-1}]$, and the identity class is nonzero.

For the arithmetic algebra $\mathcal{B}_I$ of Section 15.3, one has $r = 2N$. Its characteristic-zero coefficient field makes $2N - 1$ invertible. Nevertheless its marked categorical closure recovers the arithmetic values. Retain the object ρ, its duality maps X_0, X_0', and the scalar network $\mathcal{N}_g = b_g 1_\rho$. With $d = -1/b_0$ and $e_g = b_g/b_0$, the closure is

$$\mathrm{cl}_\rho(a) = dX_0' \rho(a) X_0, \qquad -\mathrm{cl}_\rho(\mathcal{N}_g) = e_g.$$

The second identity follows from $X_0' X_0 = 1$ and the fact that ρ fixes scalars. This functional has domain $\mathrm{End}(\rho)$ and uses its specified duality. Its value is compatible with the vanishing ambient unit class because it is a different trace construction.

The finite balanced-tensor realization of Theorem 15.6.1 retains this network as well. Its matrix detector is

$$M_g = b_g 1_{\omega(\rho)}, \qquad b_g = \frac{\mathrm{Tr}_k(M_g)}{3N}.$$

This formula uses the scalar endomorphism and the particular dimension $\dim_k \omega(\rho) = 3N$. It is not a replacement for categorical trace on arbitrary diagrams. The functor takes values in bimodules over k^{N+1}, with their balanced tensor. It is not a finite-dimensional unital representation of $\mathcal{B}_I$.

21.5 Extensions and regular Hochschild traces

The trace of a nonsemisimple category requires its actual complex. Extensions between simple modules give useful information, but they need not survive regular Hochschild trace. Two small algebras show both behaviors.

Let A be a finite-dimensional algebra over a field k. There are finitely many simple right A-modules up to isomorphism: each occurs among the composition factors of the regular module. If M, N are finite-dimensional, then $\operatorname{Ext}^n_A(M,N)$ is finite-dimensional for each n. Indeed successive surjections from finite free modules give a projective resolution with finite-dimensional terms. Applying $\operatorname{Hom}_A(-,N)$ proves degreewise finiteness. There is no resulting bound on the total graded dimension.

The dual numbers

Put $A = k[\epsilon]/(\epsilon^2)$ and $S = A/(\epsilon)$. Multiplication by ϵ has kernel and image $k\epsilon$, so

$$\cdots \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \xrightarrow{\epsilon} A \longrightarrow S \longrightarrow 0$$

is an exact free resolution. Applying $\operatorname{Hom}_A(-,S)$ makes every differential zero. Thus

$$\operatorname{Ext}^n_A(S,S) = k \qquad (n \geq 0).$$

The algebra has radical square zero, but its simple module has infinite projective dimension. In characteristic two it is also $k[C_2]$, under $\epsilon \mapsto g - 1$.

For the regular trace, use the enveloping algebra $A^e = A \otimes_k A^{\mathrm{op}}$ and the coefficient bimodule A. The bar resolution identifies

$$HH_n(A) = \operatorname{Tor}_n^{A^e}(A,A).$$

Here both occurrences of A retain their regular actions.

PROPOSITION 21.5.1 *(The complete regular trace of the dual numbers).* For every field k,

$$HH_0(A) = A, \qquad HH_{2r+1}(A) = A/(2\epsilon A) \quad (r \geq 0), \qquad HH_{2r}(A) = \operatorname{ann}_A(2\epsilon) \quad (r \geq 1).$$

If $\operatorname{char} k \neq 2$, each positive-degree group has dimension one. If $\operatorname{char} k = 2$, then $HH_n(A) = A$ in every nonnegative degree.

Proof. Write $A^e = k[x,y]/(x^2,y^2)$, with x acting on the left and y on the right. Set $u = x - y$ and $v = x + y$. There is a free bimodule complex

$$\cdots \xrightarrow{u} A^e \xrightarrow{v} A^e \xrightarrow{u} A^e \xrightarrow{\mu} A \longrightarrow 0, \qquad \mu(x) = \mu(y) = \epsilon.$$

The differential out of odd degree is u and that out of positive even degree is v. Their composites vanish.

For $z = \alpha + \beta x + \gamma y + \eta xy$,

$$uz = \alpha(x-y) + (\gamma - \beta)xy, \qquad vz = \alpha(x+y) + (\beta + \gamma)xy.$$

Consequently

$$\ker u = \langle x+y, xy\rangle = \operatorname{im} v, \qquad \ker v = \langle x-y, xy\rangle = \operatorname{im} u.$$

Also $\ker \mu = \langle x-y, xy\rangle$. These statements remain valid in characteristic two, and prove exactness.

Tensoring with the regular A sends u to zero and v to 2ϵ. The resulting alternating differential gives the asserted quotients and annihilators. If two is invertible, the annihilator is ϵA. If two is zero, every differential vanishes.

The normalized Hochschild formula gives the same calculation without a change of resolution. Since $\overline{A} = k\epsilon$, interior products in a normalized chain vanish, and the two outer faces give

$$b_n\big(c[\epsilon|\cdots|\epsilon]\big) = (1 + (-1)^n)c\epsilon[\epsilon|\cdots|\epsilon].$$

The bracket on the right has $n-1$ entries. In particular the cyclic last face is responsible for the factor two in even degree. □

In characteristic two, the simple-module Ext groups have dimension one while the regular Hochschild groups have dimension two. The coefficient module and the traced resolution are indispensable parts of either statement.

A directed algebra and cyclic endpoint matching

Let Q be a finite quiver, J its arrow ideal, and $B = kQ/J^2$. Concatenate paths from left to right and use right modules. For a vertex i, put $P_i = e_iB$ and $S_i = e_iB/e_iJ$. The radical of P_i is one copy of S_j for each arrow $i \to j$. Iterating projective covers therefore gives

$$\dim_k \operatorname{Ext}^n_B(S_i, S_j) = \#\{\text{oriented length-}n\text{ paths from } i \text{ to } j\}.$$

To justify the last step, every differential in this minimal resolution lands in a radical. A map to a simple module kills that radical, so the Hom complex has zero differential. All groups of degree at least two vanish precisely when the quiver has no composable pair of arrows.

Take

$$Q = (0 \xrightarrow{a} 1 \xrightarrow{b} 2), \qquad B = kQ/(ab).$$

Then $P_0 = \langle e_0, a\rangle$, $P_1 = \langle e_1, b\rangle$, and $P_2 = \langle e_2\rangle$. The sequence

$$0 \longrightarrow P_2 \xrightarrow{e_2 \mapsto b} P_1 \xrightarrow{e_1 \mapsto a} P_0 \longrightarrow S_0 \longrightarrow 0$$

is exact: the middle kernel is kb because $ab = 0$. It gives

$$\operatorname{Ext}^1_B(S_0, S_1) = k, \qquad \operatorname{Ext}^1_B(S_1, S_2) = k, \qquad \operatorname{Ext}^2_B(S_0, S_2) = k.$$

The product of the two adjacent degree-one classes is nonzero. The exact sequence $0 \to S_1 \to P_0 \to S_0 \to 0$ identifies its Yoneda product with the dimension-shifting isomorphism $\operatorname{Ext}^1_B(S_1, S_2) \simeq \operatorname{Ext}^2_B(S_0, S_2)$. Thus the algebra relation $ab = 0$ does not make this product zero.

For comparison, the path algebra kQ before imposing $ab = 0$ has $\operatorname{rad} P_0 \simeq P_1$ and $\operatorname{rad} P_1 \simeq P_2$. Its simple modules have projective resolutions of length at most one. It is a different algebra, and its P_0 has Loewy length three.

Proposition 21.5.2 *(Regular trace of the directed model).* For $B = kQ/(ab)$ as above,

$$HH_0(B) = ke_0 \oplus ke_1 \oplus ke_2, \qquad HH_n(B) = 0 \quad (n \geq 1).$$

Proof. Set $S = ke_0 \oplus ke_1 \oplus ke_2$ and $J = ka \oplus kb$. The relative normalized bar terms $P_n = B \otimes_S J^{\otimes_S n} \otimes_S B$ are

$$\begin{aligned} P_0 &= \bigoplus_{i=0}^{2} Be_i \otimes_k e_i B, \\ P_1 &= (Be_0 \otimes_k e_1 B) \oplus (Be_1 \otimes_k e_2 B), \\ P_2 &= Be_0 \otimes_k e_2 B, \end{aligned}$$

and $P_n = 0$ for $n \geq 3$. Each summand is a projective bimodule, being an idempotent summand of $B \otimes_k B$. The differentials are

$$\begin{aligned} d_1(l \otimes j \otimes r) &= lj \otimes r - l \otimes jr, \\ d_2(l \otimes a \otimes b \otimes r) &= la \otimes b \otimes r + l \otimes a \otimes br. \end{aligned}$$

The interior term of d_2 vanishes because $ab = 0$.

For completeness, the dimensions of these terms are 8, 4, 1. A basis of P_1 consists of

$$\begin{aligned} q_1 &= e_0 \otimes a \otimes e_1, & q_2 &= e_0 \otimes a \otimes b, \\ q_3 &= e_1 \otimes b \otimes e_2, & q_4 &= a \otimes b \otimes e_2. \end{aligned}$$

Their images are

$$a \otimes e_1 - e_0 \otimes a, \quad a \otimes b, \quad b \otimes e_2 - e_1 \otimes b, \quad -a \otimes b.$$

The first three are independent. The kernel of d_1 is $k(q_2 + q_4)$, and d_2 sends its generator to $q_2 + q_4$.

Multiplication $P_0 \to B$ is surjective with a three-dimensional kernel. This proves exactness in every characteristic.

Regular trace sends each summand to

$$B \otimes_{B^e} (Be_i \otimes_k e_j B) \simeq e_j B e_i.$$

The forward map is $c \otimes (l \otimes r) \mapsto rcl$. The inverse is $t \mapsto t \otimes (e_i \otimes e_j)$. The balancing relations prove that these maps are inverse.

All off-diagonal terms here vanish, because a directed path has no return path. The diagonal terms are ke_i. The traced complex is consequently k^3 in degree zero and zero in every positive degree. □

The relation contributes a nonzero degree-two bimodule-resolution term. Taking the regular trace kills that term by its endpoints. An arithmetic use of simple-module extensions must therefore construct the map into its trace complex and determine the image of the Yoneda products.

21.6 Tensoring local trace complexes

Local degree bounds do not simply add their positive parts. Fix a commutative ring R. We use homological shifts, so a module $M[1]$ is concentrated in degree one. Suppose two complexes have specified splittings

$$C_2 \simeq B_2 \oplus W_2[1], \qquad C_3 \simeq B_3 \oplus W_3[1],$$

Here B_2, W_2, B_3, W_3 are R-modules in degree zero. The subscripts label two local factors.

Proposition 21.6.1 *(All four tensor terms).* There is an equivalence

$$\begin{aligned} C_2 \otimes^{\mathrm{L}}_R C_3 \simeq\ & B_2 \otimes^{\mathrm{L}}_R B_3 \\ & \oplus (W_2 \otimes^{\mathrm{L}}_R B_3)[1] \\ & \oplus (B_2 \otimes^{\mathrm{L}}_R W_3)[1] \\ & \oplus (W_2 \otimes^{\mathrm{L}}_R W_3)[2]. \end{aligned}$$

If all remaining local factors assemble into a degree-zero complex D, their contribution is the derived tensor of D with every displayed term.

Proof. Choose projective resolutions of the modules. Distribute the tensor product over the two finite direct sums. The tensor differential is $d(x \otimes y) = dx \otimes y + (-1)^{|x|} x \otimes dy$, and the two shifts in the last term add to two. Associativity of derived tensor gives the assertion about D. □

Over a field, take $B_2 = B_3 = k$, $W_2 = k$, and $W_3 = k^2$. The result is

$$k \oplus k^3[1] \oplus k^2[2].$$

If x spans W_2 and y, z form a basis of W_3, then $x \otimes y$ and $x \otimes z$ are independent degree-two cycles. Every differential is zero, so they are not boundaries. Anticommutativity does not cancel products in distinct factors. Taking unit reference vectors at almost all primes still permits non-unit entries at both selected primes.

Integral coefficients can give a different result, for a specific algebraic reason.

Proposition 21.6.2 *(Distinct-primary vanishing).* If M_2 is a 2-primary torsion abelian group and M_3 is a 3-primary torsion abelian group, then

$$M_2 \otimes^{\mathrm{L}}_{\mathbb{Z}} M_3 = 0.$$

If B_2, B_3 are flat abelian groups, the tensor of $B_2 \oplus M_2[1]$ and $B_3 \oplus M_3[1]$ is concentrated in degrees zero and one.

Proof. The free resolution of $\mathbb{Z}/2^a$ is $[\mathbb{Z} \xrightarrow{2^a} \mathbb{Z}]$. After tensoring with $\mathbb{Z}/3^b$, its differential is invertible. Its tensor product and first Tor therefore vanish. Finite primary groups are sums of such cyclic groups. Every primary torsion abelian group is the filtered union of its finite subgroups, and tensor and Tor commute with these filtered colimits.

There is no higher Tor over $\mathbb{Z}$: the kernel of a surjection from a free abelian group is free. This proves the first assertion. Flatness removes higher Tor from the other three terms of Proposition 21.6.1. □

For $B_2 = B_3 = \mathbb{Z}$, $M_2 = \mathbb{Z}/2$, and $M_3 = (\mathbb{Z}/3)^2$, the result is

$$\mathbb{Z} \oplus \big(\mathbb{Z}/2 \oplus (\mathbb{Z}/3)^2\big)[1].$$

This calculation does not replace the common-field example. They have different coefficients. An arithmetic comparison needs its integral models, change-of-coefficient maps, and a proof that the chosen completion preserves the asserted tensor.

Question 21.6.3 *(Arithmetic trace assembly).* Construct the local arithmetic categories and regular trace complexes, the maps from their extension data, and the completed restricted tensor that assembles them globally. Determine whether the mixed term survives, vanishes by a coefficient argument, or is removed by a specified quotient. In the last case, construct the quotient map and prove its compatibility with the trace operations. A degree-one truncation and the full trace have different comparison problems.

21.7 ORTHOGONAL BLOCKS AND CYCLIC DECOMPOSITION

Let k now be a commutative ring, and let $(\mathcal{A}_i)_{i\in I}$ be small k-linear differential graded categories with K-flat morphism complexes. Here K-flat means that tensoring with the complex preserves quasi-isomorphisms. This hypothesis lets ordinary tensor products compute the derived tensors used below.

Form the orthogonal union $\mathcal{A}$: objects belong to one of the $\mathcal{A}_i$, and the morphism complex between different blocks is zero. Let $\mathrm{Perf}(\mathcal{A})$ be the category obtained from its representable modules by finite sums, shifts, cones and retracts. Write $C_\bullet(\mathcal{B})$ for the derived Hochschild mixed complex of a dg category $\mathcal{B}$.

PROPOSITION 21.7.1 *(Cyclic block decomposition).* There is an S^1-equivariant equivalence

$$C_\bullet(\mathrm{Perf}(\mathcal{A})) \simeq \bigoplus_{i\in I} C_\bullet(\mathrm{Perf}(\mathcal{A}_i)).$$

Every perfect module has finite block support.

Proof. In cyclic degree n, the bar construction is the sum of

$$\mathcal{A}(X_n, X_0) \otimes_k \mathcal{A}(X_{n-1}, X_n) \otimes_k \cdots \otimes_k \mathcal{A}(X_0, X_1)$$

over its cyclic words of objects. A word using two blocks has a zero morphism factor, including when the change of block occurs at the closing pair. Every surviving word therefore lies in one block. Composition faces, unit degeneracies, internal differentials and cyclic rotation preserve it.

Thus the cyclic object itself decomposes as the direct sum of the block cyclic objects. The K-flat assumption computes the derived tensors, and realization commutes with direct sums. The cyclic structure, hence the circle action, is preserved. Passing to perfect modules is the dg Morita invariance of this derived trace.

A representable is supported in one block. Each finite sum, shift, cone or retract preserves finite support, so every perfect object has it. Conversely, a finite-support family of perfect block modules is perfect over $\mathcal{A}$. This identifies the compact model used in the formula. □

For a compactly generated presentable category, this statement applies when its compact objects have the specified model. A product description of a presentable category alone does not identify the relevant trace or its compact support. Moreover the proposition is an equivalence of cyclic complexes. A multiplicative trace comparison needs a compatible monoidal enhancement and preservation of its operations.

Even coordinatewise multiplication on the right has a unit only under an additional finiteness condition. If infinitely many blocks are nonzero unital algebras, every element of their direct sum omits some block. It cannot act as identity on that block. The infinite coordinatewise direct sum is then nonunital. Finally, negative cyclic completion need not preserve this sum, as Example 21.2.3 shows.

For arithmetic block comparisons, the coefficient ring, dg models and indexing maps must be given before applying this decomposition. The perfect-stack loop comparisons of Chapter 18 also retain their own geometric hypotheses. The topological circle, a finite cyclic classifying stack, and a profinite mapping object define different constructions. Passing between them requires comparison maps and continuity theorems on the chosen carriers.

Filtered continuity on a specified trace carrier

The same finite-word argument applies to a filtered union of dg categories. Every cyclic word, morphism tensor and relation appears at a common finite stage. For K-flat models over a common ring, tensoring and filtered colimits commute. Thus the cyclic complex of that union is the filtered colimit of its cyclic complexes, before taking homology or cyclic completion.

There is also a categorical version with a different output. Let $\mathcal{V}$ be a presentable symmetric monoidal category whose tensor preserves colimits separately. For an associative algebra object A of $\mathcal{V}$, define

$$\mathrm{Tr}_{\mathcal{V}}(A) = \left| [n] \longmapsto A^{\otimes(n+1)} \right|.$$

The faces multiply adjacent entries, including the cyclic closing pair, and the degeneracies insert the unit. The bars denote geometric realization of the cyclic object.

For $\mathcal{V} = D(k)$ this is a derived Hochschild complex. For $\mathcal{V} = \mathrm{Pr}^{\mathrm{L}}_{k,\mathrm{st}}$ it is a category, as in Section 18.29.

Proposition 21.7.2 *(Filtered continuity of cyclic realization).* Let $(A_i)_{i\in I}$ be a filtered diagram of associative algebra objects in $\mathcal{V}$, and let A be its colimit. Then there is a natural circle-equivariant equivalence

$$\operatorname*{colim}_i \mathrm{Tr}_{\mathcal{V}}(A_i) \simeq \mathrm{Tr}_{\mathcal{V}}(A).$$

If the diagram has compatible E_2 structures, this equivalence preserves the induced E_1 multiplication on the trace.

Proof. Filtered colimits of associative algebras are computed on their underlying objects. Indeed all operations have finite arity, and the diagonal $I \to I^m$ is cofinal for every finite m. Separate preservation of colimits therefore gives

$$A^{\otimes(n+1)} \simeq \operatorname*{colim}_i A_i^{\otimes(n+1)}.$$

These equivalences preserve multiplication, the unit and permutations. They consequently identify every cyclic face, degeneracy and rotation.

Geometric realization is a colimit and commutes with the filtered colimit. Realizing the degreewise equivalence proves the assertion with its circle action. For E_2 inputs, use their description as associative algebras in associative algebras. The cyclic construction in one direction retains the multiplication in the other, with its interchange coherences. The same colimit argument preserves these operations and proves the last assertion. □

To apply this result to an arithmetic formal presentation, one must identify its category with the stated colimit of its finite-stage categories. The transition functors must preserve the convolution structure being used. A closed immersion of parameter spaces does not by itself establish this categorical equivalence or its support conditions.

After that input, the trace-continuity step is positive. If $T_i \simeq Q_i$ are compatible finite-stage trace comparisons and $\mathrm{colim}_i Q_i \simeq Q$ is independently proved, their colimits give $T \simeq Q$. The loop-space computation and passage of a singular-support condition to Q remain separate hypotheses. Functions on an inverse limit, a pro-étale mapping object, and negative cyclic completion cannot be exchanged with these colimits without their own arguments.

An arithmetic determinant trace is different again. The trace coefficient of a universal Chenevier determinant is a function on a deformation ring. Identifying it with the invariant trace of a universal (φ, Γ)-module requires a comparison of those coefficient objects. Compatibility with a specified Nygaard

filtration is an additional equation on that comparison. Neither scalar Hochschild continuity nor the categorical trace theorem constructs it.

21.8 ARITHMETIC SHIFTS, PHASES, AND OCCUPATION TRACES

The Bost–Connes algebra gives a concrete arithmetic representation. Its occupation trace, algebraic Hochschild cochains, and smooth Hochschild cochains can all be studied. Relating any of them to an independently defined arithmetic trace category is a further comparison.

Definition 21.8.1 *(The Bost–Connes algebra).* Let A_{BC} be the complex unital C^*-algebra generated by isometries μ_n, for $n \geq 1$, and unitaries $e(\gamma)$, for $\gamma \in \mathbb{Q}/\mathbb{Z}$, with relations

$$\begin{aligned} \mu_1 &= 1, & \mu_m\mu_n &= \mu_{mn}, & \mu_n^*\mu_n &= 1, \\ e(0) &= 1, & e(\gamma)e(\eta) &= e(\gamma+\eta), & e(\gamma)^* &= e(-\gamma), \\ \mu_m^*\mu_n &= \mu_n\mu_m^* & &\text{if } (m,n)=1, & & \\ \mu_n e(\gamma)\mu_n^* &= \frac{1}{n}\sum_{n\delta=\gamma} e(\delta). & & & & \end{aligned}$$

In particular $\mu_n\mu_n^* = e_n = n^{-1}\sum_{n\delta=0} e(\delta)$. The time evolution is

$$\sigma_t(\mu_n) = n^{it}\mu_n, \qquad \sigma_t(e(\gamma)) = e(\gamma).$$

On $\mathcal{L} = \ell^2(\mathbb{N}^\times)$, with orthonormal basis δ_m, define

$$\mu_n\delta_m = \delta_{nm}, \qquad e(\gamma)\delta_m = \exp(2\pi i m\gamma)\delta_m.$$

We use the same notation for the abstract generators and these operators once faithfulness is proved.

PROPOSITION 21.8.2 *(The faithful occupation representation).* These operators define a faithful representation of A_{BC} on $\mathcal{L}$. The range projection $\mu_n\mu_n^*$ selects the integers divisible by n. Its spectrum is $\{0,1\}$ for $n > 1$.

Proof. The adjoint shift sends δ_m to $\delta_{m/n}$ if $n \mid m$, and to zero otherwise. This gives the isometry, semigroup and coprime-adjoint relations. The transfer relation is the finite character identity

$$\frac{1}{n}\sum_{n\delta=\gamma}\exp(2\pi i m\delta) = \begin{cases} \exp(2\pi i(m/n)\gamma), & n \mid m, \\ 0, & n \nmid m. \end{cases}$$

It also gives the range projection. For $n > 1$, its range contains δ_n and its kernel contains δ_1, so both spectral values occur.

To prove faithfulness, let $K = \prod_p U(1)$, with the product topology. For $z \in K$, write $z(n) = \prod_p z_p^{v_p(n)}$. The gauge action α_z fixes the phases and sends μ_n to $z(n)\mu_n$. It preserves the defining relations.

The finite normal sums

$$A_{\mathrm{alg}} = \mathrm{span}_{\mathbb{C}}\{\mu_r e(\gamma)\mu_s^* : r,s \geq 1,\ \gamma \in \mathbb{Q}/\mathbb{Z}\}$$

form a dense star subalgebra. Indeed the transfer identities give $e(\gamma)\mu_n = \mu_n e(n\gamma)$ and its adjoint. If $s = ds'$, $u = du'$, and $(s', u') = 1$, multiplication becomes

$$(\mu_r e(\gamma)\mu_s^*)(\mu_u e(\eta)\mu_v^*) = \mu_{ru'} e(u'\gamma + s'\eta)\mu_{vs'}^*.$$

Adjoint exchanges r, s and negates γ. The gauge orbit of each normal term is continuous. Density and isometry prove continuity on every element of A_{BC}.

A normal term has gauge character $z(r/s)$. Haar averaging therefore kills it unless $r = s$, in which case the transfer relation puts it in the phase algebra D. Thus $E(a) = \int_K \alpha_z(a)\, dz$ is a conditional expectation onto D. The representation of $C^*(\mathbb{Q}/\mathbb{Z}) = C(\widehat{\mathbb{Z}})$ on $\mathcal{L}$ evaluates at the positive integers. Those integers meet every residue class and are dense in $\widehat{\mathbb{Z}}$. Their evaluations are faithful, so $D = C(\widehat{\mathbb{Z}})$ and the representation is faithful on D.

The expectation itself is faithful. For $a \geq 0$ and a state ω, the function $z \mapsto \omega(\alpha_z(a))$ is continuous and nonnegative. If $E(a) = 0$, its integral vanishes. Full support of Haar measure makes its value at the identity zero. States separate positive elements, so $a = 0$.

Finally, $V_z \delta_m = z(m)\delta_m$ implements α_z in the occupation representation π. If $\pi(a) = 0$, then $\pi(E(a^*a)) = 0$. Faithfulness on D, followed by faithfulness of E, gives $a^*a = 0$ and $a = 0$. □

Normalized creation and higher modes

For each prime p, let $\mathscr{F}_p = \ell^2(\mathbb{N}_0)$, with number states $|r\rangle_p$. Form the Hilbert restricted tensor product with vacuum reference vectors $|0\rangle_p$. On finite occupation vectors, define

$$a_p|r\rangle_p = \sqrt{r}\,|r-1\rangle_p, \qquad a_p^\dagger|r\rangle_p = \sqrt{r+1}\,|r+1\rangle_p, \qquad N_p = a_p^\dagger a_p.$$

Unique prime factorization gives a unitary

$$U : \mathcal{L} \longrightarrow \widehat{\bigotimes_p}{}' \mathscr{F}_p, \qquad U\delta_m = \bigotimes_p |v_p(m)\rangle_p.$$

The arithmetic prime shift is

$$U\mu_p U^{-1} = a_p^\dagger (N_p + 1)^{-1/2}.$$

The diagonal factor cancels the creation coefficient, leaving an isometry. This identity begins on finite occupation vectors and extends boundedly. The unnormalized creation operator is unbounded.

For $z \in \mathbb{C}$, the coherent vector

$$\exp(-|z|^2/2) \sum_{k\geq 0} \frac{z^k}{\sqrt{k!}} U\delta_{p^k}$$

has norm one. It lies in the arithmetic algebra orbit of the vacuum: apply the norm-convergent series $\exp(-|z|^2/2)\sum_{k\geq 0} z^k (U\mu_p U^{-1})^k/\sqrt{k!}$. The ratio test proves convergence of its scalar coefficient norms.

For a finite prime set F, consider the bosonic current Fock space

$$\mathscr{F}_F^{\mathrm{cur}} = \Gamma_s\big(\ell^2(F \times \mathbb{N}_{\geq 1})\big).$$

Here Γ_s is the Hilbert direct sum of symmetric powers. Mode j corresponds to the normalized Heisenberg creation operator $a_{-j}^{(p)}/\sqrt{j}$. Splitting the one-particle space into modes $j = 1$ and $j \geq 2$ gives

$$\mathscr{F}_F^{\mathrm{cur}} \simeq L_F \widehat{\otimes} \mathscr{F}_F^{\geq 2}, \qquad L_F = \widehat{\bigotimes}_{p\in F} \mathscr{F}_p.$$

The orthonormal number-state bases prove this unitary directly, and it preserves the grading assigning degree j to a mode-j creation.

Let $\mathbb{N}_F$ be the integers supported on F. The phases and shifts μ_n, $n \in \mathbb{N}_F$, act on $L_F \simeq \ell^2(\mathbb{N}_F)$ and extend by the identity on $\mathscr{F}_F^{\geq 2}$. Every closed subspace $L_F \widehat{\otimes} K_0$, with $K_0 \subset \mathscr{F}_F^{\geq 2}$, is invariant under these operators and their adjoints. If F is nonempty, the higher-mode vacuum is properly contained in larger such stable sectors.

This restricted representation need not be faithful on all phases. If $q \notin F$, the nonzero projection

$$e_q = \frac{1}{q} \sum_{j=0}^{q-1} e(j/q)$$

acts as zero on L_F, since no integer in $\mathbb{N}_F$ is divisible by q. Also the higher-mode factor by itself is not the full vacuum Heisenberg vertex algebra: it omits every mode-one creation.

The Gibbs trace and its domain

Define the occupation Hamiltonian by

$$H\delta_m = (\log m)\delta_m, \qquad \operatorname{Dom} H = \left\{ \xi : \sum_m (\log m)^2 |\xi_m|^2 < \infty \right\}.$$

This is a self-adjoint diagonal operator with finite-support core. For a real $\beta > 1$,

$$\operatorname{Tr}(e^{-\beta H}) = \sum_{m \geq 1} m^{-\beta} = \prod_p (1 - p^{-\beta})^{-1} = \zeta(\beta). \tag{21.2}$$

The series is positive and convergent. Unique factorization proves the Euler product by increasing finite prime sets. At $\beta = 1$ the trace is the divergent harmonic series.

With the KMS convention $\varphi(ab) = \varphi(b\sigma_{i\beta}(a))$ for analytic elements, the Gibbs state is

$$\varphi_\beta(a) = \zeta(\beta)^{-1} \operatorname{Tr}(ae^{-\beta H}).$$

Indeed $e^{-\beta H} a = \sigma_{i\beta}(a) e^{-\beta H}$ on analytic normal terms, and trace cyclicity proves the identity. The full Bost–Connes classification gives a unique β-KMS state for $0 < \beta \leq 1$. For $\beta > 1$ its extremal states are indexed by embeddings of the cyclotomic field into $\mathbb{C}$. These are Bost–Connes, Theorems 5 and 25, with the critical case in Section 7. At the critical temperature, existence of a KMS state does not give a trace-class density in the occupation representation.

The spherical $GL_2(\mathbb{Q}_p)$ measure and the Jordan-quiver groupoid mass have their own constructions in Chapters 13 and 12. Relating those objects to the Bost–Connes system requires an operator or categorical comparison preserving their states and normalizations. Their prime indexing supplies no such map.

21.9 Gauge classes in Hochschild cohomology

We now use cochains with regular coefficients on A_{alg}. These compute a cohomology algebra, whereas the earlier cyclic chains compute a trace complex. All cochains in this first calculation are algebraic $\mathbb{C}$-multilinear maps.

Let

$$W = \operatorname{Hom}_{\mathbb{Z}}(\mathbb{Q}_{>0}^{\times}, (\mathbb{C}, +)) = \prod_p \mathbb{C}.$$

A family $\lambda = (\lambda_p)_p$ evaluates on a positive rational by $\lambda(g) = \sum_p v_p(g)\lambda_p$. Every such sum has finite support, even if the family does not.

Proposition 21.9.1 *(Algebraic gauge derivations).* The formula

$$D_\lambda(\mu_r e(\gamma)\mu_s^*) = \lambda(r/s)\mu_r e(\gamma)\mu_s^*$$

defines a derivation. The map $\lambda \mapsto [D_\lambda]$ injects W into $HH^1_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}})$. Every nonzero D_λ is unbounded in the inherited C^*-norm and has no bounded spatial implementer on $\mathcal{L}$. Moreover $HH^0_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}}) = \mathbb{C}$.

Proof. Gauge averaging against characters decomposes the normal algebra as

$$A_{\mathrm{alg}} = \bigoplus_{g \in \mathbb{Q}^\times_{>0}} (A_{\mathrm{alg}})_g, \qquad (A_{\mathrm{alg}})_g (A_{\mathrm{alg}})_h \subseteq (A_{\mathrm{alg}})_{gh}.$$

This uses homogeneous components, and does not assert independence of normal terms of the same degree. Multiplying the component of degree g by $\lambda(g)$ is consequently well defined. Since $\lambda(gh) = \lambda(g) + \lambda(h)$, it is a derivation.

One-cocycles are derivations and one-coboundaries are inner derivations. If $D_\lambda = [b, -]$ for a bounded operator b, the norm-one isometries μ_p^k give

$$k|\lambda_p| = \|D_\lambda(\mu_p^k)\| \le 2\|b\| \qquad (k \ge 1).$$

Thus $\lambda_p = 0$ for every prime. This also proves injectivity on classes by taking differences, and proves unboundedness for every nonzero family.

An operator commuting with all phases is diagonal: any two distinct integer indices are separated by some character $\exp(2\pi i m\gamma)$. Write it as $T\delta_m = t_m \delta_m$. Commutation with every shift requires $t_{nm} = t_m$, hence $t_n = t_1$. The represented commutant is scalar. Faithfulness gives the asserted center and degree-zero cohomology. □

The derivation preserves adjoint exactly when every λ_p is purely imaginary. This follows by comparing its values on μ_p and μ_p^*. The product $\prod_p \mathbb{C}$ parametrizes algebraic derivations. It is not a convergent sum of bounded operators.

Finite cycles detecting every exterior degree

There is a character $\varepsilon : A_{\mathrm{BC}} \to \mathbb{C}$ defined by

$$\varepsilon(\mu_n) = \varepsilon(\mu_n^*) = \varepsilon(e(\gamma)) = 1.$$

The presentation verifies every relation, including the transfer average of n ones. This is a norm-one unital star homomorphism. It is different from the vacuum vector state, which takes μ_p to zero.

Let $\mathbb{C}_\varepsilon$ be the bimodule with left and right actions through ε. Composition of a regular-coefficient cochain with ε is a cochain map. For clarity, the two differentials are

$$\begin{aligned}(bF)(a_1, \dots, a_{n+1}) &= a_1 F(a_2, \dots, a_{n+1}) \\ &\quad + \sum_{i=1}^{n} (-1)^i F(a_1, \dots, a_i a_{i+1}, \dots, a_{n+1}) \\ &\quad + (-1)^{n+1} F(a_1, \dots, a_n) a_{n+1},\end{aligned}$$

and

$$\begin{aligned} b\big(c[a_1|\cdots|a_n]\big) = {} & c\varepsilon(a_1)[a_2|\cdots|a_n] \\ & + \sum_{i=1}^{n-1}(-1)^i c[a_1|\cdots|a_i a_{i+1}|\cdots|a_n] \\ & + (-1)^n \varepsilon(a_n) c[a_1|\cdots|a_{n-1}]. \end{aligned}$$

Evaluation makes these formulas dual after changing cochain coefficients by ε.

For distinct primes $P = (p_1, \dots, p_n)$, write $s_j = \mu_{p_j}$ and set

$$c_P = \sum_{\pi \in S_n} \operatorname{sgn}(\pi) 1[s_{\pi(1)}|\cdots|s_{\pi(n)}].$$

This is a cycle with coefficients in $\mathbb{C}_\varepsilon$. For an interior face, exchange the adjacent multiplied factors: they commute and their permutation signs are opposite. For the outer faces, pair a word with its cyclic rotation. Rotation has sign $(-1)^{n-1}$ and the last face has sign $(-1)^n$, so those terms cancel as well. For $n = 1$ the boundary is directly zero.

Therefore

$$L_P(F) = \sum_{\pi \in S_n} \operatorname{sgn}(\pi) \varepsilon\big(F(s_{\pi(1)}, \dots, s_{\pi(n)})\big)$$

vanishes on every regular-coefficient coboundary.

THEOREM 21.9.2 *(An exterior algebra of gauge classes).* Cup product defines an injective graded-algebra map

$$\Lambda^*_{\mathbb{C}} W \hookrightarrow HH^*_{\mathrm{alg}}(A_{\mathrm{alg}}, A_{\mathrm{alg}}), \qquad \lambda \longmapsto [D_\lambda].$$

The exterior algebra consists of finite sums of finite wedges. It has no completion in this statement.

Proof. The cup of n derivations is the cochain

$$F_{\lambda_1,\dots,\lambda_n}(a_1, \dots, a_n) = D_{\lambda_1}(a_1) \cdots D_{\lambda_n}(a_n).$$

The cochain differential obeys the graded product rule, as follows by cancellation of its interior multiplication terms. Hence this cup is a cocycle. For two derivations D, E, expansion of the Leibniz rules gives

$$b(DE)(a, b) = -D(a)E(b) - E(a)D(b).$$

Their classes anticommute, and their squares vanish over $\mathbb{C}$. This constructs the exterior-algebra map.

The finite cycle evaluation is exactly

$$L_P(F_{\lambda_1,\dots,\lambda_n}) = \det\big(\lambda_i(p_j)\big)_{1 \le i,j \le n}.$$

Every exterior element belongs to $\Lambda^* U$ for some finite-dimensional subspace $U \subset W$. Prime-coordinate functionals separate points of U, so they span U^*. Otherwise their span would have a nonzero annihilator whose every prime coordinate vanished. A finite selection already spans U^*, and its exterior products detect every nonzero element of $\Lambda^n U$.

The corresponding L_P proves injectivity in degree n. The character detects degree zero. □

For two distinct primes, the cycle is $1[\mu_p|\mu_q] - 1[\mu_q|\mu_p]$. Its boundary is zero term by term after commuting the shifts, and $L_{(p,q)}(D_p \smile D_q) = 1$, where D_p is the coordinate derivation. For three primes the six-term alternating cycle gives $L_{(p,q,r)}(D_p \smile D_q \smile D_r) = 1$. Thus these lower bounds are nonzero in every degree. They are not a classification of all Hochschild classes.

21.10 Smooth algebras and the time generator

The topological domain changes the gauge calculation. For a finite prime set F, let B_F consist of the elements whose orbit under the finite torus $\mathbb{T}^F \subset K$ is norm-smooth. Angular derivatives are denoted δ_p, so $\delta_p(\mu_q) = i\delta_{pq}\mu_q$ and $D_p = \delta_p/i$. For a nonnegative multiindex α supported in F, put

$$q_\alpha(a) = \|\delta^\alpha a\|, \qquad q_0(a) = \|a\|.$$

Define

$$B_{\mathrm{g}} = \bigcap_{F \text{ finite}} B_F$$

with all these finite-support seminorms. This uses smoothness on ordinary finite-dimensional tori.

Proposition 21.10.1 *(Smooth gauge cohomology).* The spaces B_F and B_{g} are Fréchet star algebras, norm-dense in A_{BC}. For jointly continuous multilinear cochains with regular coefficients, there are injections

$$\Lambda^*\left(\bigoplus_{p\in F} \mathbb{C}D_p\right) \hookrightarrow HH^*_{\mathrm{cont}}(B_F, B_F), \qquad \Lambda^*\left(\bigoplus_{p} \mathbb{C}D_p\right) \hookrightarrow HH^*_{\mathrm{cont}}(B_{\mathrm{g}}, B_{\mathrm{g}}).$$

Proof. For B_F, a Cauchy sequence in every seminorm gives orbit maps that are Cauchy in every uniform derivative norm. Smooth Banach-valued functions on a compact torus are complete. The fundamental theorem of calculus identifies the uniform limit of first derivatives with the derivative of the uniform limit. Iteration handles every order. The limit orbit is $\alpha_z(a)$ for the norm limit a. Thus B_F is complete.

There are countably many finite-support multiindices. A Cauchy sequence for B_{g} converges in every B_F, and all limits agree with its norm limit. This proves completeness and metrizability. The iterated product rule

$$\delta^\alpha(ab) = \sum_{\beta\le\alpha} \binom{\alpha}{\beta} (\delta^\beta a)(\delta^{\alpha-\beta} b)$$

proves continuous multiplication. Real angular derivatives commute with adjoint. Normal sums lie in every smooth algebra and are norm-dense.

Each permitted D_p is continuous, with its seminorm bounded by the seminorm having one additional p derivative. For B_{g} this follows by differentiating on $F \cup \{p\}$ before restricting to F. Finite cup cochains are consequently continuous. The character is continuous because $|\varepsilon(a)| \le q_0(a)$. The finite cycles and determinant evaluations of Theorem 21.9.2 therefore detect these continuous cohomology classes as well. □

Proposition 21.10.2 *(The continuity criterion).* The algebraic D_λ extends to a continuous linear map $B_{\mathrm{g}} \to A_{\mathrm{BC}}$ exactly when λ has finite support. It then extends as a continuous derivation $B_{\mathrm{g}} \to B_{\mathrm{g}}$. On B_F the criterion is support contained in F.

Proof. Continuity would give

$$\|D_\lambda(a)\| \le C \max_{\alpha\in E} q_\alpha(a)$$

for some finite set E of multiindices, including zero. Let F_0 contain their supports. For $q \notin F_0$, every positive derivative on the right vanishes on μ_q^k, while its norm is one. Hence $k|\lambda_q| \le C$ for all k, forcing $\lambda_q = 0$. On B_F the same argument excludes every $q \notin F$. Conversely a finite linear combination of the permitted continuous derivatives has the required extension. □

This criterion concerns this particular family of derivations. It does not classify every continuous derivation of these algebras.

It also separates gauge smoothness from physical-time smoothness. Enumerate distinct primes p_j and form

$$a = \sum_{j \geq 1} 2^{-j} \mu_{p_j}^{2^j}.$$

The series converges in norm. Only finitely many terms move under any fixed finite prime torus, so $a \in B_{\mathrm{g}}$.

If its time derivative existed in norm, applying it to δ_1 would give coordinate $i \log p_j$ at each distinct basis vector $\delta_{p_j^{2^j}}$. Those coordinates are not square summable. Thus a is not even norm-differentiable under σ.

Closed differentiation in physical time

Let δ be the norm generator of σ:

$$\operatorname{Dom} \delta = \left\{ a : \lim_{t \to 0} \frac{\sigma_t(a) - a}{t} \text{ exists in norm} \right\}.$$

Every normal term is entire analytic, and

$$\delta(\mu_r e(\gamma) \mu_s^*) = i \log(r/s) \mu_r e(\gamma) \mu_s^*.$$

The domain is dense and proper. For a direct one-prime example of properness, use $\sum_{j \geq 1} 2^{-j} \mu_p^{2^j}$. The derivative on δ_1 would have the same nonzero coordinate $i \log p$ at infinitely many states.

The generator is closed. For a in its domain, differentiating the orbit gives the Bochner integral identity

$$\sigma_t(a) - a = \int_0^t \sigma_s(\delta a)\, ds.$$

If $a_n \to a$ and $\delta a_n \to b$ in norm, isometry permits passage to the limit. Division by t and norm continuity then give $\delta a = b$.

The norm-smooth orbit algebra is

$$A_\sigma^\infty = \bigcap_{j \geq 0} \operatorname{Dom} \delta^j, \qquad p_k(a) = \sum_{j=0}^{k} \|\delta^j a\|.$$

Repeated differentiation identifies this intersection with smoothness of the orbit. Closedness of δ, applied successively to a Cauchy sequence of derivatives, proves completeness. The iterated Leibniz rule proves continuous multiplication, and adjoint is continuous. Thus it is a dense Fréchet star algebra. The estimate $p_k(\delta a) \leq p_{k+1}(a)$ makes δ continuous on it.

The class of δ in $HH^1_{\mathrm{cont}}(A_\sigma^\infty, A_\sigma^\infty)$ is nonzero. An inner implementer would be a bounded element of A_{BC}, contrary to the prime-power estimate in Proposition 21.9.1. Here the algebraic family is $\lambda_p = i \log p$. Its infinite support also explains why it does not extend continuously from the gauge-smooth topology.

In the occupation representation it has an unbounded spatial implementer. Normal terms preserve $\operatorname{Dom} H$, since their nonzero action changes the logarithmic weight by the constant $\log(r/s)$. On that domain,

$$[H, \mu_r e(\gamma) \mu_s^*] = \log(r/s) \mu_r e(\gamma) \mu_s^*, \qquad \delta = i[H, -].$$

Truncation in the weighted norm proves the finite-support core assertion for H and justifies passage from basis vectors to its maximal domain. The scalar commutant computed above and the bicommutant theorem give $A_{\mathrm{BC}}'' = B(\mathcal{L})$ in this representation. A GNS representation from a specified KMS state is another carrier and need not have this weak closure.

Logarithmic dilation and an actual circle quotient

Logarithmic coordinates give a useful comparison of continuous actions. The map

$$Uf(t) = f(e^t) : L^2(\mathbb{R}_{>0}, dr/r) \xrightarrow{\sim} L^2(\mathbb{R}, dt)$$

is unitary. For $D_a f(r) = f(e^{-a} r)$, substitution gives $U D_a U^{-1} F(t) = F(t - a)$.

Fix $L > 0$. The quotient group $\mathbb{R}_{>0}/e^{L\mathbb{Z}}$ instead becomes $\mathbb{R}/L\mathbb{Z}$. With measure dt on $[0, L)$, its orthonormal Fourier basis is

$$L^{-1/2} e^{2\pi i n t/L}, \qquad n \in \mathbb{Z}.$$

Inverse translation has eigenvalue $e^{-2\pi i n a/L}$ on this basis. The logarithm gives the quotient isomorphism, and Fourier orthogonality proves the normalization.

This circle Hilbert space is not a nonzero periodic subspace of $L^2(\mathbb{R}, dt)$. The squared norm of a periodic function is the sum of its identical integrals over disjoint periods. It is finite only when the function is zero almost everywhere.

A period L for Bost–Connes time would require $L \log n \in 2\pi\mathbb{Z}$ for every surviving shift. It cannot hold for both $n = 2$ and $n = 3$. Otherwise $\log 2/\log 3$ would be rational, implying $2^a = 3^b$ for positive integers a, b, contrary to unique factorization. A circle KMS comparison therefore needs its actual quotient or representation, periodic dynamics, state and intertwiner. The logarithmic coordinate alone does not construct these data.

Question 21.10.3 *(The arithmetic Hochschild comparison).* Specify an arithmetic category or algebra, its coefficient ring, trace bimodule, grading, topology and completion. Construct its comparison with the Bost–Connes normal algebra or one of the stated smooth algebras. Determine which gauge classes survive and whether the arithmetic theory has an integral degree-one carrier generated by logarithmic prime data. An integral lattice, a degree bound, or a map to a Witt cotangent complex requires its own construction.

For a Hilbert realization, fix a pre-Hilbert space L_{alg} and an arithmetic trace complex $(C_\bullet, b)$. Give a cycle map $J : L_{\mathrm{alg}} \to Z_d(C_\bullet)$ and a positive semidefinite form q on $H_d(C_\bullet)$. If

$$q([Jv], [Jw]) = \langle v, w \rangle,$$

then $v \mapsto [Jv]$ induces an isometry from the completion of L_{alg} into the completion of $H_d(C_\bullet)/\ker q$. Density is needed for surjectivity onto a proposed sector. The action on homology and its intertwining with J are additional data. The occupation representation by itself does not supply them.

21.11 Explicit positive local pairings

A bilinear evaluation becomes a Hermitian form only after specifying an antilinear map in one slot. We use inner products linear in the first variable throughout this section. The following models calculate the map, its normalization, and its domain.

The Segal form and an archimedean line

Let $\mathscr{F}_{\mathrm{alg}}$ be the Heisenberg vacuum module generated by α_{-n}, $n \geq 1$, with

$$[\alpha_m, \alpha_n] = m\delta_{m+n,0}, \qquad \alpha_n\Omega = 0 \quad (n > 0).$$

Normalize $H_\infty(\Omega, \Omega) = 1$ and impose $\alpha_{-n}^\dagger = \alpha_n$. For a finite occupation array $\mathbf{r} = (r_1, r_2, \ldots)$, put $v_{\mathbf{r}} = \prod_n \alpha_{-n}^{r_n}\Omega$. Commuting each annihilation operator to the right gives

$$H_\infty(v_{\mathbf{r}}, v_{\mathbf{s}}) = \delta_{\mathbf{r},\mathbf{s}} \prod_n n^{r_n} r_n!.$$

The factorial counts repeated contractions of the same mode. The factor n comes from its commutator. Equivalently, for two monomials of lengths k, l,

$$H_\infty(\alpha_{-n_1}\cdots\alpha_{-n_k}\Omega, \alpha_{-m_1}\cdots\alpha_{-m_l}\Omega) = \delta_{kl} \sum_{\pi\in S_k} \prod_{i=1}^{k} n_i \delta_{n_i, m_{\pi(i)}}.$$

This defines a positive form and its Segal Hilbert completion.

Let J_∞ conjugate coefficients in the monomial basis. The Gram matrix is real, so J_∞ is an isometric antilinear involution. The bilinear form

$$B_\infty(v, w) = H_\infty(v, J_\infty w)$$

is bounded by $\|v\|\|w\|$, extends to the completion, and satisfies $B_\infty(v, J_\infty w) = H_\infty(v, w)$. The complex-linear identity cannot replace J_∞: on the vacuum, $B_\infty(\Omega, i\Omega) = i$ while $H_\infty(\Omega, i\Omega) = -i$.

There is also an explicit archimedean comparison of lines. On $\mathbb{R}^\times$ use measure $da/|a|$ and set

$$W_0(a) = |a|^{1/2} K_0(2\pi|a|), \qquad K_0(x) = \int_0^\infty e^{-x\cosh u}\, du \quad (x > 0).$$

This is the parameter-zero spherical Whittaker function in the chosen normalization. Its squared norm is $\pi/4$. To see the constant, Tonelli gives

$$\int_0^\infty K_0(x)^2\, dx = \int_0^\infty \int_0^\infty \frac{du\, dv}{\cosh u + \cosh v}.$$

Put $a = (u + v)/2$ and $b = (u - v)/2$. The Jacobian is two, the region is $a \geq 0$, $|b| \leq a$, and the denominator is $2\cosh a \cosh b$. With $F(a) = \int_0^a \operatorname{sech} b\, db$, the integral is

$$2\int_0^\infty F'(a)F(a)\, da = F(\infty)^2 = \frac{\pi^2}{4}.$$

Scaling $x = 2\pi|a|$ and including both signs gives $\|W_0\|^2 = \pi/4$.

Hence

$$\mathbb{C}\Omega \longrightarrow \mathbb{C}W_0, \qquad z\Omega \longmapsto \frac{2z}{\sqrt{\pi}} W_0$$

is an isometry. Extending it to a full Whittaker or arithmetic representation requires an intertwiner for the specified actions. A line isometry does not determine one.

Weighted occupations and two isometries

Fix a prime p, and define

$$H_{\mathrm{occ},p} = \ell^2(\mathbb{N}_0, p^{-j}), \qquad H_{\mathrm{occ}}(v,w) = \sum_{j\ge 0} p^{-j} v_j \overline{w_j}.$$

Its coordinate vector δ_j has squared norm p^{-j}. The raw shift $R\delta_j = \delta_{j+1}$ has norm $p^{-1/2}$, and $\sqrt{p}\,R$ is an isometry. Coordinate conjugation J_{occ} gives the continuous bilinear form

$$B_{\mathrm{occ}}(v,w) = \sum_{j\ge 0} p^{-j} v_j w_j, \qquad B_{\mathrm{occ}}(v, J_{\mathrm{occ}} w) = H_{\mathrm{occ}}(v,w).$$

Cauchy–Schwarz proves absolute convergence and continuity.

Let E_{ij} be the matrix units on $\ell^2(\mathbb{N}_0)$. Choose a multiplicative Haar measure on $\mathbb{Q}_p^\times$ and put $m_p = \mathrm{vol}(\mathbb{Z}_p^\times) > 0$. There are isometries

$$D\delta_j = p^{-j/2} E_{jj}, \qquad T\delta_j = p^{-j/2} m_p^{-1/2} \mathbf{1}_{p^j \mathbb{Z}_p^\times}. \tag{21.3}$$

Their ranges are the diagonal Hilbert–Schmidt subspace and the closed radial-function subspace supported on nonnegative valuations, respectively.

Indeed matrix units are Hilbert–Schmidt orthonormal. The disjoint shells $p^j \mathbb{Z}_p^\times$ each have multiplicative measure m_p. Both displayed families therefore have Gram matrix $p^{-j}\delta_{jk}$. Finite spans are dense in the stated ranges, proving the isometric extensions.

Their basis vectors are fixed by adjunction or function conjugation. Thus

$$H_{\mathrm{occ}}(v,w) = \mathrm{Tr}(Dv(Dw)^*) = \int_{\mathbb{Q}_p^\times} Tv(a)\overline{Tw(a)}\, d^\times a.$$

Also $B_{\mathrm{occ}}(v,w) = \mathrm{Tr}(DvDw)$.

The diagonal Hilbert–Schmidt range is not invariant under left multiplication by the shift. For example, $VE_{jj} = E_{j+1,j}$. Consequently this isometry does not identify the whole prime GNS representation. Nor can its dual basis be realized as $\mu^*_{p^j}\delta_1$ in the occupation representation: those vectors vanish for $j > 0$.

The spherical norm depends on the representation

Fix a normalized unramified tempered representation π_p of $GL_2(\mathbb{Q}_p)$, with Satake parameters $|\alpha| = |\beta| = 1$ and an additive character of conductor $\mathbb{Z}_p$. Its spherical Whittaker function normalized by $W(1) = 1$ has shell values

$$W(\mathrm{diag}(p^j, 1)) = p^{-j/2} h_j(\alpha,\beta), \qquad h_j(\alpha,\beta) = \sum_{r=0}^{j} \alpha^{j-r}\beta^r \quad (j \ge 0),$$

and vanishes at negative valuations. We use this standard spherical Whittaker formula with the stated normalization.

Proposition 21.11.1 *(The full spherical norm).* For $\mathrm{Re}\, s > 0$,

$$Z_p(s) = \int_{\mathbb{Q}_p^\times} |W(a)|^2 |a|^{s-1}\, d^\times a = m_p \frac{L_p(s, \pi_p \times \widetilde{\pi}_p)}{\zeta_p(2s)}.$$

In particular,

$$C_p = \|W\|^2 = m_p(1 + p^{-1}) L_p(1, \mathrm{Ad}\,\pi_p) > 0.$$

Proof. Shell integration gives $Z_p(s) = m_p \sum_{j\ge 0} |h_j|^2 p^{-js}$. The bound $|h_j| \le j+1$ proves absolute convergence on the indicated half-plane. Put $r = \alpha/\beta$. For $|x| < 1$, geometric summation gives

$$\sum_{j\ge 0} |h_j|^2 x^j = \frac{1+x}{(1-x)(1-rx)(1-r^{-1}x)}.$$

For $r \ne 1$, expand $|h_j|^2 = (2 - r^{j+1} - r^{-j-1})/|1-r|^2$ and sum its three geometric series. For $r = 1$, use $\sum_{j\ge 0}(j+1)^2 x^j = (1+x)/(1-x)^3$.

The Rankin–Selberg denominator is $(1-x)^2(1-rx)(1-r^{-1}x)$. Multiplication by $1-x^2$ proves the formula with $x = p^{-s}$. Since

$$L_p(s, \pi_p \times \widetilde{\pi}_p) = \zeta_p(s) L_p(s, \operatorname{Ad} \pi_p),$$

evaluation at one gives C_p. It is a positive norm, and its denominator factors are nonzero because $p^{-1} < 1$. □

For $d^\times a = da/|a|$ with additive unit volume, $m_p = 1 - p^{-1}$ and $C_p = (1-p^{-2}) L_p(1, \operatorname{Ad}\pi_p)$. In contrast, the compact subgroup volume for the invariant matrix measure $|\det g|^{-2} \prod dg_{ij}$ is

$$\operatorname{vol}(GL_2(\mathbb{Z}_p)) = \frac{(p^2-1)(p^2-p)}{p^4} = (1-p^{-1})(1-p^{-2}).$$

Reduction modulo p proves this formula by counting the two independent columns. It is not the Whittaker norm, which depends on α/β. Inserting an additional $|a|^{-1}$ into the norm integral changes the question to $Z_p(0)$. For $\alpha = \beta = 1$, the resulting shell series is $m_p \sum_{j\ge 0}(j+1)^2$ and diverges.

The radial isometry of (21.3) identifies

$$W = T\left(\sqrt{m_p} \sum_{j\ge 0} h_j(\alpha,\beta)\, \delta_j\right).$$

This vector converges in $H_{\mathrm{occ},p}$ and has squared norm C_p. It is generally different from $T\delta_0$. Unit normalization uses $W/\sqrt{C_p}$. Dividing a pairing by the adjoint factor alone gives spherical squared norm $m_p(1+p^{-1})$, rather than one.

21.12 The prime Gibbs state and its modular conjugation

The full prime cyclic space can also be constructed explicitly. Let $K_0 = \ell^2(\mathbb{N}_0)$, $V e_j = e_{j+1}$, and $H_p e_j = j \log p\, e_j$, with maximal domain $\{\xi : \sum j^2 |\xi_j|^2 < \infty\}$. For $\beta > 0$, put

$$q = p^{-\beta}, \qquad r_j = (1-q)q^j, \qquad \rho e_j = r_j e_j.$$

The positive injective operator ρ has trace one. Its state on the Toeplitz algebra $\mathcal{T} = C^*(V)$ is

$$\varphi_{p,\beta}(a) = \operatorname{Tr}(\rho a), \qquad \varphi_{p,\beta}(V^m V^{*n}) = \delta_{mn} q^m.$$

The physical time is $\alpha_t(a) = e^{itH_p} a e^{-itH_p}$, with $\alpha_t(V) = p^{it} V$.

This is the unique β-KMS state on $(\mathcal{T}, \alpha)$. On analytic monomials, $\rho a = \alpha_{i\beta}(a)\rho$, so the KMS identity follows by trace cyclicity. Conversely that identity with second entry one kills each monomial of nonzero degree. With first entry V^m and second entry V^{*m}, it gives the value q^m. Density of the analytic monomials proves uniqueness.

Proposition 21.12.1 *(The Hilbert–Schmidt GNS model).* The GNS space and representation are

$$\mathcal{H}_{p,\beta} = \mathrm{HS}(K_0), \qquad \pi(a)X = aX, \qquad \Omega = \rho^{1/2},$$

with inner product $\langle X, Y\rangle = \mathrm{Tr}(XY^*)$. The GNS map is $[a] \mapsto a\rho^{1/2}$. The vector Ω is cyclic and separating for left $B(K_0) = \pi(\mathcal{T})''$.

Proof. The map is isometric because its inner product is $\mathrm{Tr}(\rho b^* a) = \varphi_{p,\beta}(b^* a)$. The matrix units $E_{ij} = V^i(1 - VV^*)V^{*j}$ belong to $\mathcal{T}$, and $E_{ij}\rho^{1/2} = \sqrt{r_j}E_{ij}$. They span a dense subspace of $\mathrm{HS}(K_0)$. Finite matrix corners strongly approximate bounded operators, proving the weak-closure assertion. If $a\Omega = 0$, every column of a vanishes because $r_j > 0$ for all j. Thus Ω is separating. □

Define the antilinear operator $S_0(a\Omega) = a^*\Omega$ on $\mathcal{T}\Omega$.

Proposition 21.12.2 *(Closed modular operators and their domains).* Set $JX = X^*$. For $X = \sum x_{ij}E_{ij}$, the positive modular operator satisfies

$$\Delta E_{ij} = q^{i-j}E_{ij}, \qquad \mathrm{Dom}\,\Delta^a = \left\{X : \sum_{i,j} q^{2a(i-j)}|x_{ij}|^2 < \infty\right\} \quad (a \in \mathbb{R}).$$

One has $\overline{S_0} = J\Delta^{1/2}$ and

$$\Delta^{it}X = e^{-i\beta t H_p} X e^{i\beta t H_p}.$$

The modular action on left multiplication is physical time $\alpha_{-\beta t}$. Both Δ and Δ^{-1} are unbounded.

Proof. On matrix units, $S_0 E_{ij} = q^{(i-j)/2}E_{ji}$ antilinearly. Truncation of a convergent weighted double sum makes finite matrix sums graph-dense in the displayed domain for $a = 1/2$. For bounded a, the vector $a\Omega$ belongs to that domain and the formula gives $a^*\Omega$. It follows that the closure is precisely $J\Delta^{1/2}$. Diagonal spectral calculus proves all powers and the unitary group. Its eigenvalues range through $q^{\mathbb{Z}}$, proving both unboundedness assertions. □

The logarithm has eigenvalue $(i - j)\log q$ on E_{ij} and maximal domain $\{X : \sum |(i - j)\log q|^2|x_{ij}|^2 < \infty\}$. The conjugation acts on prime-shift vectors by

$$J(V^k\Omega) = p^{\beta k/2}V^{*k}\Omega, \qquad J(V^{*k}\Omega) = p^{-\beta k/2}V^k\Omega.$$

Expand $V^k\Omega = \sum_j \sqrt{r_j}E_{j+k,j}$ and use $r_{j+k} = q^k r_j$ to verify the factors. In particular $\|V^k\Omega\| = 1$ and $\|V^{*k}\Omega\| = q^{k/2}$. The algebra star operation alone is not this antiunitary on the cyclic space.

For left and right multiplication, $JL_aJ = R_{a^*}$. The continuous bilinear form $B(X, Z) = \mathrm{Tr}(XZ)$ satisfies

$$B(X, JY) = \mathrm{Tr}(XY^*) = \langle X, Y\rangle.$$

The product of two Hilbert–Schmidt operators is trace class and $|\mathrm{Tr}(XZ)| \le \|X\|_2\|Z\|_2$, which proves the asserted continuity.

Proposition 21.12.3 *(Comparison with a specified prime cyclic space).* Let $(\mathcal{A}, \alpha, \psi_\beta)$ be a dynamical C^*-algebra with a β-KMS state and an isometry μ_p satisfying $\alpha_t(\mu_p) = p^{it}\mu_p$. The map $\iota_p : \mathcal{T} \to \mathcal{A}$ sending V to μ_p induces a unitary

$$U_p : \mathrm{HS}(K_0) \longrightarrow \overline{\pi_{\psi_\beta}(C^*(\mu_p))\Omega_{\psi_\beta}}, \qquad a\rho^{1/2} \longmapsto \pi_{\psi_\beta}(\iota_p(a))\Omega_{\psi_\beta}.$$

It preserves the prime algebra action, cyclic vector, and closed modular operators of this restricted cyclic representation, including when $\beta = 1$.

Proof. The pulled-back state is a KMS state on $\mathcal{T}$, so uniqueness identifies it with $\varphi_{p,\beta}$. The displayed map is therefore isometric on $\mathcal{T}\rho^{1/2}$ and has dense image in the specified cyclic subspace. It extends to a unitary. It intertwines multiplication and $a\Omega \mapsto a^*\Omega$ on the core, hence their closures and polar decompositions. □

The target is the prime-generated cyclic subspace, not the whole global GNS space. Its identification says nothing yet about additional phase operators or an arithmetic automorphic placement. For finitely many primes, tensoring the densities and matrix formulas gives their finite Gibbs and GNS products for every $\beta > 0$. The global occupation heat trace still diverges at $\beta = 1$, as (21.2) shows.

21.13 Restricted tensor pairings and arithmetic placement

Choose complex Hilbert spaces (H_v, e_v) indexed by the places, with unit reference vectors. Suppose each has a conjugation J_v, with $J_v e_v = e_v$, and a bilinear form $B_v(x, J_v y) = H_v(x, y)$. The algebraic restricted tensor consists of elementary tensors equal to e_v outside a finite set.

PROPOSITION 21.13.1 *(Assembly of normalized forms).* There are forms

$$H(\otimes'_v x_v, \otimes'_v y_v) = \prod_v H_v(x_v, y_v), \qquad B(\otimes'_v x_v, \otimes'_v y_v) = \prod_v B_v(x_v, y_v),$$

and a conjugation $J = \otimes'_v J_v$. They extend to the Hilbert restricted tensor product, where $H(x, y) = B(x, Jy)$. Its reference vector has squared norm one.

Proof. At each finite set of places, use the Hilbert tensor form. Enlarging the set tensors with unit reference vectors, so its insertion maps are isometries. The directed union is a pre-Hilbert space. The local conjugations give compatible antilinear isometries, whose square is the identity. They extend to a conjugation on its completion.

Define $B(x, y) = H(x, Jy)$ there. It is bounded and agrees with the displayed finite products. All omitted reference factors equal one. □

Raw local norms cannot be multiplied without addressing convergence. For the invariant matrix measure on $GL_n(\mathbb{Q}_p)$,

$$\operatorname{vol}(GL_n(\mathbb{Z}_p)) = \prod_{j=1}^{n} (1 - p^{-j}).$$

Counting independent columns modulo p proves this identity. The product of its $j = 1$ factors tends to zero. The factors with $j \geq 2$ multiply to $\prod_{j=2}^{n} \zeta(j)^{-1}$.

A Tamagawa measure inserts its convergence factors, global residue normalization, and rational-character quotient. It is not the raw product of these volumes. Nor does the volume of an automorphic quotient determine the Petersson norm of a specified cusp form.

For example, with the Tamagawa measure disintegrated along $|\det|$ using dt/t, the volume of

$$GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})^1, \qquad GL_2(\mathbb{A})^1 = \ker |\det|_{\mathbb{A}},$$

is one. This is the classical Tamagawa number in its rational-character normalization, as in Lai, Section 1.7 and Theorem 7.1.

In that formula the split diagonal torus has Tamagawa number one. Restricting its character (a, b) to the scalar torus and the derived diagonal torus gives $(a + b, a - b)$, a sublattice of index two. The central characters trivial on their intersection μ_2 are also a sublattice of index two. The two index factors cancel, giving $\tau(GL_2) = \tau(\mathbb{G}_m^2) = 1$.

This global volume calculation does not normalize the vector W or an individual automorphic form.

The local spherical factors are likewise representation dependent. If a specified global adjoint L-function continues holomorphically to one with $c_\pi = L(1, \operatorname{Ad}\pi) \neq 0$, then $c_\pi^{-1}B$ is a well-defined rescaled pairing. Rescaling both sides of a pairing identity by that same scalar preserves the identity. It does not prove ordinary convergence of the local product at one.

For tempered unramified parameters and $\sigma > 1$, the adjoint logarithmic series has the bound

$$\sum_p \sum_{j \geq 1} \frac{3p^{-j\sigma}}{j} \leq \frac{3}{1 - 2^{-\sigma}} \sum_p p^{-\sigma} < \infty.$$

This gives an initial half-plane of absolute convergence. Continuation and nonvanishing at one are additional analytic inputs for the representation in question. Finitely many ramified factors require their own normalization and pole conditions.

Hypothesis 21.13.2 *(Arithmetic pairing comparison).* Fix an arithmetic state space V, a dual coefficient space $V^!$, a bilinear evaluation $B^{\mathrm{Ar}} : V \otimes V^! \to \mathbb{C}$, and an antilinear map $\sigma : V \to V^!$. Specify an injective placement ι of a common dense domain into an automorphic Hilbert space with fixed central character and fixed Haar normalization. At each place require maps on both pairing carriers, preserving the stated actions. They must carry the evaluation to a chosen local model and σ to its conjugation.

Require the maps to preserve the reference vectors at almost all places and to identify the placed local Petersson form with the model Hermitian form. Specify the resulting adelic factorization with a common global scalar. Finally require continuous extension on the stated completion, or a specified regularized extension compatible with those maps. Every included ramified, residual, or continuous sector requires its own local maps and normalization.

Proposition 21.13.3 *(The conditional Koszul–Petersson identity).* Under Hypothesis 21.13.2, on its specified domain,

$$\langle \iota v, \iota w \rangle_{\mathrm{Pet}} = B^{\mathrm{Ar}}(v, \sigma w).$$

If the placement is into an actual L^2 space, this transported Hermitian form is positive definite.

Proof. For elementary restricted tensors, the local model identity $H_v(x, y) = B_v(x, J_v y)$ gives equality at each place. The reference normalization and common global scalar make their finite products equal. The stipulated extension carries the equality to its stated domain. If $v \neq 0$, injectivity gives $\|\iota v\|^2 > 0$, proving positivity. □

The holomorphic sector supplies concrete local examples. Let $f = \sum_{n \geq 1} a_n q^n$ be a normalized holomorphic cuspidal newform of weight $k \geq 2$, level N and nebentypus χ. At $p \nmid N$, write

$$X^2 - a_p X + \chi(p) p^{k-1} = (X - \alpha_p^{\mathrm{alg}})(X - \beta_p^{\mathrm{alg}}).$$

Deligne's Theorem 8.2 in *La conjecture de Weil I* gives $|\alpha_p^{\mathrm{alg}}| = |\beta_p^{\mathrm{alg}}| = p^{(k-1)/2}$. The unitary parameters $\alpha_p = p^{-(k-1)/2}\alpha_p^{\mathrm{alg}}$ and $\beta_p = p^{-(k-1)/2}\beta_p^{\mathrm{alg}}$ therefore satisfy the hypotheses of the spherical norm calculation.

For a cuspidal weight-one eigenform, Deligne–Serre's Theorem 4.1 constructs the associated continuous complex Galois representation. Its finite-image Frobenius eigenvalues are roots of unity, giving the same unitary conclusion at unramified primes. This is their Corollary 4.2. The archimedean weight-one representation is a limit of discrete series. It is not a discrete-series representation of weight at least two.

These theorems identify the unramified local parameters. They do not supply the arithmetic placement, ramified pairing maps or adelic extension in Hypothesis 21.13.2. Once those data are given on a selected holomorphic sector, the preceding proposition proves its pairing identity. The same implication applies to a selected Maass sector with its own local models and maps.

The positivity implication itself needs no temperedness assumption. Temperedness enters the separate local spherical model above. Using that model for a Maass sector requires the relevant local bounds as well as the arithmetic maps. A local exponent estimate is neither such a map nor an adelic summability statement. For example $\sum_p p^{-25/64}$ diverges, so this power cannot be an absolutely summable prime error bound.

The hypothesis preserves the original comparison problem even on a normalized cuspidal core. An adjunction alone does not identify its counit target with $\mathbb{C}$, its dual carrier with Bost–Connes operators, or its conjugation with an automorphic one. If a placement U intertwines the model conjugation with function conjugation on a dense domain, continuity extends that equality to the completion. In a fixed central-character space, function conjugation naturally lands in the conjugate-character space, which must be included in the specified target.

Positive forms also do not by themselves make an action unitary. One must prove the adjoint identities for its operators on invariant domains and establish any closures used by the representation. The bounded local isometries above provide the pairings and lines they state. The arithmetic intertwiners remain to be constructed.

PROPOSITION 21.13.4 *(Two dense realizations of one pairing).* Let E be a complex vector space with a positive semidefinite Hermitian form q. Suppose linear maps $I : E \to H_1$ and $J : E \to H_2$ have dense images in Hilbert spaces and satisfy

$$q(v, w) = \langle Iv, Iw\rangle_1 = \langle Jv, Jw\rangle_2.$$

Then $Iv \mapsto Jv$ extends uniquely to a unitary $H_1 \to H_2$.

Proof. Both kernels are $\{v : q(v, v) = 0\}$. The proposed map is consequently well defined and isometric on the dense image of I. Extend by continuity. An isometry from a complete space has closed range, and this range contains the dense image of J. It is therefore all of H_2. Density proves uniqueness. □

For a Petersson–chiral comparison, one must construct E, B, σ, I, J with $q(v, w) = B(v, \sigma w)$ on the stated automorphic and chiral carriers. An Arnold or Knizhnik–Zamolodchikov connection further requires bundles over an identified base and a map preserving their connections. A Hilbert-space isometry does not by itself compare those connections.

Meromorphic comparison

Suppose two scalar pairings of specified meromorphic families of vectors extend to meromorphic functions on a connected parameter domain. If the actual comparison identifies them on a nonempty open subset, they agree everywhere meromorphically. Locally clear their poles and apply the identity theorem. Their Laurent coefficients, pole orders and residues then agree.

This implication requires both families and the comparison. The local spherical function $Z_p(s) = m_p L_p(s, \pi_p \times \widetilde{\pi}_p)/\zeta_p(2s)$ uses a rank-four Rankin–Selberg factor. It is not the rank-two standard factor $(1-\alpha p^{-s})^{-1}(1-\beta p^{-s})^{-1}$. It does not imply a universal assertion that every arithmetic pairing has only two Tate boundary poles. A meromorphic line bundle alone has no pole divisor: that divisor belongs to a specified meromorphic section in its local trivializations.

21.14 Instanton sums, Fock traces, and their comparison

An equivariant instanton integral and a trace on symmetric powers weight partitions differently. Their distinction is visible before taking an arithmetic product.

Let $\lambda = (\lambda_1 \geq \lambda_2 \geq \cdots)$ be a partition, with $\lambda_i = 0$ beyond its last row. For a box $s = (i, j)$, define

$$A_\lambda(s) = \lambda_i - j, \qquad L_\lambda(s) = \lambda'_j - i.$$

For a box outside the diagram these integers can be negative. In particular the leg of a box in one partition, measured against a different partition, is not necessarily nonnegative.

For a rank r framing, let $\boldsymbol{\lambda} = (\lambda^{(1)}, \ldots, \lambda^{(r)})$, $|\boldsymbol{\lambda}| = \sum_\alpha |\lambda^{(\alpha)}|$, and choose equivariant parameters $a_1, \ldots, a_r, \epsilon_1, \epsilon_2$. Write $\epsilon_+ = \epsilon_1 + \epsilon_2$ and

$$E_{\alpha\beta}(s) = a_\alpha - a_\beta - \epsilon_1 L_{\lambda^{(\beta)}}(s) + \epsilon_2 (A_{\lambda^{(\alpha)}}(s) + 1).$$

The pure vector-multiplet fixed-point sum is

$$Z_{\mathrm{inst}} = \sum_{\boldsymbol{\lambda}} q^{|\boldsymbol{\lambda}|} \prod_{\alpha,\beta=1}^{r} \prod_{s \in \lambda^{(\alpha)}} \frac{1}{E_{\alpha\beta}(s)(\epsilon_+ - E_{\alpha\beta}(s))}. \tag{21.4}$$

This is a formal series in the instanton-counting parameter q, with rational equivariant coefficients. Specialization requires its denominators to be defined. In the pure-gauge scale convention of Nekrasov–Okounkov, $q = \Lambda^{2r}$. Keeping q explicit avoids confusing that convention with a change in rank. Matter multiplets contribute additional fixed-point factors.

The localization construction uses framed sheaves on $\mathbb{C}^2$, or its projective compactification with a framing at infinity. This is the equivariant instanton sum of Nekrasov and Okounkov. For the signed arm and leg convention, see Alday, Gaiotto and Tachikawa, Appendix B.1.

Proposition 21.14.1 *(The fixed-parameter large-equivariant limit).* For $r = 1$, the one-box coefficient is $1/(\epsilon_1\epsilon_2)$. If $\epsilon_1 \neq 0$ and q are fixed while $\epsilon_2 \to \infty$, the series (21.4) tends coefficientwise in q to 1.

Proof. For the single box, $A = L = 0$ and $E = \epsilon_2$, $\epsilon_+ - E = \epsilon_1$. For a general box in a single partition,

$$E = -\epsilon_1 L + \epsilon_2 (A + 1), \qquad \epsilon_+ - E = \epsilon_1 (L + 1) - \epsilon_2 A.$$

Here $A, L \geq 0$. The first factor has nonzero leading coefficient in ϵ_2. If $A > 0$, the second also grows linearly. If $A = 0$, it is the nonzero constant $\epsilon_1(L+1)$.

Every nonempty partition therefore contributes a coefficient tending to zero. There are only finitely many partitions of each fixed size, so their sum tends to zero as well. □

Thus retaining a term $1 + q$ requires a different scaling or normalization. Such a scaling must be specified and tested on all charges. Even an actual two-term local series would not be the bosonic Euler factor $(1-q)^{-1}$.

The hook-weighted specialization

On the slice $\epsilon_1 = -\epsilon_2 = \hbar \neq 0$, the rank-one denominator of each box is $-\hbar^2 h_\lambda(s)^2$, where $h_\lambda(s) = A_\lambda(s) + L_\lambda(s) + 1$. After setting $x = q/(-\hbar^2)$, the normalized sum is

$$Z_{\mathrm{hook}}(x) = \sum_\lambda \frac{x^{|\lambda|}}{\prod_{s\in\lambda} h_\lambda(s)^2}.$$

The hook-length formula for the irreducible S_n-representation indexed by λ says $f^\lambda = n!/\prod_s h_\lambda(s)$. Decomposing the regular representation of S_n gives $\sum_{\lambda\vdash n}(f^\lambda)^2 = n!$. Consequently

$$\sum_{\lambda\vdash n}\prod_{s\in\lambda} h_\lambda(s)^{-2} = \frac{1}{n!}, \qquad Z_{\mathrm{hook}}(x) = e^x.$$

This is the Plancherel specialization in Nekrasov–Okounkov, Section 3.2. For $n = 2$, the two diagrams each contribute $1/4$, so the coefficient is $1/2$, already different from the coefficient one of $(1-x)^{-1}$.

Substituting $x = p^{-s}$ and multiplying over primes gives $\exp(\sum_p p^{-s})$ when $\operatorname{Re} s > 1$. It retains the first prime-power term of the logarithm of the Euler product. The higher prime powers are different coefficients.

The all-charge Fock trace

Let V be finite-dimensional over $\mathbb{C}$, and let $T \in \operatorname{End}(V)$. Then

$$\sum_{n\geq 0} q^n \operatorname{Tr}(\operatorname{Sym}^n T) = \det(1-qT)^{-1}$$

as a formal series. Triangularize T. On monomials in a triangular basis, the diagonal entries are products of its eigenvalues. Summing their nonnegative multiplicities gives the product of geometric series, proving the identity without a semisimplicity assumption. For the Hilbert direct sum of symmetric powers, $|q|\|T\| < 1$ is a sufficient trace-class condition.

For one oscillator with $T = 1$, every charge occurs once, so its trace is $(1-q)^{-1}$. At $q = p^{-s}$ this is the primon local factor. For a specified unramified Frobenius operator F_p on a rank-r space, the corresponding local trace is $\det(1-p^{-s}F_p)^{-1}$. This rank is the dimension of that coefficient space. It is not inferred from the number of primes in an indexing set.

For $\operatorname{Re} s > 1$, choose the logarithm of $\zeta(s)$ that tends to zero as $\operatorname{Re} s \to +\infty$. Absolute convergence gives

$$\log\zeta(s) = \sum_p \sum_{k\geq 1} \frac{p^{-ks}}{k}. \tag{21.5}$$

The bound $\sum_{p,k} p^{-k\sigma}/k \leq (1-2^{-\sigma})^{-1}\sum_p p^{-\sigma}$ justifies rearrangement. The identical argument applies to the specified unramified factors of a character in a half-plane of absolute convergence.

One may define a local scalar $\mathcal{W}_p(s) = -\log(1-p^{-s})$ by this formula. Identifying it with a Nekrasov–Shatashvili superpotential requires an equivariant family and the actual scaled limit defining that superpotential. The equality (21.5) alone does not construct such a family.

The arithmetic instanton comparison

An arithmetic curve and the framed complex surface used in localization are different geometric inputs. A proposed arithmetic self-product must specify its base category, structure sheaf, moduli problem,

equivariant action, fixed loci and integration theory. Listing prime pairs does not construct those data. Likewise a countable family of local oscillators does not determine a gauge group or its Coulomb branch.

The real parameter in a metrized arithmetic line can be recorded by its Arakelov degree. A unitary character supplies separate phase data. This gives meaningful scalar parameters, but no identification with the Coulomb differences $a_\alpha - a_\beta$ in (21.4) until the comparison maps are supplied. An arithmetic intersection pairing must first specify its arithmetic surface, metrized bundles, and cycle classes.

Question 21.14.2 *(From an arithmetic moduli problem to Euler factors).* Construct an arithmetic moduli problem with an equivariant or motivic integration theory and a comparison to the framed instanton construction. Specify the coefficient ring, potential or vanishing-cycle data when used, and every parameter scaling. Determine whether its all-charge trace is the prescribed Frobenius determinant and prove that comparison on the actual objects. The fixed-parameter limit and hook-weighted specialization above do not supply it.

21.15 Geometric transfer operators and Liouville scaling

The geometric R-matrix construction contains commuting transfer operators, but it retains more than their scalar traces. Suppose $R_{F,W}(u)$ is a compatible family of invertible R-matrices satisfying the Yang–Baxter equation. For a finite-dimensional auxiliary space F and an endomorphism g_F, define

$$T_F(g,u) = \operatorname{Tr}_F\big((g_F \otimes 1)R_{F,W}(u)\big).$$

Assume the family g commutes with the R-matrices on each pair of auxiliary spaces. The Yang–Baxter equation conjugates the two ordered products by the auxiliary R-matrix. Taking the trace over both auxiliary factors therefore gives

$$[T_{F_1}(g,u_1), T_{F_2}(g,u_2)] = 0.$$

For infinite-dimensional auxiliary spaces, the trace needs its specified grading, completion, or convergence condition.

Maulik–Okounkov construct such operators from stable envelopes of Nakajima varieties. Their Theorem 1.3.1 identifies the cohomological degree-two part of the Baxter algebra with modified quantum multiplication by tautological degree-two classes. The modification includes the theta-characteristic sign on curve classes. In the divisor formula, the nonclassical part has the form

$$-\hbar \sum_{\theta\cdot\alpha>0} (\lambda,\alpha)\frac{q^\alpha}{1-q^\alpha} e_\alpha e_{-\alpha},$$

with dual root-space bases and the scalar term fixed by the unit condition. This is a geometric theorem on its equivariant cohomology carrier.

For the Jordan quiver, with one vertex and one loop, the variety $\mathcal{M}(r,n)$ parametrizes framed rank-r torsion-free sheaves on $\mathbb{P}^2$ with second Chern class n. Its Yangian belongs to the affine $\widehat{\mathfrak{gl}}_1$ construction. The integer r is the framing rank and labels the representation. It does not replace the quiver by affine $\mathfrak{gl}_r$. At $r = 1$, the Hilbert-scheme cohomology has its Heisenberg Fock realization. Stable envelopes relate the rank-r cohomology to r such bosonic factors on the equivariant domain.

A comparison with arithmetic Hecke operators must specify the geometric representation, arithmetic representation, parameter map and intertwiner. Commutativity of a Baxter algebra does not erase the R-matrix or its tensor structure. Identifying a scalar instanton partition sum with a holonomy trace requires another comparison. These are additional equalities to construct.

The semiclassical Liouville equation

For Liouville theory with a reference metric $\widetilde{g}$, use

$$S_L(\phi) = \frac{1}{4\pi}\int \left(|d\phi|^2_{\widetilde{g}} + Q\widetilde{R}\phi + 4\pi\mu e^{2b\phi}\right) d\,\mathrm{vol}_{\widetilde{g}}, \qquad Q = b + b^{-1}.$$

The stress tensor and primary weights are

$$T(z) = -(\partial\phi)^2 + Q\partial^2\phi, \qquad c = 1 + 6Q^2, \qquad \Delta_\alpha = \alpha(Q-\alpha)$$

for $V_\alpha = e^{2\alpha\phi}$. These formulas retain the background charge.

Set $\phi_c = 2b\phi$ and hold $\lambda = \pi\mu b^2$ fixed as $b \to 0$. Then the leading rescaled action is

$$b^2 S_L = \frac{1}{16\pi}\int \left(|d\phi_c|^2 + 2\widetilde{R}\phi_c + 16\lambda e^{\phi_c}\right) d\,\mathrm{vol}_{\widetilde{g}} + O(b^2),$$

with the corresponding boundary terms when the surface is represented by a punctured or unbounded coordinate chart. In a flat coordinate its equation of motion is

$$\partial\bar\partial\phi_c = 2\lambda e^{\phi_c}.$$

The exponential interaction survives at fixed nonzero λ. Thus this semiclassical limit is not a free-boson equation. Sending b to zero also sends c to infinity. It does not by itself construct a contraction of Virasoro conformal blocks to free-boson correlators.

The distinction is visible in primary weights. For a heavy scaling $\alpha = \eta/b$,

$$\Delta_\alpha = \frac{\eta(1-\eta)}{b^2} + \eta.$$

For a light scaling $\alpha = b\sigma$,

$$\Delta_\alpha = \sigma + b^2\sigma(1-\sigma).$$

An unscaled nonzero α has a different asymptotic behavior. A proposed limiting operator must specify which scaling it uses.

The original Alday–Gaiotto–Tachikawa correspondence relates specified four-dimensional gauge theories and their matter to Liouville blocks, with the required $U(1)$ factors and parameter conventions. The relation $b^2 = \epsilon_1/\epsilon_2$ is part of such conventions. Applying it does not turn every rank-one instanton sum into an oscillator trace. An arithmetic version would require its own theory, comparison functor, and controlled parameter limit. The positive geometric constructions and the failed fixed-parameter limit leave that question open.

21.16 TATE INTEGRALS AND MEROMORPHIC LINES

Tate theory supplies local integrals, Euler products, and a global functional equation. These are precise scalar constructions. We first retain them on their actual domains, then describe what geometric sewing would require in addition.

Normalize multiplicative Haar measure on $\mathbb{Q}_p^\times$ by $\mathrm{vol}(\mathbb{Z}_p^\times) = 1$. For an unramified character χ_p with $\chi_p(p) = \alpha_p$, shell integration gives

$$Z_p(\mathbf{1}_{\mathbb{Z}_p}, \chi_p, s) := \int_{\mathbb{Q}_p^\times} \mathbf{1}_{\mathbb{Z}_p}(x)\chi_p(x)|x|^s\, d^\times x = \sum_{j\ge 0} \alpha_p^j p^{-js} = \frac{1}{1-\alpha_p p^{-s}}$$

when $|\alpha_p p^{-s}| < 1$. Using $\mathbf{1}_{\mathbb{Z}_p^\times}$ instead gives one. Thus changing the local test function can remove the unramified Euler factor.

At the real place, with $dx/|x|$ and $\Phi_\infty(x) = e^{-\pi x^2}$,

$$Z_\infty(\Phi_\infty, 1, s) = 2\int_0^\infty e^{-\pi x^2} x^{s-1}\, dx = \pi^{-s/2}\Gamma(s/2) \qquad (\operatorname{Re} s > 0).$$

The substitution $u = \pi x^2$ proves the last equality. For the trivial global character, their product is

$$\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s) \qquad (\operatorname{Re} s > 1).$$

Proposition 21.16.1 *(Finite removal and reinsertion).* For a finite prime set S, put

$$P_S(s) = \prod_{p\in S}(1 - p^{-s}), \qquad \Phi_S(s) = P_S(s)\Lambda_\zeta(s).$$

Using the unit-shell test function at the places in S gives Φ_S in the half-plane of absolute convergence. Reinserting their standard unramified tests multiplies by $P_S(s)^{-1}$. The identities extend meromorphically.

Proof. The local shell computation replaces precisely the factors indexed by S. Absolute convergence allows the finite factors to be separated from the remaining product. The meromorphic continuation of both sides preserves the identity. □

For $S = \{2, 3\}$, replacing the two factors by specified local parameters gives

$$\Lambda_\zeta(s)\frac{(1 - 2^{-s})(1 - 3^{-s})}{(1 - \alpha_2 2^{-s})(1 - \alpha_3 3^{-s})}.$$

It equals $\Lambda_\zeta(s)$ when both parameters are one. Otherwise it is the stated partial replacement. A full character L-function needs its Euler factors at every place, its conductor, and the archimedean parity factor. Arbitrary choices at two primes do not specify a global character.

The functional equation and its normalization

For completeness, the scalar zeta symmetry follows from the Gaussian Poisson identity

$$\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t} = t^{-1/2}\theta(t^{-1}).$$

For $\operatorname{Re} s > 1$, termwise integration gives

$$\Lambda_\zeta(s) = \frac{1}{2}\int_0^\infty (\theta(t) - 1)t^{s/2}\frac{dt}{t}.$$

Split at one and apply the theta identity to the first integral. The result is

$$\Lambda_\zeta(s) = \frac{1}{s(s-1)} + \frac{1}{2}\int_1^\infty (\theta(t) - 1)\left(t^{s/2} + t^{(1-s)/2}\right)\frac{dt}{t}. \tag{21.6}$$

The tail decays exponentially, so the integral is entire in s, locally uniformly with all derivatives. This proves meromorphic continuation, simple poles at zero and one with residues -1 and 1, and $\Lambda_\zeta(s) = \Lambda_\zeta(1 - s)$.

The entire normalization is $\xi(s) = \frac{1}{2}s(s-1)\Lambda_\zeta(s)$.

For a primitive Dirichlet character χ of conductor f, let $\chi(-1) = (-1)^a$, $a \in \{0, 1\}$. The completed function and root number are

$$\Lambda(s,\chi) = \left(\frac{f}{\pi}\right)^{(s+a)/2} \Gamma\Big(\frac{s+a}{2}\Big) L(s,\chi), \qquad \varepsilon(\chi) = \frac{\tau(\chi)}{i^a\sqrt{f}},$$

where $\tau(\chi) = \sum_{x \bmod f} \chi(x) e^{2\pi i x/f}$. Tate's global functional equation, with these conventions, is

$$\Lambda(s,\chi) = \varepsilon(\chi)\Lambda(1-s,\overline{\chi}).$$

Its adelic proof uses Fourier transform and Poisson summation, together with the local character and measure data. An imprimitive character requires the corresponding removed local factors. It cannot be inserted unchanged in the primitive formula.

These identities construct meromorphic sections of scalar lines. For instance, let $\mathcal{M}$ be the field of meromorphic functions of s, and attach the line $\mathcal{M}e_S$ to each finite set S. The map deleting a prime $p \in S$ is multiplication by $(1-p^{-s})^{-1}$. Maps for different primes commute, so this is a functor from the finite-deletion category to meromorphic lines. The sections $\Phi_S e_S$ are compatible with deletion.

The unmarked involution is $s \mapsto 1-s$. On a marked section it has the explicit factor

$$\Phi_S(s) = \frac{P_S(s)}{P_S(1-s)}\Phi_S(1-s).$$

This is an actual comparison of the specified lines and sections. Its source is the finite-deletion category. It is not yet a category of arithmetic surfaces with boundary sewings.

A scattering phase and a positive measure

The two completed zeta normalizations also give different scattering ratios. Put

$$m_\Lambda(s) = \frac{\Lambda_\zeta(2s-1)}{\Lambda_\zeta(2s)}, \qquad m_\xi(s) = \frac{\xi(2s-1)}{\xi(2s)}.$$

For the standard weight-zero Eisenstein series on $SL_2(\mathbb{Z})\backslash\mathbb{H}$, the constant term is $y^s + m_\Lambda(s)\,y^{1-s}$. The ratio using the entire function instead satisfies

$$m_\xi(s) = \frac{s-1}{s} m_\Lambda(s).$$

This follows by substituting $\xi(w) = \frac{1}{2}w(w-1)\Lambda_\zeta(w)$ and cancelling. Thus the two scalar conventions cannot be interchanged in a claimed normalization of an intertwining operator.

Both ratios satisfy $m(s)m(1-s) = 1$ meromorphically. On $s = 1/2 + it$, their modulus is one wherever they are finite and nonzero. Indeed the functional equation and real conjugation give

$$\xi(2s-1) = \xi(1-2it) = \overline{\xi(2s)},$$

and the same calculation applies to Λ_ζ. The rational factor $(s-1)/s$ also has unit modulus on this line. At the removable central value, $m_\Lambda(1/2) = -1$ and $m_\xi(1/2) = 1$. The residues $-1, 1$ in (21.6) prove the first value, and $\xi(0) = \xi(1) = 1/2$ proves the second.

Write $\Gamma_{\mathbb{R}}(w) = \pi^{-w/2}\Gamma(w/2)$. There is a precise Euler product for the first ratio:

$$m_{\Lambda}(s) = \frac{\Gamma_{\mathbb{R}}(2s-1)}{\Gamma_{\mathbb{R}}(2s)} \prod_{p} \frac{1-p^{-2s}}{1-p^{1-2s}} \qquad (\operatorname{Re} s > 1).$$

Both zeta products converge absolutely on this half-plane, so taking their quotient proves the formula.

Meromorphic continuation defines its other values. It does not assert absolute Euler-product convergence on $\operatorname{Re} s = 1/2$. Ramified representations require their actual local L- and epsilon-factors, character and measure data. They are not obtained by appending arbitrary phases to this unramified zeta ratio.

To see what phase removal proves, work on a domain of the unitary axis where $\xi(2s) \neq 0$ and put

$$d(s) = |\xi(2s)|^{-2}, \qquad P(s) = 2d(s), \qquad K(s) = m_{\xi}(s)^{-1}d(s).$$

These are specified scalar functions. They satisfy

$$d(s) \leq |P(s) - K(s)| \leq 3d(s), \qquad m_{\xi}(s)K(s) = d(s) = P(s)/2.$$

The triangle and reverse-triangle inequalities prove the bounds, since $|m_{\xi}| = 1$ and $d > 0$.

Multiplication by the phase removes that phase. It leaves the factor two in the proposed positive coefficient. Realizing either scalar as an actual continuous-spectrum pairing remains another question.

A measured comparison must preserve more than its diagonal density. For example, suppose P, K are positive measurable functions on a measured space (X, ν). If $|c|^2 P = K$ almost everywhere, then

$$f \longmapsto cf : L^2(X, K\,d\nu) \xrightarrow{\sim} L^2(X, P\,d\nu)$$

is unitary. Integrating $|cf|^2 P = |f|^2 K$ proves isometry. Division by the nonzero c gives its inverse. For the phase-valued K above, positivity is not available before the form and its normalization have been specified.

A proposed arithmetic extension therefore needs a bivariate Hermitian pairing, its domain, the measured spectral decomposition, and an intertwiner realizing the positive form. Multiplication by $m((s_1 + s_2)/2)$ alone need not preserve the Hermitian symmetry in the two parameters. A norm identity on individual formal spectral vectors does not provide the mixed pairings or convergence of wave packets.

On a specified decomposition $V = V_{\mathrm{disc}} \oplus V_{\mathrm{cont}}$, one may define the correction to be the identity on the first summand. If both pairings make the summands orthogonal, comparisons on the two summands combine to a comparison on V. Expanding the pairing of $v_d + v_c$ and $w_d + w_c$ proves this assertion: both mixed terms vanish. Without that orthogonality, the mixed comparisons must also be given.

A selected residual line is a particularly simple case. If the placement carries its arithmetic vector v_0 to a unit vector and $B^{\mathrm{Ar}}(v_0, \sigma v_0) = 1$, then both forms on av_0, bv_0 equal $a\overline{b}$. This calculation does not identify every residual automorphic summand with one vacuum. Nor does discreteness of a zeta zero set place its trace in this automorphic discrete summand. That placement requires the actual spectral comparison.

Finally, a scalar functional equation does not transport obstruction classes. A specified linear map $F : H \to H_{\mathrm{Ar}}$ does carry a relation $c + c^{!} = 0$ to $F(c) + F(c^{!}) = 0$. Applying this fact to duality classes requires the obstruction complexes and a comparison defined for the corrected pairing. The identity $m(s)m(1-s) = 1$ supplies no such map.

Discriminants and residues

Let K be a number field of signature (r_1, r_2) and discriminant d_K. In the standard Minkowski embedding $K \hookrightarrow \mathbb{R}^{r_1} \times \mathbb{C}^{r_2}$, use Lebesgue measure $dx\,dy$ on each complex coordinate. Then

$$\operatorname{covol}(\mathcal{O}_K) = 2^{-r_2}\sqrt{|d_K|}. \tag{21.7}$$

To prove the factor, choose an integral basis and form its complex embedding matrix. Its determinant has absolute value $\sqrt{|d_K|}$ by the discriminant identity. Replacing each conjugate pair by real and imaginary parts divides the absolute determinant by two. There are r_2 such pairs, giving (21.7).

Thus

$$\log \operatorname{covol}(\mathcal{O}_K) = \frac{1}{2}\log|d_K| - r_2 \log 2.$$

In particular $\frac{1}{2}\log|d_K|$ is neither an integer genus nor the half-logarithm of this covolume.

Metrics and measure conventions matter for arithmetic Euler characteristics as well. One can define the real discriminant expression

$$D_K = \log|d_K| - r_1 \log(\pi/4) - r_2 \log(\pi/2).$$

It is a specified normalization of discriminant data. Identifying it with a metrized determinant of cohomology or an arithmetic Euler characteristic requires the actual complex, metrics and comparison formula. The expression alone supplies none of them.

The analytic class-number formula gives the positive residue

$$\operatorname*{Res}_{s=1} \zeta_K(s) = \frac{2^{r_1}(2\pi)^{r_2} h_K R_K}{w_K \sqrt{|d_K|}}.$$

Here h_K is the ideal class number, R_K the regulator, and w_K the number of roots of unity. The standard rank-zero regulator convention is $R_K = 1$. This is a scalar residue. For example, for $K = \mathbb{Q}(i)$ it is $\pi/4$, using $h_K = R_K = 1$, $w_K = 4$, and $|d_K| = 4$. It is therefore not in general an integer dimension of conformal blocks.

21.17 The maps required for sewing

The finite Frobenius construction supplied an inverse pairing and explicit gluing maps. For a family of geometric or arithmetic objects, sewing requires their analogues, compatible under repeated gluing.

One possible coefficient for an anomaly is a determinant line. For a bounded complex $C^\bullet$ of finite-dimensional spaces, define

$$\det C^\bullet = \bigotimes_i (\det C^i)^{(-1)^i}.$$

Odd exponents mean dual lines. Cancellation of the boundary and coboundary subspaces gives its canonical identification with $\bigotimes_i (\det H^i(C))^{(-1)^i}$. Exact sequences or exact triangles give corresponding determinant-line isomorphisms with their graded signs.

A trivialization, compatible with those isomorphisms, is additional data. It cannot be replaced just by an orientation word or by a scalar functional equation.

Intermediate labels and coends

The intermediate objects in sewing belong to a specified category. For a small k-linear category C, a right module $F : C^{\mathrm{op}} \to \mathrm{Vect}_k$ and a left module $G : C \to \mathrm{Vect}_k$ have a coend

$$F \otimes_C G = \int^{a \in C} F(a) \otimes_k G(a).$$

Concretely it is the quotient of $\bigoplus_a F(a) \otimes_k G(a)$ by the relations $F(f)(x) \otimes y = x \otimes G(f)(y)$ for $f : a \to b$, $x \in F(b)$ and $y \in G(a)$. In a dg setting, the derived coend is computed by its bar construction with all strings of composable morphisms.

If C is split finite semisimple, the expression reduces to a finite sum over its simples with the specified endomorphism-field balancing. Without semisimplicity, replacing the derived coend by a sum over simple isomorphism classes can lose extensions and higher Tor. A measured direct integral instead requires a measurable family, a measure, Hilbert completions and a convergence theorem. It is a different construction.

For local Weil–Deligne data, one must fix the local field, coefficient field, rank, topology, Frobenius convention, monodromy, and allowable inertia types. A list of all such isomorphism classes does not specify a coend or a measure. Likewise local Langlands does not, by itself, construct a sewing functor on arithmetic surfaces or identify its objects with WZW labels.

The finite and archimedean actions also have different types. A change of coefficient embedding can transport Galois labels when its semilinear maps are given. A Hecke correspondence acts on its specified automorphic or sheaf-theoretic carrier. The quotient $G(\mathbb{A})/G(K)$ is not a group in general, so it cannot serve as a symmetry group without a separate action construction. Inertia and wild inertia remain part of ramified local data.

Question 21.17.1 *(Arithmetic sewing).* Construct the source category of marked arithmetic objects and its gluing operations. Give the intermediate coefficient category, the two variances of the boundary modules, and the derived coend or measured integral that supplies their gluing. Construct its map to the coefficient object of the glued arithmetic space. Require compatible units, dualities, determinant lines and repeated-sewing isomorphisms.

Compare the resulting scalar evaluations with the Tate sections on their common domains, including the conductor, archimedean and local normalization factors. Both the separating sewing and the self-gluing that creates a handle are part of this question.

The meromorphic-line functor above provides finite Euler-factor compatibility and functional-equation symmetry. Those results leave the stated geometric maps to be constructed. Conversely, a geometric sewing theorem can exist on a different specified coefficient category without yet giving the arithmetic comparison.

A finite analytic sewing construction

There is a positive analytic example already constructed in Theorem 16.7.1. It uses the holomorphic lattice algebra $W = V_{E_8}$ and the finite marked coefficient objects (P, λ) of the arithmetic fusion category. For a compatible junction $f : P \otimes_{R_\circ} Q \to S$, the field is

$$\mathcal{J}_f(u \otimes p, z)(v \otimes q) = Y_W(u, z)v \otimes f(p \otimes_{R_\circ} q).$$

The coefficient tensor is balanced over the boundary algebra $R_\circ$. Its duality maps and associators retain the original finite fusion data.

The sewing domain is explicit. Start with finitely many compact pointed Riemann surfaces, possibly disconnected. Choose disjoint coordinate discs of radii r_j, r'_j at each paired marking and glue by $u_j v_j = t_j$, with $0 < |t_j| < r_j r'_j$. Each initial connected component retains an unsewn marked point. Fix the initial conformal block, contragredient pairings, coordinates and branches for fractional powers.

On this domain the descendant propagator sums converge absolutely and locally uniformly, including simultaneous sewings that create handles. The reason is that each coefficient contraction is finite-dimensional: the sewn expression is a finite linear combination of ordinary W conformal block sewings. The lattice algebra is rational and C_2-cofinite, and its modules here are finite sums of the vacuum module. Gui's sewing theorem applies with the stated retained-marking hypothesis. Finite sums preserve its convergence and sewing identities.

If an initial component has no unsewn mark, propagation of vacua first inserts one. Its propagation isomorphism removes it afterward. The hypothesis is not removed by silently omitting the point. This theorem supplies actual analytic sewing for the constructed marked fusion realization. It does not choose a globally normalized partition scalar or the arithmetic coend in Question 21.17.1.

21.18 Genus, rank, and coefficient data

The genus of a smooth proper curve controls the rank of its first cohomology. A field degree, a framing rank, and a Siegel parameter are different inputs, even when their numerical values coincide.

For a smooth projective curve C/K of genus g, the Jacobian has dimension g and its first cohomology has rank $2g$. At a complex embedding its Hodge dimensions are (g, g), and $\deg \omega_C = 2g - 2$. Arithmetic intersection and determinant formulas additionally use a regular arithmetic model, metrics, singular fiber contributions and analytic torsion. The topological formula $2 - 2g$ is not by itself an arithmetic Euler characteristic or a Koszul level identity.

Several possible coefficient constructions should therefore be kept distinct.

(i) A smooth proper curve gives its Jacobian's weight-one cohomology. An arithmetic surface model permits metrized intersections and a determinant of cohomology, subject to their actual hypotheses.

(ii) A totally imaginary field K of degree $2g$ gives a Minkowski lattice in $\mathbb{C}^g$ after selecting one embedding from each conjugate pair. Its quotient is a complex torus. An abelian variety requires a positive integral Riemann form. In a CM construction one specifies a CM type and polarization. This torus is not the weight-zero motive whose L-function is ζ_K.

(iii) A rank-$2g$ ordinary crystalline representation has its coefficient field, Hodge–Tate multiset, ordinary filtration and semilinear Frobenius. Its moduli dimension depends on the imposed type and deformation conditions. Frobenius is not automatically an operator with square -1.

(iv) A theta construction on a principally polarized abelian g-fold uses a chosen level and theta line. Its level-n section space has dimension n^g, whereas its first cohomology has rank $2g$. Comparing these carriers requires an actual map. The Steinberg relation $\{a, 1 - a\} = 0$ in $K_2^M(K)$, for $a \neq 0, 1$, is a field relation and does not supply that map.

(v) A surface factorization construction needs both local operations and their interchange coherences. Two separately named E_1 structures do not give an E_2 structure until the hypotheses of the iterated-algebra construction hold. Double-residue and completed duality comparisons must preserve the specified coefficients and signs.

(vi) A Siegel or other Shimura construction uses its actual automorphic representation and L-group representation. For GSp_{2g}, the standard representation of the dual GSpin_{2g+1} has dimension $2g+1$, while the spin representation has dimension 2^g. Neither is automatically the rank-$2g$ Jacobian representation.

These alternatives name different objects. They permit comparison problems. They do not define six presentations of an already identified arithmetic object. In particular an almost-complex structure belongs to a real tangent bundle of an analytic space, whereas a crystalline Frobenius belongs to its specified coefficient realization. An arithmetic scheme does not acquire the former from the latter by notation.

Weights and the zero-rank case

For a weight-m realization in motivic normalization, the expected functional-equation involution is $s \mapsto m+1-s$. Its existence and normalization must be established for the chosen L-function. The Dedekind zeta function is weight zero and has $s \mapsto 1-s$, independently of $[K:\mathbb{Q}]$. The Jacobian H^1 function is weight one and, when its completed functional equation is available, uses $s \mapsto 2-s$. A spin or standard automorphic function has the shifts and conductor of its own chosen normalization.

Gamma factors likewise come from the Hodge or archimedean representation. The number g alone does not select them. For example, with $\Gamma_{\mathbb{R}}(s) = \pi^{-s/2}\Gamma(s/2)$ and $\Gamma_{\mathbb{C}}(s) = 2(2\pi)^{-s}\Gamma(s)$, the Dedekind completion is

$$\Lambda_K(s) = |d_K|^{s/2}\Gamma_{\mathbb{R}}(s)^{r_1}\Gamma_{\mathbb{C}}(s)^{r_2}\zeta_K(s).$$

A curve's weight-one completion also requires its conductor and all local factors, including bad reduction.

At rank zero the determinant $\det(1 - tF \mid 0)$ is one and $\mathrm{Sym}(0) = k$. Its all-charge trace is one. For $\mathbb{P}^1$, the Jacobian is trivial and $H^1 = 0$. Its H^1 Euler factor is also one.

The full zeta function of $\mathbb{P}^1_{\mathbb{F}_q}$ is instead

$$Z(\mathbb{P}^1_{\mathbb{F}_q}, t) = \frac{1}{(1-t)(1-qt)},$$

because $\#\mathbb{P}^1(\mathbb{F}_{q^n}) = q^n + 1$. It includes degrees zero and two. Over a number field the corresponding finite Euler product is $\zeta_K(s)\zeta_K(s-1)$ in its initial half-plane. None of these is the H^1 factor.

A number field cannot have degree zero. Thus setting $2g = 0$ in a totally imaginary degree-$2g$ family does not produce $\mathbb{Q}$. A Riemann Tate sector or a rank-two Wilson label can be added as separate data. The empty tensor contributes only its scalar unit.

For positive rank, specify the Frobenius carrier as well. If $V_\ell J$ is the Tate module of an abelian variety, its dual $H^1_{\text{ét}}(J, \mathbb{Q}_\ell)$ has the dual action. Arithmetic and geometric Frobenius are inverse. On the cohomological geometric convention for weight one, polarization pairs eigenvalues with product q. On the Tate-module geometric convention the product is q^{-1}. These distinctions persist through the determinant trace and any Wilson comparison.

21.19 Naturality and stabilization

A genus-wise identity of scalar functions does not define maps between coefficient objects of different rank. We state the chain-level construction that does give such comparisons when its maps are known.

Let $\mathcal{D}$ be a specified category of arithmetic coefficient systems. An object includes its local complexes, reference vectors, local actions, completed or algebraic tensors, and all merger and residue maps being used. Morphisms preserve these data. If conformal vectors or pairings are part of the structure, their

preservation is an additional equation. Composition of such morphisms remains compatible because its defining squares compose. No compatibility of a completion is inferred solely from the presence of almost-everywhere reference vectors.

Suppose two stage constructions have differentials $D_S^{(a)} = D_{\mathrm{o},S}^{(a)} + \tau_S^{(a)}$, $a = 1, 2$, with

$$(D_{\mathrm{o},S}^{(a)})^2 = 0, \qquad D_{\mathrm{o},S}^{(a)}\tau_S^{(a)} + \tau_S^{(a)}D_{\mathrm{o},S}^{(a)} + (\tau_S^{(a)})^2 = 0.$$

The second identity is the precise condition for the total differential to square to zero. Its validity for two complexes does not yet give a map between them.

PROPOSITION 21.19.1 *(Comparison from natural stage maps).* Over a common coefficient ring, suppose quasi-isomorphisms $\Xi_{\mathsf{A},S} : C_S^{(1)}(\mathsf{A}) \to C_S^{(2)}(\mathsf{A})$ are given. Require naturality in A, compatibility with the stage transitions, and

$$\Xi D_{\mathrm{o},S}^{(1)} = D_{\mathrm{o},S}^{(2)}\Xi, \qquad \Xi\tau_S^{(1)} = \tau_S^{(2)}\Xi.$$

Then their algebraic filtered colimits are naturally quasi-isomorphic. Any additional completed comparison requires preservation of this quasi-isomorphism by the chosen completion.

Proof. Adding the two equations gives the chain-map identity. Transition compatibility defines the colimit map. Filtered colimits of modules are exact, so homology commutes with these colimits and the map remains a quasi-isomorphism. The naturality squares descend from those at each stage. The final assertion specifies the extra limiting operation and its needed property. □

For ordered, arithmetic-chiral, Deninger-type and bulk-boundary constructions, the complexes and stage maps must each be given on their independent carriers. Defining one assignment to be another produces an identity natural transformation, but not an independent geometric comparison. An independently defined bulk theory also needs its boundary functor and the comparison of its operations. Frobenius and duality pairings are transported only when the specified maps preserve them.

Changing the rank

For categories $\mathcal{D}_g$, supply an actual stabilization functor $S_g : \mathcal{D}_g \to \mathcal{D}_{g+1}$. Let $F_{\star,g}$ be specified chain functors and V_2 a fixed graded coefficient space with zero differential. Suppose there are natural quasi-isomorphisms

$$q_{\star,g} : F_{\star,g}(\mathsf{A}) \otimes V_2 \longrightarrow F_{\star,g+1}(S_g\mathsf{A}).$$

Over a field, algebraic tensoring with V_2 gives

$$H(F_{\star,g} \otimes V_2) \simeq H(F_{\star,g}) \otimes V_2.$$

One proof splits each complex as its cohomology and a contractible complex. Tensor its contracting homotopy with 1_{V_2}. For other coefficients or completed tensors, the corresponding Künneth statement is an additional hypothesis.

If the maps $q_{\star,g}$ commute with the comparison maps η up to specified chain homotopies, then their cohomology isomorphisms commute with η. In particular,

$$\eta_{g+1}q_{\mathrm{ch},g} \simeq q_{\partial,g}(\eta_g \otimes 1)$$

becomes equality on homology. The same argument transports specified Frobenius actions, retractions and pairings, provided their compatibility is included. This gives uniformity for every g where all those data exist.

An oscillator splitting alone does not construct the maps $q_{\star,g}$ for a differential whose differential includes maps coupling residues at different places. Even a trivial action does not imply flatness: for $\Lambda = \mathbb{Z}_p[[T]]$ and $M = \Lambda/(T)$, the resolution

$$0 \longrightarrow \Lambda \xrightarrow{T} \Lambda \longrightarrow M \longrightarrow 0$$

gives $\operatorname{Tor}_1^{\Lambda}(M, M) = M$. The p-primary Iwasawa μ-invariant of this module is zero, but M is not Λ-flat. In several variables the corresponding completion and duality hypotheses must still be proved.

A block-diagonal group map $GL_{2g} \times GL_2 \hookrightarrow GL_{2g+2}$ also does not give a tensor decomposition of the ambient current algebra. The latter has off-diagonal matrix currents absent from the two block Lie algebras. A retraction of coefficient complexes requires a chosen splitting and a chain map. It is not an automatic retraction of vertex algebras.

Three different diagonal constructions

For a rank-r Heisenberg vertex algebra V_r at level one, the tensor $V_r \otimes V_r$ has rank $2r$ and standard central charge $2r$. Writing the two current families as $J_i^{(1)}$ and $J_i^{(2)}$, their unscaled sums obey

$$(J_i^{(1)} + J_i^{(2)})(z)(J_j^{(1)} + J_j^{(2)})(w) \sim \frac{2\delta_{ij}}{(z-w)^2}.$$

They therefore do not give a level-one diagonal map. The normalized sums $(J_i^{(1)} + J_i^{(2)})/\sqrt{2}$ do give a Heisenberg embedding, but its image conformal vector is the Sugawara vector of only the diagonal currents. It is different from the full tensor conformal vector: the complementary anti-diagonal currents contribute central charge r.

The coordinatewise product $V_r \times V_r$ is a different vertex algebra. Its vacuum is $(1, 1)$ and its conformal vector is (ω, ω). The map $v \mapsto (v, v)$ preserves both and all products. Its central term is $(r/2)(1, 1)$, so the central charge remains r. Its weight-zero space is two-dimensional, unlike that of the rank-$2r$ Heisenberg tensor product. Neither construction is the free product merely by its notation.

Nor is the reduced bar an additive construction on arbitrary coefficient algebras. Let $A = k \oplus kx$ and $B = k \oplus ky$ have square-zero augmentation ideals. The square-zero algebra $C = k \oplus (kx \oplus ky)$ has zero reduced-bar differential. Its bar length-two term has basis

$$[x|x], \quad [x|y], \quad [y|x], \quad [y|y].$$

The direct sum of the positive reduced bars of A and B has only the first and last terms in that length. The mixed terms survive in homology. Thus an additive diagonal claim for bar constructions needs the actual carrier and comparison. It cannot follow from linearity of one residue operator.

Evaluating a duality defect

The same requirement applies to a proposed all-genus level identity. Suppose an independently defined defect $\mathfrak{d}_g$ has a specified scalar evaluation $\mathcal{E}_g$ such that

$$\mathcal{E}_g(\mathfrak{d}_g)(s) = \Lambda_g(s) - \varepsilon_g \Lambda_g(w_g - s).$$

If the functional equation holds, the evaluated defect vanishes. Concluding $\mathfrak{d}_g = 0$ requires that $\mathcal{E}_g$ detect zero on the actual defect space. This criterion is immediate from injectivity, and preserves the need to construct both the evaluation and detection. Euler factors, weights, and a scalar functional equation alone do not provide them.

21.20 The level-dependent Hecke trace

A Hecke trace on a finite space of cusp forms is another concrete scalar. Its relation to a categorical arithmetic trace requires a map carrying the chosen endomorphism to that Hecke operator. The classical trace itself retains the level in both its elliptic and cusp terms.

Let $N \geq 1$, $k \geq 2$, and $n \geq 1$. Write

$$\Gamma_1(N) = \left\{ \begin{pmatrix} a & b \\ c & d \end{pmatrix} \in SL_2(\mathbb{Z}) : a \equiv d \equiv 1,\ c \equiv 0 \pmod{N} \right\}.$$

Let $S_k(\Gamma_1(N))$ be its holomorphic cusp forms and T_n the usual Hecke operator. One precise normalization is obtained by decomposing under diamond characters χ and using on $S_k(\Gamma_0(N), \chi)$

$$f|T_n = \sum_{\sigma \in \Gamma_0(N)\backslash \Delta_n} (\det \sigma)^{k-1} \chi(a_\sigma)\, f|_k \sigma,$$

where

$$\Delta_n = \{\sigma \in M_2(\mathbb{Z}) : \det \sigma = n,\ N \mid c_\sigma,\ (a_\sigma, N) = 1\},$$

$$f|_k \begin{pmatrix} a & b \\ c & d \end{pmatrix}(z) = (cz + d)^{-k} f\left(\frac{az + b}{cz + d}\right).$$

This convention includes indices not coprime to N.

Define the polynomials $P_j(t, n)$ by

$$\frac{1}{1 - tx + nx^2} = \sum_{j \geq 0} P_j(t, n) x^j.$$

Thus $P_0 = 1$, $P_1 = t$, and $P_j = tP_{j-1} - nP_{j-2}$. If $\alpha + \beta = t$ and $\alpha\beta = n$, then $P_{k-2}(t, n) = (\alpha^{k-1} - \beta^{k-1})/(\alpha - \beta)$ when the roots are distinct. The polynomial defines the repeated-root value.

Let φ be Euler's totient, and put

$$I(N) = N \prod_{p \mid N} (1 + p^{-1}), \qquad \sigma_{1,N}(n) = \sum_{\substack{d \mid n \\ (d,N)=1}} \frac{n}{d}.$$

For $u \mid N$ and $u^2 \mid t^2 - 4n$, define

$$B_N(u, t, n) = \begin{cases} I(N)/I(N/u), & Nu \mid t - n - 1, \\ 0, & \text{otherwise}, \end{cases} \qquad D_N(u, t, n) = \sum_{d \mid u} \mu(d) B_N(u/d, t, n).$$

Here μ is the Möbius function. For integers a, d, set

$$\Psi_N(a, d) = \sum_{\substack{rs = N \\ r \mid a-1,\ s \mid d-1}} \varphi((r, s))\varphi(N/(r, s)).$$

For $D > 0$, let $H(D)$ be the Hurwitz class number of positive definite integral binary quadratic forms of discriminant $-D$, including imprimitive forms. A class has weight the reciprocal of its stabilizer order in $PSL_2(\mathbb{Z})$. Thus $H(3) = 1/3$, $H(4) = 1/2$. Set $H(0) = -1/12$, and set $H(D) = 0$ for a nonintegral argument or an inadmissible discriminant.

Theorem 21.20.1 *(Eichler–Selberg at level $\Gamma_1(N)$).* With the preceding conventions,

$$\begin{aligned}\operatorname{Tr}(T_n | S_k(\Gamma_1(N))) = {} & \delta_{k,2}\sigma_{1,N}(n) \\ & - \frac{\varphi(N)}{2} \sum_{\substack{t\in\mathbb{Z} \\ t^2\le 4n}} P_{k-2}(t,n) \sum_{\substack{u\mid N \\ u^2\mid t^2-4n}} H\left(\frac{4n-t^2}{u^2}\right) D_N(u,t,n) \\ & - \frac{1}{4} \sum_{\substack{a,d>0 \\ ad=n}} \min(a,d)^{k-1}\left(\Psi_N(a,d) + (-1)^k \Psi_N(-a,-d)\right).\end{aligned}$$

This holds for all $n \ge 1$, including bad-level indices.

The formula is Popa's Theorem 5 in *On the trace formula for Hecke operators on congruence subgroups, II*. Its elliptic level factor is D_N. The terms $t^2 = 4n$ include the scalar contribution through $H(0)$. The last line and the weight-two term retain the cusp and Eisenstein corrections.

For $N = 1$, $D_1 = 1$, $\Psi_1 = 1$, and the even-weight formula reduces to

$$\delta_{k,2}\sigma_1(n) - \frac{1}{2} \sum_{t^2\le 4n} P_{k-2}(t,n) H(4n-t^2) - \frac{1}{2} \sum_{ad=n} \min(a,d)^{k-1}.$$

At $n = 1$, $k = 2$, the class-number sum is $2H(0) + 2H(3) + H(4) = 1$. The three contributions are 1, $-1/2$, $-1/2$, giving $\dim S_2(SL_2(\mathbb{Z})) = 0$. At $k = 12$, the class-number sum is -3, and the trace is $3/2 - 1/2 = 1$. These finite examples check the normalization. They do not replace the level-dependent formula.

A universal arithmetic trace family needs a coefficient space over its actual weight and level base. Its specializations to cusp-form spaces must commute with every T_n. Matching the traces does not construct the eigenobjects, their extensions, or their categorical endomorphisms.

21.21 Trace functionals and their analytic domains

To compare an ordered bar character with an analytic trace, first turn its homology into a scalar on a specified domain. For example, suppose H_i are Hilbert realizations and $T_i(s)$ are holomorphic trace-class families on a half-plane Ω, with $\sum_i \|T_i(s)\|_1$ locally uniformly convergent. Then

$$Z(s) = \sum_i (-1)^i \operatorname{Tr} T_i(s)$$

is holomorphic there. Continuity of trace and locally uniform convergence prove the assertion. A regularized character needs its own prescription and normalization. Homology itself is not this scalar.

Suppose a comparison identifies the local factors and proves $Z(s) = \xi(s)$ after the archimedean and polar normalizations. If both sides have meromorphic continuations, the identity theorem preserves that equality. The argument principle then computes the same zero distribution. It does not add an independent Hilbert spectral realization.

A common compact test class

Take an even $f \in C_c^\infty(\mathbb{R})$ and define

$$h(z) = \int_{\mathbb{R}} f(u) e^{izu}\, du, \qquad H(s) = h(-i(s - \tfrac{1}{2})).$$

The function h is entire and rapidly decreasing in each horizontal strip. With $\psi_\Gamma = \Gamma'/\Gamma$, the compact Weil explicit formula is

$$\begin{aligned}\sum_\rho H(\rho) &= h(i/2) + h(-i/2) \\ &\quad + \frac{1}{2\pi} \int_{\mathbb{R}} h(t) \big(\operatorname{Re} \psi_\Gamma(1/4 + it/2) - \log \pi\big)\, dt \\ &\quad - \sum_p \sum_{j \geq 1} (\log p) p^{-j/2} \big(f(j \log p) + f(-j \log p)\big).\end{aligned}$$

Zeros are counted with multiplicity, without assuming they are on the critical line. The prime sum is finite because f is compactly supported. Rapid decay in strips and the classical $O(T \log(T + 2))$ zero count give absolute convergence of the zero sum.

The gamma integral converges by its logarithmic growth.

For a positively oriented rectangle Γ_T avoiding zeros on its boundary, the argument principle gives

$$\frac{1}{2\pi i} \int_{\Gamma_T} H(s) \frac{\xi'(s)}{\xi(s)}\, ds = \sum_{\rho \text{ inside } \Gamma_T} H(\rho).$$

The entire function ξ is nonzero at zero and one. Its logarithmic derivative has no polar residues there. If one instead uses Λ_ζ, its poles at zero and one contribute with negative multiplicity. The choice determines the boundary terms.

When an independent arithmetic construction has $Z = \xi$ on the proved common domain, its argument-principle functional is the one just displayed. A comparison with a distributional scaling trace also requires equality of that trace on this same test class, including the gamma, prime and polar terms. No expansion of $-\zeta'/\zeta$ on the critical line is used: its Dirichlet series starts in $\operatorname{Re} s > 1$.

A finite trace difference with a negative value

Even complete unitary scattering does not force a positive trace distribution. On $L^2(\mathbb{R}, d\lambda) \oplus \mathbb{C}$, take

$$A_0 = M_\lambda \oplus 0, \qquad A_1 = M_\lambda \oplus a, \qquad a > 0,$$

with common maximal domain $\operatorname{Dom} M_\lambda \oplus \mathbb{C}$. Their difference is positive and rank one.

Both absolutely continuous subspaces are the first summand. The wave operators are the identity there, so scattering is complete and its scattering operator is one.

Nevertheless,

$$\operatorname{Tr}(h(A_1) - h(A_0)) = h(a) - h(0) = \int_0^a h'(\lambda)\, d\lambda.$$

The spectral shift is $\mathbf{1}_{(0,a)}$. The corresponding trace distribution is $\delta_a - \delta_0$.

This distribution is negative on an explicit Fourier square. Choose $\phi \in C_c^\infty(\mathbb{R})$ with $\int \phi = 1$, and put $f(u) = \phi(u) + \phi(u - \pi/a)$. Then

$$h_f(z) = (1 + e^{i\pi z/a}) h_\phi(z), \qquad |h_f(a)|^2 - |h_f(0)|^2 = -4.$$

The scattering phase is still $e^{-2\pi i \mathbf{1}_{(0,a)}} = 1$ almost everywhere. Thus its unit modulus does not determine the sign of the trace functional.

A restriction to a smaller test space needs its own comparison. If a Hermitian form is known on $\ker m$ for a moment functional m, and $m(\psi) = 1$, write $f = f_0 + m(f)\psi$. Then

$$q(f,f) = q(f_0,f_0) + 2\,\mathrm{Re}\big(\overline{m(f)}\, q(f_0,\psi)\big) + |m(f)|^2 q(\psi,\psi).$$

The complementary value and mixed pairing are needed to extend a positivity statement. They cannot be discarded by a mean-zero reduction. The complete arithmetic Weil form and its spectral comparison retain these terms.

21.22 The enhanced arithmetic comparisons

The constructions above provide several actual traces: a mixed complex, a marked categorical closure, finite Frobenius contractions, Gibbs traces, and classical Hecke traces. Each has its own coefficients, unit, completion and evaluation. Their arithmetic comparison must retain those data.

The enhanced Hall question asks for a functor realizing the correspondence operations and their collision coherences on an independently defined arithmetic carrier. The marked-center question asks for the map preserving the chosen center, object and action. Nonlinear norm transport requires its maps on parameters and their multiplicative distribution laws. These are different from constructing all-genus sewing.

An integral Frobenius trace comparison further requires the commuting square between the chiral operations, their arithmetic sheaf realizations, the Frobenius actions and the trace evaluations. An automorphy comparison must identify the actual chiral functions with independently arithmetic ones, including their Euler factors, analytic continuation, functional equation and bounds. Neither follows from an equal scalar character.

These maps are the remaining mathematical questions. The finite counterexamples specify what a comparison must preserve. The positive constructions specify data available for such a comparison. The gluing maps, their inverses where an equivalence is claimed, and their compatibility under sewing still have to be constructed on the stated arithmetic domains.

Chapter 22

Arithmetic Chern–Simons and boundary realization

A gauge theory assigns an amplitude to a field and sums over fields when regions are glued. These are two different operations. For the group $C_2 = \{1, -1\}$, the sign representation has Wilson values 1 and -1 on the two circle holonomies. With trivial action their normalized average is zero. Specifying one holonomy instead gives one of the two values. An arithmetic Wilson comparison must determine which operation produces the Frobenius trace.

Finite gauge groups make the distinction exact. Automorphisms determine the integration measure, a three-cocycle determines the action, and transgression determines the boundary line. Over a number field, arithmetic duality supplies a different integration map in cohomological degree three. It gives a scalar Chern–Simons invariant and torsors over local representation spaces. In the abelian case it also gives a linking pairing whose Gaussian sum computes Wilson correlations. These are constructions on specified arithmetic objects.

We develop these finite theories before passing to congruence towers. The transition maps expose the lifting measures required by a profinite limit. A free holomorphic–topological model then supplies an explicit physical boundary comparison, with its current algebra, coefficient complex and Gaussian cap. The final question is to construct arithmetic bulk and boundary objects for which these operations agree. Neither an Euler product nor a boundary character supplies those maps.

The prerequisites are group cohomology, finite groupoids and the coefficient and trace distinctions of Chapters 10 and 21. Continuous cochains are used for profinite groups. Tensor products are algebraic unless a completion is specified.

22.1 Finite gauge fields and their integration

A *finite groupoid* is a groupoid with finitely many isomorphism classes and finite automorphism groups. Its integral of an isomorphism-invariant complex function is

$$\int_{\mathcal{X}} f = \sum_{[x]\in\pi_0\mathcal{X}} \frac{f(x)}{|\operatorname{Aut}_{\mathcal{X}}(x)|}, \qquad |\mathcal{X}| = \int_{\mathcal{X}} 1. \tag{22.1}$$

The symbol BG denotes the one-object groupoid with automorphism group G. Thus $|BG| = 1/|G|$. For a finite G-set X, the action groupoid $X//G$ has objects X and arrows the action of G. Orbit–stabilizer gives

$$\int_{X//G} f = \frac{1}{|G|} \sum_{x\in X} f(x).$$

For a connected space with fundamental group Γ, finite gauge fields with group G form $\mathcal{F}_G = \operatorname{Hom}(\Gamma, G)//G$, whenever this groupoid is finite. An object is a homomorphism σ. Its automorphism group is the centralizer of $\sigma(\Gamma)$. In the arithmetic case Γ is a specified profinite fundamental group

and the homomorphisms are continuous. Ramification conditions are part of that specification. They cannot be recovered from the finite group alone.

Integration over homotopy fibers

Let $p : \mathcal{X} \to \mathcal{Y}$ be a functor of finite groupoids. Its *homotopy fiber* at y has objects (x, ϕ), where $\phi : p(x) \xrightarrow{\sim} y$. An arrow $a : (x, \phi) \to (x', \phi')$ satisfies $\phi' p(a) = \phi$. Define

$$(p_! f)(y) = \int_{\mathcal{X}_y} f(x), \qquad (p^* g)(x) = g(p(x)).$$

Keeping ϕ is necessary for the measure.

THEOREM 22.1.1 *(Finite integration).* For functors of finite groupoids the following identities hold:

$$\int_{\mathcal{Y}} p_! f = \int_{\mathcal{X}} f, \qquad (qp)_! = q_! p_!, \qquad p_!(f\ p^* g) = (p_! f)\, g.$$

In a homotopy Cartesian square

$$\begin{array}{ccc} \mathcal{X}' & \xrightarrow{q'} & \mathcal{X} \\ {\scriptstyle p'}\downarrow & & \downarrow{\scriptstyle p} \\ \mathcal{Y}' & \xrightarrow[q]{} & \mathcal{Y}, \end{array}$$

one has $q^* p_! = p'_! q'^*$.

Proof. Fix an isomorphism class $[x]$ and a representative y of $[p(x)]$. The set $\mathrm{Iso}(p(x), y)$ has $|\operatorname{Aut} y|$ elements. The contribution of the component over $[x]$ to $\mathcal{X}_y$ is its action groupoid under $\operatorname{Aut} x$, and hence has mass $|\operatorname{Aut} y|/|\operatorname{Aut} x|$. Integration over $[y]$ cancels the numerator and gives (22.1).

For a composite, an object in an iterated fiber consists of x, y, an isomorphism $p(x) \to y$, and an isomorphism $q(y) \to z$. Composing the latter with the image of the former identifies the iterated fiber with the fiber of qp, with its automorphisms. Applying the same count proves composition. The projection formula follows because $g(p(x)) = g(y)$ in the fiber. Finally, the fiber of p' at y' is equivalent to $\mathcal{X}_{q(y')}$. This equivalence preserves the integrand and proves base change. □

For example, $\mathrm{pt} \times^h_{BG} \mathrm{pt}$ is the discrete set G. The two trivial objects must be supplied with an isomorphism, and that is an element of G. Its mass is $|G|$. The pullback of the two sets of isomorphism classes is one point and has mass one. It gives the wrong gluing factor as soon as G is nontrivial.

Boundary lines and adjoints

A Hermitian line L on a groupoid $\mathcal{Y}$ assigns a Hermitian one-dimensional space to each object and unitary transport to each arrow. The transport is functorial. Its invariant sections form a Hilbert space

$$H(\mathcal{Y}, L) = \Gamma(\mathcal{Y}, L), \qquad \langle s, t \rangle = \sum_{[y]} \frac{\langle s(y), t(y) \rangle_{L_y}}{|\operatorname{Aut} y|}. \tag{22.2}$$

The pairing is linear in its first variable. If an automorphism acts nontrivially on L_y, every invariant section vanishes at y. The corresponding component contributes no state.

Pullback of sections along p has an adjoint. For $s \in H(X, p^*L)$, it is

$$(p_!s)(y) = \sum_{[(x,\phi)]\in\pi_0 X_y} \frac{L(\phi)s(x)}{|\operatorname{Aut}(x,\phi)|}. \tag{22.3}$$

The transport makes each summand lie in L_y. Fubini and unitarity give $\langle p_!s, t\rangle = \langle s, p^*t\rangle$. Thus orientation reversal, when it conjugates the action and reverses the field span, reverses the corresponding operator by its Hilbert adjoint.

This integral is distinct from categorical pushforward of a representation. For $p : BG \to \mathrm{pt}$, the invariants of the trivial complex representation are $\mathbb{C}$, of dimension one. The integral of the constant function is $1/|G|$. Both operations exist. Identifying one with a trace of the other requires a specified trace construction and normalization.

Circle and surface counts

For the circle, $\mathcal{F}_G(S^1) = G//G$, with conjugation action, so its mass is one. The space of class functions on this groupoid has dimension the number of conjugacy classes. These two numbers already distinguish a partition mass from a state-space dimension.

For a closed oriented genus-g surface, the untwisted mass is

$$|\mathcal{F}_G(\Sigma_g)| = \frac{1}{|G|}\#\left\{(a_i,b_i)_{i=1}^g : \prod_i [a_i,b_i] = 1\right\} = |G|^{2g-2}\sum_{\rho\in\widehat{G}} (\dim\rho)^{2-2g}. \tag{22.4}$$

Here $\widehat{G}$ is the set of irreducible complex representations.

To verify the formula, put $K = \sum_{a,b\in G}[a,b] \in \mathbb{C}[G]$. For an irreducible representation of dimension d, averaging $\rho(a)\rho(b)\rho(a)^{-1}$ over a gives $|G|\chi_\rho(b)I/d$. Character orthogonality then gives $\rho(K) = |G|^2 I/d^2$. The coefficient of the identity in K^g is $|G|^{-1}$ times its regular trace. Since ρ occurs d times in the regular representation, division by the additional $|G|$ gives (22.4).

For S_3, whose irreducible dimensions are 1, 1, 2, the torus and genus-two masses are respectively 3 and 81. In three dimensions a different count occurs:

$$|\mathcal{F}_G(T^3)| = \frac{\#\{(a,b,c) : a,b,c \text{ commute pairwise}\}}{|G|} = \sum_{[a]} \#\widehat{C_G(a)}.$$

For fixed a, the number of commuting pairs in its centralizer is $|C_G(a)|$ times the number of its conjugacy classes. Summing over the class of a proves the equality. For S_3 the three centralizers are S_3, C_2, C_3, and the answer is $3 + 2 + 3 = 8$.

22.2 Three-cocycles and finite topological gluing

Let G be finite. A normalized multiplicative three-cocycle $\omega : G^3 \to U(1)$ is one when any argument is the identity and satisfies

$$\omega(h,k,l)\omega(g,hk,l)\omega(g,h,k) = \omega(gh,k,l)\omega(g,h,kl). \tag{22.5}$$

For an oriented triangulated closed three-manifold, assign $g_{ij} \in G$ to oriented edges, with $g_{ji} = g_{ij}^{-1}$ and $g_{ij}g_{jk} = g_{ik}$ on each face. The action phase is

$$a(g) = \prod_{[0123]} \omega(g_{01}, g_{12}, g_{23})^{\epsilon_{0123}}, \qquad Z_\omega(M) = |G|^{-N_0}\sum_{\text{flat } g} a(g),$$

where N_0 is the number of vertices and ϵ_{0123} records orientation. The factor $|G|^{-N_0}$ integrates the action of vertex gauge transformations. It remains necessary when the action has stabilizers.

The two-to-three Pachner identity is precisely (22.5). In a one-to-four move, an extension of a fixed flat boundary field has $|G|$ choices for the new vertex label. The cocycle identity makes each extended phase equal to the original phase, and the new vertex factor cancels these choices. Normalization handles degenerate simplices. This gives the finite Dijkgraaf–Witten state sum. Boundary amplitudes require the line determined by the same cocycle.

The degree of transgression

Suppose a space K and its field space admit an evaluation map $\mathrm{ev} : K \times \mathcal{F}_G(K) \to BG$. For a chain $c \in C_d(K)$, define the transgression of an additive cochain u by $(\tau_c u)(a) = \mathrm{ev}^* u(c \times a)$. The cross-product boundary formula gives

$$\delta \tau_c u = (-1)^d \big(\tau_c \delta u - \tau_{\partial c} u\big). \tag{22.6}$$

Indeed, evaluating δu on $c \times a$ gives $u(\partial c \times a) + (-1)^d u(c \times \partial a)$. Solving for the second term proves the identity.

For a degree-three cocycle, integration over a closed three-manifold gives a degree-zero phase. Over a closed surface it gives a degree-one cocycle, hence a flat line on the field groupoid. Over a circle it gives a degree-two cocycle, hence twisting data for representations of that field groupoid. At a point the degree-three class supplies an associator.

The degrees are

dimension integrated	degree remaining	recipient
3	0	action phase
2	1	line on fields
1	2	twisted representation category
0	3	monoidal associator.

In particular, the boundary of a tubular neighborhood of a line in a three-manifold is a surface. Its transgression is a line on surface fields. The twisted category belongs one categorical degree lower, at a circle, with the indicated transgression.

For a three-chain with boundary, (22.6) says that the boundary of its action cochain is the boundary-line cocycle. Its exponential is therefore a section of that line, rather than an invariant scalar on unrestricted boundary fields. Changing the orientation conjugates the line and the phase. These constructions are the finite topological ones of Freed–Quinn, Theorems 1.7 and 2.13. They use oriented manifolds and the actual integration of their chains. An arithmetic analogue must supply its own duality and boundary integration.

THEOREM 22.2.1 *(Finite gluing on specified field data).* Suppose regions have finite field groupoids, boundary Hermitian lines, and invariant action sections. Assume gluing regions gives the homotopy pullback of their field groupoids, and that the action sections contract under the boundary-line pairing.

Assign to a boundary its Hilbert space (22.2). For a region from Σ_0 to Σ_1, let r_i be restriction of fields and let a be the section of $r_0^* L_0^* \otimes r_1^* L_1$. Then

$$T_M s = (r_1)_! \big(a\, r_0^* s\big) \tag{22.7}$$

composes under gluing.

A cylinder whose field restriction is the identity and whose section is the identity gives the identity operator. Disjoint unions give tensor products. Reversing a region and conjugating its action gives T_M^*.

Proof. In the composite of two expressions (22.7), base change replaces restriction followed by integration with integration over the homotopy pullback. The two action sections multiply and contract there to the glued section. Fubini combines the two integrations. The cylinder and disjoint-union assertions follow from the identity functor and multiplication of automorphism orders. Finally, (22.3) is adjoint to pullback, and the adjoint of multiplication by a line section uses its Hermitian conjugate. This reverses the span and proves the last assertion. □

Descent of fields supplies the homotopy pullback in this theorem. The action sections and their contraction are additional hypotheses. An equality of field groupoids without those sections does not determine the glued amplitude.

22.3 The arithmetic action and its boundary torsor

Let F be a totally imaginary number field containing μ_n, put $X = \operatorname{Spec} O_F$, and fix $\zeta : \mathbb{Z}/n \xrightarrow{\sim} \mu_n$. Arithmetic duality gives an invariant map

$$\operatorname{inv}_\zeta : H^3_{\text{ét}}(X, \mathbb{Z}/n) \xrightarrow{\sim} \tfrac{1}{n}\mathbb{Z}/\mathbb{Z}.$$

The choice of ζ identifies the constant coefficients with the roots-of-unity coefficients in this map.

Write $\pi = \pi_1^{\text{ét}}(X)$. For a finite group G and $c \in Z^3(G, \mathbb{Z}/n)$, define

$$\operatorname{CS}_c(\sigma) = \operatorname{inv}_\zeta\big(j^3\sigma^*[c]\big), \qquad j^3 : H^3_{\text{cont}}(\pi, \mathbb{Z}/n) \longrightarrow H^3_{\text{ét}}(X, \mathbb{Z}/n). \tag{22.8}$$

This is Kim's finite arithmetic action. The displayed comparison j^3 is used as a map. No equivalence between the entire group cohomology and étale cohomology is needed.

The value in (22.8) is a scalar in $\frac{1}{n}\mathbb{Z}/\mathbb{Z}$. Before evaluation, the input is a degree-three class. The coefficient sheaf $\mathbb{G}_m$ appearing in arithmetic duality is not the finite gauge group G. Nor does cohomological degree three make the one-dimensional scheme X a real three-manifold.

Conjugation acts trivially on the pulled-back cohomology class, so the action descends to the finite field groupoid $\operatorname{Hom}_{\text{cont}}(\pi, G)//G$. Its finite partition value, with the measure already fixed, is

$$Z_{G,c}(X) = \sum_{[\sigma]} \frac{\exp(2\pi i \operatorname{CS}_c(\sigma))}{|C_G(\sigma(\pi))|}.$$

Finiteness here is the arithmetic finiteness of the specified representation set, as follows from bounded-degree extension finiteness with the stated ramification conditions. A different arithmetic region needs its own such assertion.

An explicit gauge homotopy

The boundary construction needs conjugation on cochains, including its composition. Use the inhomogeneous differential with trivial G-action on $\mathbb{Z}/n$. For a two-cochain b,

$$(db)(g,h,k) = b(h,k) - b(gh,k) + b(g,hk) - b(g,h).$$

Put $\mathrm{Ad}_a\, g = a g a^{-1}$. For a normalized three-cocycle c, define

$$h_a(g,h) = c(a^{-1}, \mathrm{Ad}_a\, g, \mathrm{Ad}_a\, h) - c(g, a^{-1}, \mathrm{Ad}_a\, h) + c(g, h, a^{-1}),$$
$$H_{a,b}(g) = c(b^{-1}, a^{-1}, \mathrm{Ad}_{ab}\, g) - c(b^{-1}, \mathrm{Ad}_b\, g, a^{-1}) + c(g, b^{-1}, a^{-1}). \tag{22.9}$$

The cochain identities are

$$dh_a = c \circ \mathrm{Ad}_a - c, \qquad h_{ab} - h_a \circ \mathrm{Ad}_b - h_b = dH_{a,b}. \tag{22.10}$$

They follow by expanding the differential and cancelling the three-cocycle identities on the successive simplices of a prism. The alternating signs in (22.9) are essential. These are also the explicit conjugation homotopies in Chung–Kim–Kim–Park–Yoo, Appendix B, in the inhomogeneous convention above.

If $db = \sigma^* c$, conjugation by a sends the primitive to $b + \sigma^* h_a$, a primitive for $(\mathrm{Ad}_a\, \sigma)^* c$. The second identity in (22.10) makes these maps compose after quotienting primitives by two-coboundaries. Thus the construction retains the gauge action on the torsor itself.

Local torsors and the global section

Let S be a nonempty finite set of finite places containing every place dividing n. Put

$$U = \operatorname{Spec} \mathcal{O}_F[1/S], \qquad \pi_S = \pi_1^{\text{ét}}(U).$$

Choose restriction maps from $\pi_v = \mathrm{Gal}(\overline{F}_v / F_v)$ to π_S. For a local field $\sigma_v : \pi_v \to G$, consider

$$P_v(\sigma_v) = \{ b_v \in C^2(\pi_v, \mathbb{Z}/n) : db_v = \sigma_v^* c \} / B^2. \tag{22.11}$$

Local cohomological dimension gives $H^3(\pi_v, \mathbb{Z}/n) = 0$, so this set is nonempty. The difference of two primitives is a two-cocycle. Consequently $P_v(\sigma_v)$ is a torsor for $H^2(\pi_v, \mathbb{Z}/n)$, identified by local duality and ζ with $\frac{1}{n}\mathbb{Z}/\mathbb{Z}$.

Take the product of these torsors and push it out along the sum of the local invariant maps. The result is a $\frac{1}{n}\mathbb{Z}/\mathbb{Z}$-torsor $P_S(\sigma_S)$. Here the pushout of a torsor means its contracted product along the specified homomorphism of acting groups. Exponentiation along $t \mapsto e^{2\pi i t}$ makes the associated Hermitian complex line. Formula (22.9) defines its maps under local conjugations.

For a global $\sigma : \pi_S \to G$, the same cohomological dimension theorem gives a primitive b_+ with $db_+ = \sigma^* c$. Its local restrictions determine an element

$$\mathrm{CS}_{U,c}(\sigma) = [\mathrm{res}_v\, b_+]_{v \in S} \quad \text{in } P_S(\mathrm{res}\, \sigma). \tag{22.12}$$

Changing b_+ by a global two-cocycle does not change this element: global reciprocity says that the sum of its local invariants is zero. Changing it by a coboundary already has no effect in (22.11). The gauge homotopies make (22.12) an invariant section over the restriction functor from global to local fields.

The arithmetic input is vanishing in degree three, local invariants in degree two, and reciprocity for restrictions of global degree-two classes. It supplies the torsor and its section. Gluing arbitrary arithmetic bordisms would add the corresponding regions, field descent and compatible action-section identifications of Theorem 22.2.1.

The decomposition formula

Suppose now that σ is unramified on X. At each $v \in S$, its local restriction factors through $\pi_v/I_v \cong \widehat{\mathbb{Z}}$. This group has cohomological dimension one for the finite coefficients in use. Thus its degree-three cocycle has a primitive $b_{-,v}$ unique modulo two-coboundaries. Inflation gives a canonical class of unramified local primitives in (22.11).

Theorem 22.3.1 *(Arithmetic decomposition).* With the coefficients and hypotheses above,

$$\mathrm{CS}_c(\sigma) = \sum_{v \in S} \mathrm{inv}_v[b_{-,v} - \mathrm{res}_v\, b_+].$$

Each bracket is a two-cocycle class. The right side is independent of the chosen global primitive and of the representatives of the local primitive classes.

Proof. Use the compact-support mapping fiber, with differential

$$C_c^j = C^j(\pi_S, \mathbb{Z}/n) \oplus \prod_{v \in S} C^{j-1}(\pi_v, \mathbb{Z}/n), \qquad d(a,b) = (da, \mathrm{res}\, a - db).$$

The pair $(\sigma^* c, b_-)$ represents the unramified class on X. Subtracting $d(b_+, 0)$ gives $(0, b_- - \mathrm{res}\, b_+)$. Arithmetic duality identifies its invariant with the sum of the displayed local invariants. Reciprocity removes a change in b_+, and local coboundaries remove a change in b_-. This is the mapping-fiber proof of Chung–Kim–Kim–Park–Yoo, Theorem 1.1 and §4. □

Both primitive classes belong to the same boundary torsor. Their difference is a scalar. Reversing the difference reverses the action, so the compact-support differential fixes a necessary sign.

Compact p-adic coefficients

There is also a torsor construction with compact coefficients. For an odd prime p, write $\Gamma = \mathbb{Z}_p^\times = \Delta \times \Gamma_1$, where Δ has order $p-1$ and $\Gamma_1 = 1 + p\mathbb{Z}_p$. Let A be a p-adic Lie group with a homomorphism $t : A \to \Gamma$, and let χ be the cyclotomic character. Fix an actual continuous automorphism σ of Γ and restrict to representations ρ satisfying $t\rho = \sigma\chi$. Gauge transformations are taken in $\ker t$.

Let $\mathbb{Z}_p[[\Gamma]]_\rho$ have the left action through $t\rho$. A compatible choice of roots of unity gives a basis ζ of $\mathbb{Z}_p(1)$. There is an equivariant isomorphism

$$\mathbb{Z}_p[[\Gamma]]_\rho \longrightarrow \Lambda = \mathbb{Z}_p[[\Gamma]] \widehat{\otimes} \mathbb{Z}_p(1), \qquad [\gamma] \longmapsto [\sigma^{-1}\gamma] \otimes (\sigma^{-1}\gamma)\zeta. \tag{22.13}$$

The first factor on the right has left action through χ, and the second has the Tate action. To check equivariance, put $u = \chi(g)$. The image of $[\sigma(u)\gamma]$ is $[u\sigma^{-1}\gamma] \otimes u(\sigma^{-1}\gamma)\zeta$, which is exactly the action of g on the displayed image.

For a continuous class $c \in H^3(A, \mathbb{Z}_p[[\Gamma]])$, use (22.13) on the pulled-back cocycle. Under vanishing of degree-three continuous cohomology with these compact coefficients, its local primitives form $H^2(\pi_v, \Lambda)$-torsors. The augmentation $\Lambda \to \mathbb{Z}_p(1)$, followed by the local invariant $H^2(\pi_v, \mathbb{Z}_p(1)) \cong \mathbb{Z}_p$, pushes their product to a $\mathbb{Z}_p$-torsor. A global primitive gives a section by the same reciprocity argument. Gauge maps use the conjugation prism with this coefficient action.

A sufficient setting uses finite quotient modules that compute the continuous compact-coefficient cochains by an inverse sequence. Assume finite degree-two cohomology and vanishing degree-three cohomology. The finite degree-two systems satisfy the Mittag–Leffler condition. The derived inverse-limit exact sequence then gives degree-three vanishing. The augmentations, local duality and reciprocity

must be compatible with this sequence. These hypotheses describe the coefficient passage used in the p-adic construction of Arithmetic Chern–Simons II, §3.

The automorphism condition in (22.13) matters. A p-adic unit exponent acts invertibly on Γ_1, but does not automatically define an automorphism of the full Γ. At $p = 5$, the integer exponent 2 is a 5-adic unit and sends -1 to 1.

For an integer exponent m, the full power map is an automorphism precisely when $\gcd(m, p(p-1)) = 1$. One may instead specify a power automorphism on Γ_1 and an independent automorphism on Δ. The resulting torsor construction is positive on this domain. It supplies no complex Hilbert measure without additional scalar and pairing data.

22.4 Abelian linking and Wilson correlations

The abelian theory has a computable arithmetic correlation, beyond the definition of a finite sum. Assume now $\mu_{n^2} \subset F$ and retain the trivialization ζ. Put

$$V = H^1(X, \mathbb{Z}/n), \qquad V^\vee = \operatorname{Hom}(V, \tfrac{1}{n}\mathbb{Z}/\mathbb{Z}).$$

Artin–Verdier duality identifies $V^\vee$ with $\operatorname{Ext}^2_X(\mathbb{Z}/n, \mathbb{G}_m)$ and with $\operatorname{Cl}(F)/n$. Let δ be the Bockstein from $0 \to \mu_n \to \mu_{n^2} \to \mu_n \to 0$. Define $D : V \to V^\vee$ by

$$(Dy)(x) = B(x, y) := \operatorname{inv}_\zeta\big(x \smile \delta(\zeta_* y)\big), \tag{22.14}$$

where the notation for the invariant includes the indicated coefficient pairing.

Proposition 22.4.1 *(Arithmetic linking pairing).* The form B is symmetric. Its radical is $K = \ker D$. For $\xi, \eta \in \operatorname{im} D$, the expression

$$\operatorname{ht}_n(\xi, \eta) = B(x, y), \qquad Dx = \xi, \quad Dy = \eta,$$

is well defined and symmetric. A homologically n-trivial ideal means an ideal whose class modulo n lies in $\operatorname{im} D$. It need not have zero class modulo n.

Proof. The compatible trivialization modulo n^2 identifies the constant and roots-of-unity Bocksteins. Their cup-product identity in degree one is

$$\delta_2(x \smile \zeta_* y) = \delta' x \smile \zeta_* y - x \smile \delta(\zeta_* y).$$

In this arithmetic setting $\delta_2 = 0$. Indeed the n-adic duality group $H^3(X, \mathbb{Z}_n(1)) \cong \mathbb{Z}_n$ is torsion free, so reduction in degree two from $\mathbb{Z}_n(1)$ to μ_n is surjective. It factors through μ_{n^2}, which makes the Bockstein zero. Graded commutativity between degrees two and one now gives $B(x, y) = B(y, x)$. This is the argument of Chung–Kim–Kim–Pappas–Park–Yoo, Lemmas 2.1–2.2.

Perfect duality shows that $B(x, y) = 0$ for all x exactly when $Dy = 0$. Symmetry gives the same radical in the other variable. Changing either lift by an element of K therefore leaves the height unchanged. □

Let $G = \mathbb{Z}/n$, and let $u \in H^1(G, \mathbb{Z}/n)$ be the identity character. For the three-class $c = u \smile \delta' u$, naturality of the Bockstein identifies the arithmetic action with $\mathrm{CS}_c(x) = B(x, x)$. An ideal class $\xi \in V^\vee$ supplies the Wilson character

$$W_\xi(x) = \exp(2\pi i \langle x, \xi \rangle).$$

Under class field theory this evaluates the unramified character x on the Artin class of the ideal. Its correlation in the quadratic action is therefore an actual arithmetic finite sum.

Theorem 22.4.2 *(Finite Gaussian correlation).* Let p be odd and let V be an a-dimensional $\mathbb{F}_p$-vector space. Let $B : V \times V \to \mathbb{F}_p$ be symmetric with radical K of dimension b. Write $\psi(t) = e^{2\pi i t/p}$, $r = a - b$, and $G_p = \sum_{t \in \mathbb{F}_p} \psi(t^2)$. For $\lambda \in V^*$, put

$$S(\lambda) = \sum_{x \in V} \psi\big(B(x,x) + \lambda(x)\big).$$

If $\lambda|_K \neq 0$, then $S(\lambda) = 0$. Otherwise choose z with $\lambda(x) = B(x,z)$. If $\overline{B}$ is the induced nondegenerate form on V/K, then

$$S(\lambda) = p^b \left(\frac{\det \overline{B}}{p}\right) G_p^r \, \psi\big(-B(z,z)/4\big). \tag{22.15}$$

The determinant is taken in a basis of V/K. Its Legendre symbol is independent of that basis. The empty determinant and G_p^0 are one.

Proof. On a coset of K, the quadratic term is constant. The sum of the additive character $\psi\lambda$ over K is zero unless $\lambda|_K = 0$. In the latter case, nondegeneracy on V/K supplies z, unique modulo K.

Since 2 is invertible,

$$B(x,x) + B(x,z) = B(x + z/2, x + z/2) - B(z,z)/4.$$

Translation leaves the sum unchanged.

Diagonalize $\overline{B}$ over $\mathbb{F}_p$. Each diagonal coefficient $d \neq 0$ contributes $\sum_t \psi(dt^2) = (d/p) G_p$: counting square roots of an element gives $1 + (u/p)$, and the substitution $u \mapsto du$ proves this identity. The radical contributes p^b. Multiplying proves (22.15). □

The classical Gauss evaluation is $G_p = \epsilon_p \sqrt{p}$, with $\epsilon_p = 1$ for $p \equiv 1 \pmod 4$ and $\epsilon_p = i$ for $p \equiv 3 \pmod 4$, for the displayed additive character and the positive real square root. Thus the magnitude in (22.15) is $p^{(a+b)/2}$. The formula with this constant is Theorem 1.1 of the abelian arithmetic Chern–Simons paper.

Apply the theorem to (22.14), after identifying $\frac{1}{p}\mathbb{Z}/\mathbb{Z}$ with $\mathbb{F}_p$. If each $\xi_j = Dz_j$, then $z = \sum_j z_j$ represents $\lambda = \sum_j \xi_j$, and

$$\frac{S(\sum_j \xi_j)}{S(0)} = \psi\left(-\frac{1}{4} \sum_{i,j} \mathrm{ht}_p(\xi_i, \xi_j)\right).$$

Here $S(0) \neq 0$. In the action groupoid every abelian field has automorphism group $\mathbb{Z}/p$, so the absolute amplitude is $S(\lambda)/p$. This factor cancels in the normalized correlation. The factor $1/4$, the radical selection rule and the distinction between absolute and normalized amplitudes are all forced by the calculation.

At $p = 2$, this completion of the square is unavailable. A quadratic refinement requires separate treatment.

The linking form also has a class-field description. A $\mathbb{Z}/n$-torsor on X determines the invertible O_F-module on which the group acts through ζ. Its ideal class is the class-invariant map $\Psi : V \to \mathrm{Cl}(F)$. With the Artin convention of the duality pairing, the map D is Ψ followed by reduction modulo n. Thus the pairing is the evaluation of one unramified character on the class invariant of the other.

The proof in the same paper, Theorem 4.1, identifies the dual Bockstein with $\mathrm{Cl}(F)[n] \to \mathrm{Cl}(F)/n$ by Yoneda products. This gives the same arithmetic action, with its coefficient trivialization retained.

Local boundary conditions for linking

There is a relative version on U. For coefficient objects G on U, F_S on its specified local boundary, and a map $f : F_S \to i^*G$, its cochain complex is

$$C^j(U, G \times_S F_S) = C^j(U, G) \oplus C^j(\partial U, F_S) \oplus C^{j-1}(\partial U, i^*G),$$

with

$$d(c, b, a) = (dc, db, da + (-1)^j (f b - \operatorname{res} c)).$$

For degrees i, j, one cup product is

$$(c, b, a) \smile (c', b', a') = \big(c \smile c', b \smile b', (-1)^j a \smile f(b') + \operatorname{res}(c) \smile a'\big).$$

Expanding the differential verifies its Leibniz identity. Replacing the third component by $(-1)^j a \smile \operatorname{res}(c') + f(b) \smile a'$ changes the product of cocycles by $d(0, 0, (-1)^i a \smile a')$. Thus the two choices induce the same product in cohomology.

Take $G = \mathbb{Z}/n$, $F_S = \mu_{n^2}$, and let f be reduction followed by ζ^{-1}, with all places dividing n in S. The resulting degree-one classes specify characters with chosen local lifts to μ_{n^2}. Their connecting map lands in $H^2_c(U, \mathbb{Z}/n)$. The relative duality pairing and this connecting map define the height as above. The degree-two connecting map vanishes in this setting, and the Bockstein product identity proves symmetry. This is the relative construction in §3 of the same paper.

It also gives a local computation without confusing a knot longitude with inertia. If an ideal class $[I]$ is the connecting image of a character x, its height against $J = \prod_{v \notin S} \mathfrak{p}_v^{e_v}$ is

$$\operatorname{ht}_{S,n}(I, J) = \sum_{v \notin S} e_v \, x(\operatorname{Art}_v(\varpi_v)).$$

The Artin maps here use the normalization paired with the chosen duality invariant. If x is represented by a Kummer class, each summand is the corresponding local norm-residue symbol with that same normalization. The connecting image and reciprocity map must be fixed before replacing this formula by a Hilbert-symbol convention.

22.5 Wilson values and Frobenius

Let $\sigma : \Gamma \to G$ be a gauge field and let $\tau : G \to \mathrm{GL}(V_\tau)$ be a representation over a specified field. These maps have different sources. For a specified conjugacy class of loops γ in Γ, the Wilson function is

$$W_{\tau,\gamma}(\sigma) = \operatorname{tr} \tau(\sigma(\gamma)).$$

It is invariant under gauge conjugation.

For a complex gauge representation and an invariant phase a, its normalized expectation is

$$\langle W_{\tau,\gamma} \rangle_a = \frac{\displaystyle\int_{\mathcal{F}_G} a W_{\tau,\gamma}}{\displaystyle\int_{\mathcal{F}_G} a}, \qquad \int_{\mathcal{F}_G} a \neq 0. \tag{22.16}$$

The denominator condition is part of the definition. A complex phase can make it vanish: two discrete fields with phases 1 and -1 already give zero.

At trivial action, (22.16) is a groupoid average. It equals a selected field value when the observable is constant on the support of the weighted sum. Conditioning on one field component also gives its value. It does not concentrate on a chosen field merely because the action is zero. On $\mathcal{F}_{C_2}(S^1) = C_2//C_2$, each holonomy has weight $1/2$, so the sign character has expectation zero and square expectation one.

For fixed fields, the tensor identity is $W_{\tau\otimes\nu,\gamma} = W_{\tau,\gamma}W_{\nu,\gamma}$. Its expectation is the correlation of the two observables, not generally the product of their expectations. The sign character example proves this distinction in dimension one.

The unramified quotient

For a nonarchimedean local field F_v with residue field $\mathbb{F}_q$, write

$$1 \longrightarrow I_v \longrightarrow G_{F_v} \longrightarrow \widehat{\mathbb{Z}} \longrightarrow 1.$$

Arithmetic Frobenius is the element of the quotient acting as $x \mapsto x^q$ on residue-field extensions. Geometric Frobenius is its inverse. A lift to G_{F_v} is well defined modulo inertia. Its image in an unramified representation is therefore well defined up to conjugacy.

The tame inertia quotient is $I_v/P_v \cong \prod_{\ell\neq p} \mathbb{Z}_\ell(1)$, where P_v is wild inertia and p is the residue characteristic. It is not the unramified quotient $\widehat{\mathbb{Z}}$. In the knot analogy, inertia gives a meridian and a Frobenius lift gives a longitude. On an unramified rank-d representation every inertia element has trace d, while the Frobenius trace can be different.

Nor does $p \nmid N$ make a representation into $\mathrm{GL}_d(\mathbb{Z}/N)$ unramified. The quadratic extension $\mathbb{Q}_3(\sqrt{3})/\mathbb{Q}_3$ is totally ramified. Its quadratic character has values $\{\pm 1\} \subset \mathbb{F}_5^\times$, although $3 \nmid 5$. Unramifiedness is a condition on the kernel of the representation.

Let E_w/F_v have residue degree f. Its arithmetic Frobenius maps to the f-th power of Frobenius on the unramified quotient of F_v. The same power rule holds in geometric convention. It gives the corresponding trace-of-power identity on an unramified carrier. A map between arbitrary formal neighborhoods at different rational primes has no such interpretation. Indeed, when $p \neq q$, there is no unital $\mathbb{Z}$-algebra map $\mathbb{Z}_p \to \mathbb{Z}_q$: the integer q is a unit in the source and not in the target.

The closed immersion $\operatorname{Spec}\mathbb{F}_p \hookrightarrow \operatorname{Spec}\mathbb{Z}$ has scheme codimension one. The knot analogy is a comparison of cohomology, fundamental groups and local duality. It does not change that codimension or furnish a topological tubular neighborhood with all its gauge-theoretic operations.

Coefficient fields and congruences

The tautological representation of $\mathrm{GL}_d(\mathbb{Z}/N)$ has trace in $\mathbb{Z}/N$. For $N > 1$, there is no unital ring map from this ring to $\mathbb{C}$. Thus it is not itself a complex Wilson label. A complex representation of the same finite group has its own character, which must be compared to the modular matrix trace by additional data.

A continuous ℓ-adic representation on a finite-dimensional E-vector space, with $E/\mathbb{Q}_\ell$ finite, admits a stable $\mathcal{O}_E$-lattice when its image is compact. Fix such a lattice L and a uniformizer ϖ. The traces on $L/\varpi^r L$ are compatible and satisfy

$$\operatorname{tr}\rho(g) = \varprojlim_r \operatorname{tr}\big(\rho(g) \mid L/\varpi^r L\big) \quad \text{in } \mathcal{O}_E.$$

This is one ℓ-adic congruence tower. It does not produce reductions modulo every integer or complex characters of every congruence group.

If a trace lies in a number field, one can specify its ℓ-adic and complex embeddings. The topology still matters. Under any field embedding fixing $\mathbb{Q}$, the sequence ℓ^r, which tends to zero ℓ-adically, maps to the same real integers and diverges in $\mathbb{C}$. An abstract scalar embedding therefore cannot turn ℓ-adic convergence into complex convergence.

An arithmetic Wilson identity now has a precise form. Choose a gauge representation τ_N, a Frobenius longitude and a scalar realization. Then compare its normalized expectation with the trace of the arithmetic representation. A profinite version additionally needs the actual transition maps and convergence in the chosen scalar topology. Equality of ranks supplies none of these identities.

Power traces and Euler factors

Let F be an endomorphism of a d-dimensional vector space over a characteristic-zero field. In formal power series,

$$\det(1 - TF)^{-1} = \exp\left(\sum_{m\geq 1} \frac{\operatorname{tr}(F^m)}{m} T^m\right). \tag{22.17}$$

After scalar extension, put F in triangular form. Multiplying $(1 - T\alpha_i)^{-1}$ and expanding its logarithm gives the right side. Equivalently, differentiating logarithmically and fixing the constant term proves the identity over the original field.

Thus all power traces determine the Euler polynomial and the semisimple conjugacy class over an algebraic closure. A single trace does not. The finite-order matrices $\operatorname{diag}(1, -1)$ and $\operatorname{diag}(i, -i)$ both have trace zero, but their polynomials are $1 - T^2$ and $1 + T^2$. Even all power traces do not detect a Jordan extension: I_2 and a nontrivial unipotent Jordan block have trace two in every positive power.

Characteristic zero is also necessary for this reconstruction from unrestricted power traces. Over $\mathbb{F}_3$, the matrices I_3 and $-I_3$ have all power traces zero, while their Euler polynomials are $1 - T^3$ and $1 + T^3$. Division by m in (22.17) cannot be performed in that coefficient ring. Integral Witt coordinates retain additional data beyond their ghost traces.

For an unramified ℓ-adic representation at v, $\ell \neq p$, the chosen geometric Frobenius gives

$$L_v(s, \rho) = \det(1 - q^{-s}\rho(\operatorname{Frob}_v^{\mathrm{geom}}))^{-1}.$$

A Wilson formula for every power would determine this factor after the coefficient comparison. A Wilson formula for the first trace alone would not.

For a Weil–Deligne representation (r, N) at a ramified place, the local factor instead uses the Frobenius-stable space $(\ker N)^{I_v}$:

$$L_v(s, r, N) = \det(1 - q^{-s} r(\operatorname{Frob}_v^{\mathrm{geom}}) \mid (\ker N)^{I_v})^{-1}.$$

The conductor and epsilon factor are further local data. In particular an epsilon factor also depends on the additive character and measure convention. It is not inserted into this determinant as an unspecified correction to the first trace.

If a realization is pure of motivic weight m, its complex Frobenius eigenvalues have absolute value $q^{m/2}$. Unitary normalization multiplies them by $q^{-m/2}$. This normalization is separate from a functional-equation center of a global L-function and from an energy grading on a Fock space. For example $\mathbb{Q}_\ell(-1)$ has motivic weight two in the cohomological geometric convention. A formal scaling parameter labeled one does not change it.

An elliptic curve at five

The curve $E : y^2 = x^3 - x$ over $\mathbb{F}_5$ has affine fiber sizes 1, 1, 2, 2, 1 over $x = 0, 1, 2, 3, 4$. The point at infinity gives $\#E(\mathbb{F}_5) = 8$, so $a_5 = 5 + 1 - 8 = -2$. For $\ell \neq 5$, arithmetic Frobenius on $V_\ell E = T_\ell E \otimes \mathbb{Q}_\ell$ has trace -2 and determinant 5. Its inverse has trace $-2/5$ and determinant $1/5$.

The cohomological carrier

$$H^1_{\text{ét}}(E_{\overline{\mathbb{F}}_5}, \mathbb{Q}_\ell) = \operatorname{Hom}(V_\ell E, \mathbb{Q}_\ell)$$

therefore has geometric Frobenius trace -2 and determinant 5. Its local Euler polynomial is $1 + 2T + 5T^2$. Inertia on the good-reduction representation is trivial and has trace two, so the meridian and longitude give different observables in this example.

The Tate-module polarization takes values in $\mathbb{Q}_\ell(1)$. Dualizing gives a cohomological polarization with paired geometric eigenvalue product 5.

For a genus-g Jacobian the corresponding cohomological rank is $2g$. In a Siegel setting the standard and spin representations instead have ranks $2g + 1$ and 2^g. Their Wilson labels and Euler factors must use the actual representation.

The substitution $g = 0$ gives a rank-zero Jacobian carrier, whose trace is zero and whose symmetric-algebra character is one. A nontrivial rank-two arithmetic gauge sector requires a separate representation.

For any finite-dimensional carrier V, the graded trace on $\operatorname{Sym}(V)$ is the inverse determinant in (22.17). A Heisenberg Fock space with creation modes at every positive energy has the different character $\prod_{r \geq 1} \det(1 - q^r F)^{-1}$, when the trace is defined. The oscillator grading must therefore be specified before either expression is called a boundary character. The arithmetic equality between such a character and an Euler factor remains a map and trace comparison on the chosen realization.

22.6 Congruence towers and Hilbert limits

For a fixed rank d, reduction gives surjections $G_N = \mathrm{GL}_d(\mathbb{Z}/N) \to G_M$ when $M \mid N$. Their group limit is $\mathrm{GL}_d(\widehat{\mathbb{Z}})$. Passing from groups to fields, actions and state spaces requires more maps. In particular, a field at level M can fail to lift to level N.

For a prime-power step, put $G_r = \mathrm{GL}_d(\mathbb{Z}/\ell^r)$, $r \geq 1$. Then

$$|G_r| = \ell^{d^2(r-1)} \prod_{j=0}^{d-1} (\ell^d - \ell^j), \qquad \ker(G_{r+1} \to G_r) = 1 + \ell^r M_d(\mathbb{F}_\ell).$$

The kernel has the additive multiplication law of $M_d(\mathbb{F}_\ell)$, since $2r \geq r + 1$. It is abelian but generally not central: conjugation by the permutation matrix exchanging two basis vectors sends E_{12} to E_{21}. The cardinality formula follows by counting ordered independent columns modulo ℓ and then lifting each matrix entry. An invertible matrix modulo ℓ remains invertible over $\mathbb{Z}/\ell^r$.

The lifting measure

Consider an extension of finite groups $1 \to K \to E \xrightarrow{p} G \to 1$, and a finitely presented group Γ, or a profinite group with the specified finite representation sets. For $\rho : \Gamma \to G$, let $\mathcal{L}_\rho$ be the homotopy fiber of $\operatorname{Hom}(\Gamma, E)//E \to \operatorname{Hom}(\Gamma, G)//G$. The isomorphism to ρ is part of this fiber.

Proposition 22.6.1 *(Lifting mass).* Suppose K is abelian. If ρ has a lift, conjugation through a lift defines a Γ-module K_ρ, and

$$|\mathcal{L}_\rho| = \frac{|H^1(\Gamma, K_\rho)|}{|H^0(\Gamma, K_\rho)|}.$$

If there is no lift, the mass is zero. For compatible action phases $a_E = p^* a_G$, finite integration gives

$$Z_E = \sum_{[\rho]} \frac{a_G(\rho)|\mathcal{L}_\rho|}{|C_G(\rho(\Gamma))|}. \tag{22.18}$$

Proof. Choose a lift $\widetilde{\rho}$. Any other lift has the form $z(g)\widetilde{\rho}(g)$, and the homomorphism law is precisely the one-cocycle equation for z with values in K_ρ. The homotopy fiber is equivalent to these lifts modulo K-conjugation. Lift an isomorphism to the target field into E to make it the identity.

Conjugation changes z by a one-coboundary. Its stabilizer is $H^0(\Gamma, K_\rho)$. This proves the mass formula.

The empty case is immediate. Equation (22.18) is Theorem 22.1.1 with the phase constant on each fiber. □

For a central kernel $K = (\mathbb{F}_\ell)^e$ with trivial action, the mass is $|K|^{b_1 - b_0}$, where the b_i are the dimensions of $H^i(\Gamma, \mathbb{F}_\ell)$. For the point it is $1/|K|$, not one.

Centrality also does not remove the obstruction to lifting. Take $E = C_4$, $G = C_2$, and $\Gamma = C_2$. The trivial homomorphism to G has two lifts, each with two automorphisms in the fiber, so its mass is one. The identity homomorphism has no lift: an odd element of C_4 cannot be the image of an element of order two. Its mass is zero. No constant fiber factor works for both fields.

If all masses equal a specified $m_{N,M}$, then $Z_N = m_{N,M} Z_M$. For the chosen normalization $\widetilde{Z}_N = |G_N|^{-\chi} Z_N$, one obtains

$$\widetilde{Z}_N = |K|^{-\chi} m_{N,M} \widetilde{Z}_M.$$

The exponent χ must come from a specified cohomology theory. Compatibility requires the displayed factor to be one. The equation uses no division by a possibly zero partition value, and a scalar equality alone does not define transition maps on state spaces.

The phases also require compatible levels. Pullback of a fixed cocycle from a quotient gives one such datum on all finer quotients. If one instead requires $c_N = p_{N,M}^* c_M$ for every $M \mid N$, including $M = 1$, every normalized three-class is zero, since the bottom group is trivial. Nontrivial continuous finite-coefficient classes are naturally represented on a sufficiently fine finite quotient and pulled back above it. More general transition laws require their own cochains and coherences. A complex scalar called a level is not by itself such a family of finite-group three-classes.

A positive profinite Hilbert construction

There is a direct limit of finite Hilbert spaces when the measure and transition maps are known. Let $G_{r+1} \twoheadrightarrow G_r$ be a sequence of finite groups, with kernels K_r, and use uniform probability measure on each group. Set

$$H_r = L^2(G_r, |G_r|^{-1}\,\text{counting measure}), \qquad (i_r f)(g) = f(p_r g).$$

Then i_r is an isometry. Its adjoint is conditional averaging,

$$(P_r f)(h) = \frac{1}{|K_r|} \sum_{p_r g = h} f(g), \qquad P_r i_r = 1.$$

Both assertions follow by partitioning G_{r+1} into its equally sized fibers.

Theorem 22.6.2 *(Haar realization).* For $G = \varprojlim_r G_r$, normalized Haar measure μ has the given uniform measures as its finite pushforwards. Pullback identifies the Hilbert completion of $\operatorname{colim}_r (H_r, i_r)$ with $L^2(G, \mu)$. The finite conjugation-invariant subspaces have dense union in the conjugation-invariant subspace of $L^2(G, \mu)$.

Proof. The compatible uniform measures assign mass $1/|G_r|$ to each cylinder over a point of G_r. They define the normalized invariant measure on the compact profinite group. Every finite pullback is isometric by this cylinder formula. Locally constant cylinder functions separate points and are dense in continuous functions, hence in $L^2(G, \mu)$. This proves the completion statement.

The conditional expectation onto level r commutes with conjugation, because its fibers and Haar measure do. These orthogonal projections converge strongly to the identity on the dense union just described. Applying them to an invariant function proves density in the invariant subspace. □

This construction uses probability on the group elements. It does not replace the groupoid measure on arithmetic representations or the action phase in (22.18). To apply it to arithmetic states one must construct equally precise measures, isometries and adjoints there.

The bounded part of an inverse system

An inverse diagram always defines a pro-object in its specified category. A topological inverse limit need not have a Hilbert norm. For example, the coordinate projections $\mathbb{C}^{r+1} \to \mathbb{C}^r$ have inverse limit $\mathbb{C}^{\mathbb{N}}$ with its product topology. Every basic neighborhood constrains finitely many coordinates and contains a whole line in an unconstrained coordinate. It cannot be a bounded neighborhood for any norm inducing that topology. Passing to the associated condensed vector spaces does not supply a missing Hilbert topology.

The orthogonal projections above do have a distinguished Hilbert part. The following statement also applies to finite-dimensional state spaces once isometric transitions have been constructed.

Proposition 22.6.3 *(Bounded compatible vectors).* Let H_r be Hilbert spaces with isometric maps i_r, let $P_r = i_r^*$, and let H be the Hilbert completion of their increasing union. Then

$$H \xrightarrow{\sim} \left\{ (x_r) : P_r x_{r+1} = x_r, \sup_r \|x_r\| < \infty \right\}, \qquad \|x\|^2 = \lim_r \|x_r\|^2,$$

is an isometric isomorphism, using the projections from H on the left and the displayed norm on the right.

Proof. The projections onto the increasing closed subspaces H_r converge strongly to the identity of H. They give a compatible sequence with the asserted norm.

Conversely, view a compatible sequence in the increasing union. For $s \geq r$, orthogonality gives

$$\|x_s - x_r\|^2 = \|x_s\|^2 - \|x_r\|^2.$$

The squared norms increase and are bounded, so this sequence is Cauchy. Its limit has projections x_r, and its norm is the stated limit. This is inverse to the first map. □

For the coordinate system, the bounded part is ℓ^2, a proper subspace of the product limit. Specifying this norm condition is a substantive part of the construction. A Hilbert limit does not ensure trace continuity. The identity on $\mathbb{C}^r$ has trace r, while the identity on ℓ^2 is not trace class. Coherent finite operators alone do not define an infinite partition trace.

22.7 TWISTED TRACES AND A FINITE MODULAR EXAMPLE

The degree-two transgression on circle fields has a categorical recipient. Let $\mathcal{X}$ be a finite groupoid and let τ be a normalized complex multiplicative two-cocycle on its composable arrows. Its twisted groupoid algebra has basis u_a, one element for each arrow, and multiplication

$$u_a u_b = \tau(a,b)u_{ab} \quad \text{when } a,b \text{ are composable}, \qquad u_a u_b = 0 \quad \text{otherwise}.$$

The cocycle identity gives associativity, and the identity arrows give its unit. A finite skeleton may be used if the groupoid has more than finitely many objects.

The *inertia groupoid* $I\mathcal{X}$ has objects (x,g), with $g \in \mathrm{Aut}(x)$, and arrows $h : (x,g) \to (y, hgh^{-1})$. Conjugation in the twisted algebra gives a line on this groupoid. On a one-object component its transport is

$$u_g \longmapsto \frac{\tau(h,g)\tau(hg,h^{-1})}{\tau(h,h^{-1})} u_{hgh^{-1}}. \tag{22.19}$$

The same formula applies to composable arrows. Denote this line by L_τ. Its degree-zero homology means the direct sum of its fibers modulo these transport relations.

PROPOSITION 22.7.1 *(Finite twisted Hochschild trace).* Over $\mathbb{C}$, the twisted groupoid algebra satisfies

$$\mathrm{HH}_0(\mathbb{C}_\tau[\mathcal{X}]) \cong H_0(I\mathcal{X}, L_\tau), \qquad \mathrm{HH}_j(\mathbb{C}_\tau[\mathcal{X}]) = 0 \quad (j>0).$$

The same degree-zero trace is obtained from its category of perfect modules.

Proof. Degree-zero Hochschild homology is the quotient of the algebra by commutators. Commuting with the identity idempotents kills every non-loop arrow. For a loop, $[u_h, u_g u_h^{-1}]$ identifies its class with the conjugate loop in (22.19). Conversely the cyclic relation between any two composable arrows is one of these transported loop relations. This gives the first isomorphism.

Each connected component is Morita equivalent to a twisted algebra of a finite automorphism group H. It is semisimple: average a linear projection onto a submodule over conjugation by the invertible operators u_h. Projective scalar factors cancel under conjugation, so the average is module-linear. Equivalently, the element

$$\frac{1}{|H|}\sum_{h\in H} u_h \otimes u_h^{-1}$$

splits multiplication as a bimodule map. The algebra is therefore projective over its enveloping algebra, and positive Hochschild homology vanishes. Morita invariance proves the remaining assertions. □

The characteristic assumption is essential. Over $\mathbb{F}_p$, the untwisted algebra of C_p is $\mathbb{F}_p[\epsilon]/(\epsilon^p)$, whose module of differentials, and hence its first Hochschild homology, is nonzero. A derived trace cannot then be replaced by its degree-zero inertia quotient.

For the finite topological theory, $\mathcal{X}$ can be the groupoid of circle fields, with τ the transgression of its three-cocycle. Its category of twisted representations and its Hochschild trace have the types just described. A trace comparison with an arithmetic Hecke category still requires that arithmetic category, its coefficient realization and the actual map on cyclic complexes. Equal dimensions would not define such a map.

The double of C_2

The simplest nontrivial modular example can be given without an arithmetic hypothesis. Let $A = C_2$, written additively, and let $\widehat{A}$ be its two complex characters. Consider finite-dimensional vector spaces graded by $A \times \widehat{A}$. Simple objects are (a, χ), tensor product adds a and multiplies characters, and the associator is the identity. On simple objects set

$$c_{(a,\chi),(b,\psi)} = \chi(b), \qquad \theta_{(a,\chi)} = \chi(a).$$

The bicharacter law gives both hexagon identities. The balancing identity is

$$(\chi\psi)(a+b) = \chi(a)\psi(b)\chi(b)\psi(a),$$

so these data give a ribbon category with all simple dimensions one.

If a simple object has trivial monodromy with every simple, varying b forces $\chi = 1$ and varying ψ forces $a = 0$. Thus the braiding is nondegenerate.

In the order $(0,1)$, $(0,\mathrm{sgn})$, $(1,1)$, $(1,\mathrm{sgn})$, the normalized matrices are

$$S = \frac{1}{2}\begin{pmatrix} 1 & 1 & 1 & 1 \\ 1 & 1 & -1 & -1 \\ 1 & -1 & 1 & -1 \\ 1 & -1 & -1 & 1 \end{pmatrix}, \qquad T = \mathrm{diag}(1,1,1,-1). \tag{22.20}$$

Character orthogonality gives $S^2 = 1$, and direct multiplication gives $(ST)^3 = 1$.

These matrices can also be obtained from the untwisted finite gauge states on a torus. Its four fields are $(a,b) \in A^2$, each with automorphism group A. Normalize their delta functions by the measure (22.2) and Fourier transform in the second holonomy. The resulting basis is indexed by (a,χ).

Exchanging the two holonomies acts by $S_{(a,\chi),(b,\psi)} = \chi(b)\psi(a)/2$, while a Dehn twist acts by $\chi(a)$. This constructs the displayed comparison of finite gauge and modular data. Its dimension is four, agreeing with $|\mathcal{F}_{C_2}(T^3)| = 8/2 = 4$.

A finite semisimple complex category has finite-dimensional HH_0, with one basis vector for each simple object. It cannot be isomorphic as a vector space to a target containing a nonzero polynomial Fock space with infinitely many independent creation states. This excludes that literal finite-category trace lift. It leaves open an infinite category, an appropriate completion, a selected finite trace sector, or a compatible family of finite categories. Each choice changes the recipient and requires its own trace map.

22.8 Ordered incidence and local current algebras

An order on places gives an algebraic bar construction before it gives an arithmetic field theory. Fix a finite ordered set $S = \{s_1 < \cdots < s_r\}$. An interval partition of S is determined by a subset of the $r-1$ possible cuts. Let $\mathcal{I}_S$ have these partitions as objects and one arrow from a partition to each coarsening obtained by deleting cuts. The one-block partition t_S is terminal.

Let $D_S : \mathcal{I}_S \to \mathrm{Ch}(k)$ be any covariant diagram of chain complexes. Its simplicial replacement has

$$B_n(D_S) = \bigoplus_{P_0 \to \cdots \to P_n} D_S(P_0).$$

The first face applies the first diagram map. The other faces omit an intermediate object or the last object. Degeneracies insert identities. Write $\partial = \sum_i (-1)^i d_i$. With internal homological degree q, the direct-sum totalization has degree $n+q$ and differential $\partial + (-1)^n d_{\mathrm{int}}$.

PROPOSITION 22.8.1 *(Contraction of the incidence bar).* The augmentation induced by $P \longrightarrow t_S$ is a quasi-isomorphism

$$\mathrm{Tot}_{\oplus}\, B_\bullet(D_S) \longrightarrow D_S(t_S).$$

It holds for unbounded internal complexes. If the indexing category is the disjoint union of the $\mathcal{I}_S$, its homotopy colimit is $\bigoplus_S D_S(t_S)$.

Proof. Include $D_S(t_S)$ as the terminal summand in degree zero. On a simplex of degree n, append its unique arrow to t_S and multiply by $(-1)^{n+1}$. Denote this map by h_n. The faces cancel in pairs, except the last face, and in degree zero the terminal augmentation. Consequently $\partial h + h\partial = 1 - i\epsilon$.

The internal differential commutes with appending a terminal arrow. Its totalization signs in adjacent simplicial degrees are opposite, so the same identity holds for the total differential. Every vector uses finitely many simplices in the direct sum. No convergence or lower bound on internal degree is used. The contraction preserves S, proving the final assertion. □

For example, if all coefficient complexes are k and the available places are p, q, the nonempty components $\{p\}, \{q\}, \{p, q\}$ give k^3. The restricted tensor product of the two copies of k, with unit reference vectors, is k. The incidence category has no arrows inserting a new place. Such arrows must be supplied before its colimit can express restricted tensor assembly.

The simplicial replacement also records partitions of one ordered set, not all collision diagrams on a curve. Its order is the chosen combinatorial order on places. A comparison with physical time order or with factorization on collision strata requires maps that preserve those additional operations.

An actual tensor construction of vertex algebras

There is a positive local construction once current algebras have been supplied. For every place p, choose a finite-dimensional complex Lie algebra $\mathfrak{g}_p$, an invariant symmetric bilinear form and a level k_p. The affine brackets are

$$[x_m, y_n] = [x, y]_{m+n} + m\delta_{m+n,0} k_p(x, y).$$

The induced vacuum module $V^{k_p}(\mathfrak{g}_p)$ is a vertex algebra at every level. For a finite set S, take its tensor product over $p \in S$. Inserting the chosen vacua gives maps for inclusions of finite sets, and hence a restricted tensor vertex algebra

$$V_{\mathrm{res}} = \mathrm{colim}_{S\ \mathrm{finite}} \bigotimes_{p\in S} V^{k_p}(\mathfrak{g}_p). \tag{22.21}$$

Every vector and every pair of inputs belong to one finite tensor stage. Their vertex operation, translation and vacuum identities are defined there, are preserved by enlargement, and therefore define the colimit. Locality for a pair is the finite tensor locality bound at that stage. This proves the construction without forming an infinite product of fields on one input.

A conformal vector needs more. For a simple Lie algebra with the standard normalization, Sugawara requires $k_p + h_p^\vee \neq 0$. A relation between two shifted levels, $\kappa_p + \kappa_p^! = 0$, does not imply either is nonzero. Moreover the sum of conformal vectors over infinitely many nontrivial places need not belong to the algebraic restricted tensor product. A conformal completion must be specified if that sum is intended.

Satake eigenvalues do not themselves supply these Lie algebras, levels, vacuum modules or conformal vectors. They can give a finite-dimensional Frobenius carrier and its symmetric-algebra trace. Identifying that carrier with a current-algebra sector, and identifying (22.21) with an arithmetic Hochschild trace realization, are separate construction problems.

22.9 An explicit physical boundary model

A physical boundary comparison should identify cochains and operations before taking a character. The free abelian holomorphic–topological theory gives such an example. Its base is the actual half-space $M = [0,\infty)_t \times \mathbb{C}_z$, with incoming orientation $-dt \wedge dx \wedge dy$, where $z = x + iy$.

Partial forms use dt, $d\bar z$, with

$$D = dt\,\partial_t + d\bar z\,\partial_{\bar z}, \qquad \partial = \partial_z, \qquad \tau_+(a) = \frac{1}{2\pi i}\int_M^{dt\,dx\,dy} dz \wedge a.$$

The subscript records the auxiliary positive orientation used in the integral. Take superfields Φ, η of total degrees zero and one.

The incoming action and boundary condition are

$$S_\kappa = -\tau_+\Big(\eta D\Phi + \frac{\kappa}{2}\eta\partial\eta\Big), \qquad i^*\eta = 0.$$

We fix $\kappa \in \mathbb{C}^\times$ and $\hbar = 1$ for the Wilson-jet comparison below. The action is quadratic. No interacting arithmetic field theory is being inferred from it.

Regular observables and the ending line

The tangent fields are $E = \Omega^\bullet_{\mathrm{HT}} e_\Phi \oplus \Omega^\bullet_{\mathrm{HT}} e_\eta$, with $|e_\Phi| = 0$, $|e_\eta| = -1$, and

$$\begin{aligned} Q(\alpha e_\Phi) &= D\alpha e_\Phi, \\ Q(\beta e_\eta) &= D\beta e_\eta + (-1)^{\deg\beta+1}\kappa\partial\beta e_\Phi. \end{aligned}$$

Compactly supported fields may meet $t = 0$, with the relative condition on every tangential e_η component. The incoming pairing is

$$B_-(\alpha e_\Phi, \beta e_\eta) = -\tau_+(\alpha\beta), \qquad B_-(\beta e_\eta, \alpha e_\Phi) = (-1)^{\deg\alpha}\tau_+(\beta\alpha),$$

and vanishes on equal summands. On the suspension, $|s\xi| = |\xi| - 1$, put $d(s\xi) = -sQ\xi$ and $b_-(s\xi, s\upsilon) = (-1)^{|\xi|+1}B_-(\xi,\upsilon)$.

For $U = [0,\infty)\times V$, let $\mathcal{O}(U) = \bigoplus_{m\ge 0}\mathrm{Sym}^m_b(E_c(U)[1])$. At each field number, complete the smooth joint kernels in the projective topology at fixed compact support. Then take the limit over compact supports. The sum over field numbers is algebraic.

Let Δ_{b_-} contract unordered pairs once, with Koszul signs. The quantum differential is $d + \Delta_{b_-}$. Smoothness makes its diagonal contractions defined. A point-supported composite is outside this space.

Write a test field as $\gamma(t) + dt\,\beta(t)$, and let a superscript (0) mean Dolbeault degree zero. For $n \ge 0$, the ray and endpoint derivations are

$$\begin{aligned} \ell_n(s\xi) &= \frac{1}{n!}\int_0^\infty \partial_z^n \beta_\eta^{(0)}(t,0)\,dt, && |\ell_n| = 1, \\ r_n(s\xi) &= \frac{1}{n!}\int_0^\infty \partial_z^n \beta_\Phi^{(0)}(t,0)\,dt, && |r_n| = 0, \\ e_n(s\xi) &= \frac{1}{n!}\partial_z^n \gamma_\Phi^{(0)}(0,0), && |e_n| = 1. \end{aligned}$$

Extend them as constant derivations on kernels.

Integration of the normal derivative gives

$$[d, \ell_n] = [d, e_n] = 0, \qquad [d, r_n] = \kappa(n+1)\ell_{n+1} - e_n. \tag{22.22}$$

The first two identities use the relative boundary condition. The minus sign in the last uses $\int_0^\infty \partial_t \gamma(t)\, dt = -\gamma(0)$. All constant derivations graded-commute with one another and with Δ_{b_-}.

For a finite $F \subset \mathbb{Z}_{>0}$, introduce the commutative differential graded coefficient algebra

$$Y_F = \mathbb{C}[B_0, B_n : n \in F] \otimes \Lambda(c_{n-1} : n \in F), \quad Q_Y B_n = \kappa n c_{n-1}, \quad Q_Y B_0 = Q_Y c_j = 0. \tag{22.23}$$

The B_n have degree zero and the c_j degree one. Coefficients in operator expressions act by graded left multiplication. The module has the regular right Y_F-action. All tensors with these coefficients are algebraic.

PROPOSITION 22.9.1 *(The endpoint correction).* Put

$$\begin{aligned} D_0 &= d + \Delta_{b_-} + Q_Y + B_0 \ell_0, \\ L_F &= \sum_{n \in F} \frac{B_n}{\kappa n} r_{n-1}, \\ D_F &= D_0 + \sum_{n \in F} \left(B_n \ell_n + c_{n-1} r_{n-1} - \frac{B_n}{\kappa n} e_{n-1} \right). \end{aligned}$$

Then $D_F = e^{-L_F} D_0 e^{L_F}$, so $D_F^2 = 0$. The exponential is finite on each input and fixes the unit and the right coefficient action. Omitting the endpoint term gives the nonzero square $\sum_{n \in F} c_{n-1} e_{n-1}$.

Proof. The coefficient differential of $B_n \ell_n$ gives $\kappa n c_{n-1} \ell_n$. The commutator of d with $c_{n-1} r_{n-1}$ gives its negative plus $c_{n-1} e_{n-1}$, by (22.22). The endpoint correction cancels the latter term.

More precisely, $[D_0, L_F] = D_F - D_0$, and its commutator with L_F is zero. The conjugation formula follows. Each r_n lowers field number and kills the unit, so its exponential terminates and is right-linear. For $F = \{1\}$, a suspended e_Φ test function equal to one near the endpoint detects the omitted-term defect as c_0. □

All jets with corrected transition maps

For $F \subset F'$, coefficient inclusion alone need not commute with the source differential. The corrected map is

$$j_{F,F'} = e^{-(L_{F'} - L_F)} \iota_{F,F'}.$$

The L_F commute, so these maps are injective cochain maps and satisfy $j_{F',F''} j_{F,F'} = j_{F,F''}$.

For $Y_\infty = \operatorname{colim}_F Y_F$, there is an explicit isomorphism

$$\operatorname{colim}_F (\mathcal{O}(U) \otimes Y_F, D_F) \xrightarrow{\sim} (\mathcal{O}(U) \otimes Y_\infty, D_0), \qquad [u]_F \longmapsto e^{L_F} u. \tag{22.24}$$

The inverse takes v to $[e^{-L_F} v]_F$ at any finite stage containing its coefficients. Enlarging the stage leaves this class unchanged. Each map is continuous at fixed field number and support, and preserves products on tangentially disjoint opens.

This is not the literal all-jets differential on an unchanged smooth observable. On a small disk, choose a compact test whose ray derivatives all equal one. Its raw source term contains $\sum_{n>0} c_{n-1}$, which is not in the polynomial coefficient algebra. Formula (22.24) instead compares the representatives $u - \sum_{n \in F} B_n/(\kappa n)$ at different cutoffs. Their differentials agree under the corrected maps.

The boundary period map

Normal contraction reduces D_0 to the boundary complex

$$\mathcal{A}(V) = \Big(\mathrm{Sym}_b(\Omega_c^{0,\bullet}(V)[1]) \otimes Y_\infty, d_1 + \Delta_\mu + B_0\epsilon_0 + Q_Y\Big), \tag{22.25}$$

where $d_1(s\alpha) = -s\bar\partial\alpha$, $\epsilon_0(s\phi) = \phi(0)$ on functions, and ϵ_0 vanishes on top forms. The boundary pairing is $\mu(s\phi, s\psi) = -\kappa\tau_{\mathbb{C}}(\phi\partial\psi)$, for a function ϕ and a $(0,1)$-form ψ, with $\tau_{\mathbb{C}}(a) = (2\pi i)^{-1}\int dz \wedge a$. The reversed order is given by graded symmetry.

Here the normal contraction can be constructed with compact support. Choose a smooth compact profile $\rho(t)$ of integral one and set $F_\rho(t) = \int_0^t \rho(r)\,dr$. On the complementary e_η boundary component the linear maps are

$$\begin{aligned} P_N(\gamma + dt\,\beta) &= \int_0^\infty \beta_\eta(r)\,dr, \\ I_N g &= dt\,\rho g + (F_\rho - 1)Q_{\mathrm{rel}} g, \\ h_N(\gamma + dt\,\beta) &= -\int_t^\infty \beta(r)\,dr + (1 - F_\rho(t))\int_0^\infty \beta_\eta(r)\,dr. \end{aligned}$$

In the last term the result lies in the e_η summand, and $Q_{\mathrm{rel}} = Q - D$. The fundamental theorem of calculus gives $P_N I_N = 1$ and $Qh_N + h_N Q = 1 - I_N P_N$. The correction in h_N makes its relative boundary value zero and keeps its normal support compact.

For a boundary form a of Dolbeault degree j, set $i(sa) = sI_N((-1)^j a e_\eta)$. On a test field with Dolbeault degree j, put $p(s\xi) = s((-1)^j P_N\xi)$, and set $h(s\xi) = -sh_N\xi$. Then $pi = 1$, $dh + hd = 1 - ip$, and $hi = ph = h^2 = 0$.

Let H_2 be the graded symmetrization of $h \otimes 1 + ip \otimes h$, and put $P_2 = -b_- H_2$. Its Hom differential is $b_- - p^*\mu$. Thus $p_0 = \mathrm{Sym}(p)e^{\partial_{P_2}}$ is the quantum normal projection to (22.25).

The exponential contracts pairs and is finite on each field-polynomial input. Conjugating the linear contraction gives a homotopy inverse. On the kernel summand, the symmetric-algebra homotopy is obtained by dividing the derivation induced by h by the positive number of kernel factors. These formulas give a continuous contraction on the stated smooth joint kernels and commute with disjoint products.

For a disk D_R centered at zero, define the exterior germ space

$$\mathscr{P}(D_R) = \mathrm{colim}_{r<R}\left\{\sum_{n\geq 1} a_n w^{-n} : \sum_n |a_n| r^{-n} < \infty\right\}.$$

Each stage has the displayed weighted ℓ^1 norm. The linking maps for increasing radii are compact.

For a compact top form a, its Cauchy transform is

$$C(a)(w) = \tau_z \frac{a(z)}{w - z},$$

expanded outside its support. Set $C = 0$ on shifted functions.

The compact Dolbeault complex maps to this germ space by a continuous quasi-isomorphism. Explicitly, a germ has representative $s(\bar\partial\chi)f$ on a slightly larger annulus, where χ is one near the inner disk. If the exterior germ of a top form is zero, Cauchy convolution is its compact primitive. Cauchy estimates on two separated radii make both maps continuous. Applying this contraction in each kernel variable and averaging over permutations proves the statement for every completed symmetric power.

Let $k_1(z) = 1/z$ as a locally integrable distribution and $k_2 = -\partial_z k_1$. Put

$$P(sa, sb) = \kappa\tau_z\tau_w\big(k_2(z-w)a(z)b(w)\big), \qquad \gamma(sa) = \tau_z(a(z)/z)$$

on top forms and zero on other degrees. The distributional Cauchy identity gives $d_{\mathrm{Hom}}P = \mu$ and $d_{\mathrm{Hom}}\gamma = \epsilon_0$. Consequently $N_{B_0} = e^{\partial_P + B_0\partial_\gamma}$ conjugates the boundary differential to $d_1 + Q_Y$. Only finitely many contractions act on each input, and the distributions are paired with smooth kernels in independent variables.

The resulting period map on the corrected limit is

$$\Pi[u]_F = \mathrm{Sym}(C)N_{B_0}p_0e^{L_F}u. \tag{22.26}$$

Its target is the algebraic sum of completed symmetric powers of $\mathscr{P}(D_R)$, tensored algebraically with Y_∞.

THEOREM 22.9.2 *(Rotation-finite boundary comparison).* Rotate z and its form factors geometrically, with an additional weight one on e_Φ. Give B_n and c_{n-1} weight n, and B_0 weight zero. Let $\mathcal{J}_{\mathrm{rot}}(D_R)$ be the algebraic sum of the circle eigenspaces of the corrected source. Then (22.26) restricts to a continuous right Y_∞-linear quasi-isomorphism

$$\Pi_{\mathrm{rot}} : \mathcal{J}_{\mathrm{rot}}(D_R) \longrightarrow (F_{\mathrm{pol}} \otimes Y_\infty, Q_Y), \qquad F_{\mathrm{pol}} = \mathbb{C}[x_1, x_2, \ldots].$$

It sends 1 to 1, is compatible with centered disk inclusions, and carries separated contour currents to

$$J_{-n} = x_n, \qquad J_n = \kappa n\partial_{x_n} \quad (n > 0), \qquad J_0 = B_0. \tag{22.27}$$

For every algebraic differential graded left Y_∞-module L, ordinary tensoring over Y_∞ computes the derived tensor product and preserves this quasi-isomorphism.

Proof. The corrected transition isomorphism, normal contraction, Gaussian conjugation and compact Dolbeault contraction prove the comparison on the full germ target. They commute with rotations. A monomial $w_1^{-n_1}\cdots w_m^{-n_m}$ has weight $-\sum n_i$. For a fixed sum, only finitely many symmetric monomials occur, and m is bounded by that sum. Thus the finite-circle-spectrum part of the germ target is exactly F_{pol}. Each input has finitely many coefficient monomials, so adjoining Y_∞ preserves this conclusion.

To restrict the quasi-isomorphism, take a cocycle of finite circle spectrum in its acyclic mapping cone. Choose a primitive in the full cone and apply the finite Fourier projector onto the cocycle's weights. The rotated compact support stays in one larger compact disk. The integral therefore exists in a single smooth-kernel or germ stage and commutes with the differential. It gives a primitive of finite spectrum.

A current smeared on an outer circle has period

$$\sum_{n>0} x_n z^{n-1} + B_0 z^{-1} + \kappa \sum_{n>0} n z^{-n-1}\partial_{x_n}.$$

The uncontracted insertion gives the first sum, its charge contraction gives the middle term, and $P(sa_z, sa) = -\kappa\partial_z C(a)(z)$ gives the last. Contour coefficients yield (22.27). Moving the circle without crossing the inner support gives a cochain homotopy by Stokes' formula.

Finally filter the source by field number. Its differential does not raise that number. Every associated graded piece is a complex of vector spaces tensored with the regular coefficient algebra, and is homotopically flat over that algebra. The exhaustive, bounded-below filtration and exact filtered unions give homotopical flatness of the source. The target is free as a graded coefficient module. Tensoring the quasi-isomorphism with any algebraic differential graded module therefore preserves it, including unbounded modules. □

The Gaussian cap

On the boundary write $\Phi_\Sigma = \phi + d\bar z\,\phi_b$ and $\eta_\Sigma = c + d\bar z\,a_b$. Here $c(z)$ is the boundary ghost. The c_j in (22.23) are line coefficients. Put $x_n = \partial_z^{n-1}\phi(0)/(n-1)!$. The incoming boundary charge, including the endpoint, is

$$S^F_{\mathrm{in}} = -\frac{1}{\pi}\int c(\partial_{\bar z}\phi + \kappa\partial_z a_b)\,dx\,dy + \mu_F(0),$$
$$\mu_F(0) = B_0 c(0) + \sum_{n\in F}\left(\frac{B_n\partial_z^n c(0)}{n!} + c_{n-1}x_n\right).$$

The coefficient differential Q_Y is external to the boundary Poisson bracket, since the line coefficients are Casimirs. Its contribution $\pi\kappa n c_{n-1}\partial_z^n g(0)/n!$ to the square on $\phi_b(g)$ cancels the contribution $-\pi\kappa c_{n-1}\partial_z^n g(0)/(n-1)!$ from the line-ghost term. The remaining square is zero on every field generator.

Let $\mathcal{P}_{\mathrm{sm}}(V)$ be the polynomial functionals of ϕ, ϕ_b with compact smooth kernels. For a finite jet set F and $N \ge \max(F\cup\{1\})$, set

$$W_{F,N} = Y_F[[x_1,\dots,x_N]], \qquad \mathcal{H}^F_{\mathrm{in}} = \operatorname{colim}_N\big(\mathcal{P}_{\mathrm{sm}}(V)\otimes_{\mathbb{C}} W_{F,N}\big).$$

Completion is by jet weight, $\operatorname{wt} x_n = n$, before taking the union in N. Each weight coefficient is polynomial in the line coefficients. The tensor with smooth functionals is algebraic.

In the incoming polarization, momenta act as $\widehat{a_b} = \pi\delta/\delta\phi$ and $\widehat{c} = \pi\delta/\delta\phi_b$, with derivatives on the right. Quantizing the charge defines Ω^F_{in} on this space. A mixed contraction differentiates one of the finitely many jet variables and lowers weight by at most N. Its other factor takes finitely many derivatives of a smooth kernel at the junction. Smooth-field contractions restrict smooth joint kernels to diagonals. The operator is therefore defined and continuous at each fixed N.

The square of $Q_Y + \Omega^F_{\mathrm{in}}$ is zero. Each pair of charge terms shares at most one position–momentum contraction, so its commutator quantizes the classical bracket. The two-bulk-term contribution pairs a symmetric mixed-derivative kernel with two antisymmetric ghosts and vanishes. The endpoint bracket cancels $Q_Y\mu_F(0)$ by the displayed factorial identity.

On the pure junction subspace $W_F = \operatorname{colim}_N W_{F,N}$, every momentum term contains $\delta/\delta\phi_b$ and vanishes. The resulting differential is

$$D_{\mathrm{cap}} = Q_Y + \sum_{n\in F} x_n c_{n-1}.$$

Its multiplication term is the ghost part of the endpoint charge. Omitting it would violate the relative master equation of the coupled boundary and line system.

Consider a cap e^f with f polynomial in finitely many x_n, normalized by $f|_{x=0} = 0$. It is closed precisely when

$$f = -\sum_{n\in F}\frac{B_n x_n}{\kappa n} + h, \qquad h \in \mathbb{C}[B_0, x_1, x_2, \dots].$$

Indeed $D_{\mathrm{cap}}e^f = e^f(Q_Y f + \sum x_n c_{n-1})$, so the displayed equation integrates the coefficient derivatives.

Under rotation, x_n has weight $-n$. The first sum has weight zero and every nonconstant monomial of h has negative weight. Thus the unique rotation-invariant normalized cap in this class is

$$G_F = \exp\left(-\sum_{n\in F}\frac{B_n x_n}{\kappa n}\right).$$

The constant state is not closed when $F \neq \varnothing$. Gluing the linear exponent of G_F by the BV pairing produces exactly $-\sum(B_n/(\kappa n))e_{n-1}$, the endpoint correction of Proposition 22.9.1. Changing its sign leaves square $2\sum c_{n-1}e_{n-1}$.

For all jets, use the degreewise creation-weight completion $\prod_{N\geq 0}(F_N \otimes Y_\infty^d)$, where $F_N \subset F_{\mathrm{pol}}$ has creation weight N. In it set

$$G = \exp\left(-\sum_{n>0} \frac{x_n B_n}{\kappa n}\right), \qquad \mathsf{P}_\kappa = G(F_{\mathrm{pol}} \otimes Y_\infty).$$

Every weight coefficient is finite. On this specified image, multiplication by G is an invertible cochain map from Q_Y to $D_G = Q_Y + \sum_{n>0} x_n c_{n-1}$. Hence $G\Pi_{\mathrm{rot}}$ sends the supported unit to the cap and carries the currents to

$$\widehat{J}_{-n} = x_n, \qquad \widehat{J}_n = \kappa n \partial_{x_n} + B_n, \qquad \widehat{J}_0 = B_0.$$

Coefficientwise differentiation proves $D_G(Gf) = GQ_Y f$ and $\widehat{J}_n(Gf) = G\kappa n \partial_{x_n} f$. The chosen image P_κ, the full completion and the raw polynomial complex are different carriers.

The same formulas detect a possible Ward error. For $m > 0$, the raw operator $O_m = -(\widehat{J}_m + B_m)$ has

$$[D_G, O_m] = -\kappa m c_{m-1}, \qquad O_m G = -B_m G.$$

Adding the coefficient term B_m gives the cochain map $-\widehat{J}_m$. A residue identity for a raw insertion therefore cannot replace the correction that makes the operation a cochain map.

The order of state completion also matters. If all jet variables are completed before adjoining smooth functionals, take a smooth test equal to $(1-z)^{-1}$ near the endpoint. Applying the two-momentum part of the boundary operator to $\phi_b(g)\sum_{n=1}^{M} x_n$ has scalar term $\pi\kappa M(M+1)/2$. It does not stabilize even in weight zero. The finite-jet completion used to construct the cap avoids this undefined operation.

Rigidity in the regular polynomial class

The cap also explains which local choices survive rotation. Let $\mathfrak{J}$ be the complex of constant derivations obtained by taking finitely many normal, holomorphic and antiholomorphic derivatives of test fields at the endpoint. Its differential is $[d, -]$. The relative boundary condition makes its cohomology

$$H^1(\mathfrak{J}) = \bigoplus_{n\geq 0} \mathbb{C}[e_n], \qquad H^j(\mathfrak{J}) = 0 \quad (j \neq 1).$$

To see this, take the restricted dual of formal field jets, graded by normal and antiholomorphic order and rotation weight. Each piece is finite. The relative e_η normal complex $t\mathbb{C}[[t]] \xrightarrow{\partial_t} \mathbb{C}[[t]]dt$ is acyclic. The unrestricted e_Φ normal complex has constant cohomology, and its formal Dolbeault complex has cohomology $\mathbb{C}[[z]]$. Dualizing gives precisely the holomorphic evaluation classes $[e_n]$.

Consider junction corrections of degree one in $(Y_F \otimes \mathfrak{J}) \oplus Y_F$, the second summand acting by multiplication. Write $X_F^\circ = -\sum(B_n/(\kappa n))e_{n-1}$. The square-zero corrections are exactly

$$X = X_F^\circ + \partial Y + \sum_{n\geq 0} h_n e_n - Q_Y(q), \tag{22.28}$$

where $\partial = Q_Y + [d, -]$, Y is a degree-zero coefficient-valued constant derivation, the sum is finite, $h_n \in \mathbb{C}[B_0]$, and $q \in \mathbb{C}[B_0, B_n : n \in F]$. Indeed the square is $\partial(X - X_F^\circ)$. The polynomial de Rham contraction gives $H(Y_F) = \mathbb{C}[B_0]$, and the preceding jet calculation identifies all its degree-one classes. This proves (22.28).

The term ∂Y is removed by the finite conjugation e^{Y}, which fixes the unit and the regular right action. The classes $h_n e_n$ have weight $-(n+1)$, and a nonzero $Q_Y(q)$ has positive coefficient weight. Rotation invariance therefore forces both to vanish and permits a weight-zero Y. In this regular polynomial class, a rotation-invariant junction is isomorphic to the one used in Theorem 22.9.2. The conclusion concerns this local source and its admissible corrections. It is not a generation theorem for every boundary module.

A coefficient twist can change the polynomial ground. With correction $X_F^{\circ} - Q_Y(q)$ and $q \notin \mathbb{C}[B_0]$, the period differential becomes $Q_Y - Q_Y(q)$. A polynomial ground killed by all positive currents would satisfy $\partial_{B_n} f = (\partial_{B_n} q) f$.

For a variable with $\partial_{B_n} q \neq 0$, the right side has total polynomial degree at least that of nonzero f, while the left side has smaller degree. Thus no normalized polynomial ground exists.

Completing in the positive B_n permits the ground $e^{q - q|_{B_{>0}=0}}$. This repairs the comparison on a different coefficient space and changes the selected vector.

22.10 Sewing states and evaluating the formal comparison

For an algebraic differential graded line module L, write $\Phi_\kappa(L) = F_{\mathrm{pol}} \otimes L$ with its differential and the currents (22.27). Two endpoints carry two copies of the coefficient algebra. On $U = M \otimes N'$, their zero modes commute. Put $N = B_0' B_0'' / \kappa$. The state family for boundary fusion has carrier $F_{\mathrm{pol}} \otimes U$ and connection

$$\nabla_{\mathrm{st}} = d + \rho(N)\, d \log z,$$

where ρ denotes the coefficient action and $z \neq 0$ is the separation.

For scalar charges a, b, its normalized current operation on the first ground state is

$$K_{a,b}(z) f(x) |b\rangle = \exp\!\left(\frac{a}{\kappa} \sum_{n>0} \frac{x_n z^n}{n} \right) f(x_n - a z^{-n}) |a+b\rangle. \tag{22.29}$$

The output is completed in creation weight. Each weight coefficient on a polynomial input is a Laurent polynomial in z. Commuting $\kappa m \partial_{x_m}$ and x_m through the two factors verifies $[J_m, K_{a,b}(z)] = a z^m K_{a,b}(z)$, where the commutator uses the input and output current actions.

Negative-current descendants of the first input are determined by the normal-ordered insertion rule

$$I(J_{-n} u, z) = \frac{\partial_z^{n-1} J^-(z)}{(n-1)!} I(u,z) + I(u,z) \frac{\partial_z^{n-1} J^+(z)}{(n-1)!}.$$

Here J^- contains negative modes and J^+ nonnegative modes. Truncation on polynomial inputs and completion of output weight make each expression defined.

Removing $K_{a,b}$ from an operation satisfying these identities leaves a map commuting with all nonzero oscillators. It is determined by the image of the ground state. More generally, for a coefficient module with locally nilpotent positive modes and positive-mode truncation on each vector, the oscillator decomposition is $F_{\mathrm{pol}} \otimes \Omega_+$, where $\Omega_+ = \bigcap_{m>0} \ker J_m$. Thus normalized Ward operations are represented by the state family above.

On the charge-a Fock space, translation is

$$L_{-1}^{(a)} = \frac{a}{\kappa} x_1 + \sum_{n>0} n x_{n+1} \partial_{x_n}.$$

Substituting (22.29) into translation covariance makes its ground coefficient satisfy $\partial_z h = (N/z) h$. Its connection is therefore $d - \rho(N) d \log z$. Formally at $z = 1$, its normalized horizontal coefficient is $\exp(N \log(1 + (z-1)))$.

For scalar charges it becomes $z^{ab/\kappa}$ on a logarithmic cover. A counterclockwise half-loop transports states by $e^{-\pi i ab/\kappa}$ and operations by $e^{\pi i ab/\kappa}$. The ordinary tensor product of two level-κ Heisenberg representations has level 2κ under the diagonal current. The fusion just specified remains at level κ and adds the charges.

The jet twist

The classical Gauss constraint alone does not impose the holomorphic Ward identity. On a disk of radius R with two smaller disks of radii r', r'' removed, the partial connection $a = d\bar{t}$ is closed. With zero sources its mode-one contour defect is $\kappa(R^2 - r'^2 - r''^2)$. This follows from $\oint (t - c)d\bar{t} = -2\pi i r^2$ around a counterclockwise circle. At $\kappa = 2$, $R = 2$, $r' = r'' = 1/4$, the defect is $31/4$. The quantum comparison above uses the constructed current operations, not that constraint alone.

The line-side family has an additional jet twist. In the two coefficient algebras set

$$s(z) = \frac{1}{\kappa} \sum_{p+m \geq 1} (-1)^{p+1} \binom{p+m}{p} \frac{B'_p B''_m}{(p+m) z^{p+m}}, \qquad r = Q_Y s, \qquad h = \frac{N}{z} + \partial_z s.$$

Both indices are nonnegative. Coefficients outside a chosen finite jet set are zero when that restriction is imposed. For all jets the sum is a power series of positive order in $q = z^{-1}$.

Each coefficient is a finite sum. Its generating scalar is $\kappa^{-1} \log(1 + (u - v)/z)$, with $u^p v^m$ replaced by $B'_p B''_m$. In particular $Q_Y s = r$ and $\partial_z s = h - N/z$, with all signs fixed.

THEOREM 22.10.1 *(Formal line-to-state comparison).* Replace the coefficient complex U degreewise by $U^d((q))$, the Laurent series with a finite lower bound and arbitrary coefficient vectors. On $F_{\mathrm{pol}} \otimes U((q))$, the map

$$E(q) = e^{-\rho(s(z))}$$

is an isomorphism from the differential d_U and connection $\partial_z + \rho(N)/z$ to $d_U + \rho(r)$ and $\partial_z + \rho(h)$. It commutes with the currents and their rooted residue operations, and preserves the identity action of the vertex vacuum. It need not fix a chosen cyclic vector.

Proof. The differential graded module identity gives $[d_U, \rho(s)] = \rho(r)$. The even operator $\rho(s)$ commutes with $\rho(r)$ and $\rho(h)$, because the coefficient algebra is graded commutative. Thus

$$e^{\rho(s)}(d_U + \rho(r))e^{-\rho(s)} = d_U, \qquad e^{\rho(s)}(\partial_z + \rho(h))e^{-\rho(s)} = \partial_z + \rho(N)/z.$$

There are no further commutators. Positive q-order makes each coefficient of the exponential and its inverse finite. This proves the formulas on the stated Laurent completion for every algebraic module.

The map acts only on coefficients and commutes with all oscillator modes and the total zero mode. It therefore commutes with normal-ordered current operations and their residues. Applied to a ground vector u, it gives $e^{-\rho(s)}u$, which proves the final distinction. □

For finitely many endpoints, the pair twists commute. On a common formal separation domain, the exponential of their sum is independent of parenthesization. After removing it, the state connection is

$$d + \sum_{i<j} \frac{B_{\mathrm{o}}^{(i)} B_{\mathrm{o}}^{(j)}}{\kappa} d \log(z_i - z_j).$$

This proves formal refinement coherence on that domain. It does not evaluate an arbitrary all-jets series at numerical separations.

An exact evaluation criterion

Fix finitely many jets and write $\rho(s) = S(q) = \sum_{k=1}^{K} A_k q^k$, with commuting degree-zero operators A_k. In this paragraph, an exponential is defined when its partial sums on each vector converge within a finite-dimensional subspace. The operators are *jointly locally finite* when $\mathbb{C}[A_1, \dots, A_K]u$ is finite dimensional for every u.

Proposition 22.10.2 *(Algebraic evaluation).* At a fixed nonzero separation, $e^{-S(q)}$ is defined on algebraic states exactly when $S(q)$ is locally finite. The formal map preserves $U \otimes \mathbb{C}((q))$ exactly when the A_k are jointly locally finite. This is equivalent to evaluation being defined at every nonzero separation. Evaluation at K distinct nonzero values of q already suffices. On this domain a removable singularity of the comparison at $z = 0$ occurs exactly when every A_k vanishes, in which case the comparison is the identity.

Proof. Successive differences of partial sums on u recover $S(q)^n u/n!$. Their finite-dimensional convergence is therefore equivalent to local finiteness, and the inverse is the matrix exponential on each finite orbit. These orbits may be enlarged by those of $d_U u$, $\rho(r)u$, $\rho(r)d_U u$. The relations $[d_U, S] = \rho(r)$, $[S, \rho(r)] = 0$ and $\rho(r)^2 = 0$ then justify the cochain identity on a finite-dimensional stable space.

A vector-valued series lies in the algebraic scalar extension precisely when its coefficients span a finite-dimensional space. A finite joint orbit clearly suffices.

For necessity, identify the cyclic coefficient module of a nonzero u with the quotient

$$B = \mathbb{C}[t_1, \dots, t_K]/\mathrm{Ann}(u).$$

If the coefficients of $\exp(-\sum q^k t_k)$ span a finite space, evaluation at characters of B puts all scalar functions $\exp(-\sum q^k \chi(t_k))$ in a finite-dimensional space.

Exponentials of distinct polynomials with zero constant term are linearly independent. Choose a ray avoiding the finitely many leading real-part coincidences. Divide a dependence by its fastest growing term and let the radius tend to infinity. Proceed inductively.

Thus B has finitely many characters. The Nullstellensatz makes each polynomial $\prod_\chi (t_k - \chi(t_k))$ nilpotent in B. A power is a monic relation for t_k, so reducing all exponents shows that B is finite dimensional.

If $S(q_j)$ are locally finite at K distinct nonzero q_j, their commuting joint orbit is finite on each vector, by their monic relations. The matrix (q_j^k) is invertible, so each A_k is a linear combination of these operators. This proves joint local finiteness. Finally on each finite joint orbit $e^{-S(q)}$ is entire in q. Removability at $z = 0$ makes its entries bounded at infinity. Liouville's theorem makes it the constant identity, and the formal logarithm gives $S = 0$. □

The coefficientwise completion is strictly larger in a basic example. Let $M = \mathbb{C}[b] \otimes \Lambda(c)$, $d_M = \kappa c \partial_b$, with $B_0 = 0$, $B_1 = b$, $c_0 = c$, and all higher coefficients zero. Take a second module of scalar charge one. Then $s = b/(\kappa z)$, $r = c/z$, and

$$e^{-s}1 = \sum_{n \geq 0} \frac{(-1)^n b^n q^n}{n! \kappa^n}$$

lies in $M((q))$ but not in $M \otimes \mathbb{C}((q))$.

At fixed $z \neq 0$, the untwisted degree-zero cohomology is $\mathbb{C}$. The twisted equation $\kappa f'(b) + f(b)/z = 0$ has no nonzero polynomial solution, by its highest coefficient. The two algebraic complexes are not quasi-isomorphic. The formal theorem remains valid on its larger coefficient space.

Coincidence and nested regions

Universal coefficients also admit a distributional interpretation with fixed normalization. For $k \geq 1$, define

$$T_k = \frac{(-1)^{k-1}}{(k-1)!}\partial_z^{k-1}(1/z).$$

It extends z^{-k} and satisfies $\bar{\partial}T_k = \pi(-1)^{k-1}\partial_z^{k-1}\delta_0/(k-1)!$. At finite jet set, complete the coefficient algebra in the positive-jet ideal. Each coefficient of e^{-s} is a finite linear combination of powers z^{-k}, so this formula extends it coefficientwise and fixes its contact derivatives. It does not multiply distributions with the same singular support or evaluate the whole coefficient series on an arbitrary module.

For a smooth radial approximate identity ρ_r of mass one, these fixed coefficients satisfy $T_k * \rho_r \to T_k$ with error $O(r^2)$ on each compact smooth test. Taylor expansion of the test function has no first-moment contribution by radial symmetry. A finite-order distribution bound controls the second remainder. This gives a precise local smoothing statement with the same contact normalization.

Composition of Laurent expansions has its own domain. For example,

$$\frac{1}{(z_1 - z_2)^2} = \sum_{n\geq 0}(n+1)\frac{z_2^n}{z_1^{n+2}} \qquad (|z_2| < |z_1|).$$

The series converges with all derivatives on compact subsets of this nested region.

No distributional convergence holds on an open set crossing the boundary. In the ratio variable, take a radial test centered at a point of modulus greater than one. Holomorphicity makes its integral the value at the center, which does not tend to zero. The existence of the distribution $T_2(z_1 - z_2)$ does not enlarge the convergence domain of this particular composition series. Wick products inherit the corresponding nested domains, while their formal refinement identities use the common coefficient completion specified above.

Finally, the comparison map and the binary operation have different coincidence behavior. All positive coefficients may act by zero, making $E = 1$, while the current operation still has a pole. For scalar charges with $ab/\kappa \notin \mathbb{Z}$, the state connection has monodromy $e^{-2\pi i ab/\kappa}$, and $z^{ab/\kappa}K_{a,b}$ is defined on branches. It has no single-valued distributional extension across a disk about zero agreeing with those branches. These are conditions on the operation and its coefficient local system, not a failure of the formal coefficient isomorphism.

22.11 ARITHMETIC BULK AND BOUNDARY COMPARISONS

The finite arithmetic torsor, the topological state sum and the free physical boundary complex have now been constructed on their stated domains. An arithmetic bulk theory relating them needs a common geometric and categorical recipient. Write $\mathscr{X}$ for a specified arithmetic site and $j : \mathscr{B}_\infty \to \mathscr{X}$ for a proposed archimedean boundary morphism. An orientation consists of a dualizing coefficient object and a trace in its specified degree. In a suitable coefficient theory, it is a map $R\Gamma_c(\mathscr{X}, \omega_{\mathscr{X}}) \to k[-3]$. It must be compatible with the restriction and relative duality used by the action.

At the boundary, distinguish a linear category $\mathcal{B}$, its Hochschild complex, a marked trace class, and a chosen state realization E_∞. For example, the intended primary arithmetic datum can be a marked class in the Hochschild trace of a specified Iwahori–Hecke category. Extracting E_∞ from that trace requires its degree, coefficient theory and completion. The trace class is not a vertex algebra or a category of its own modules. A boundary comparison must give maps of these actual objects preserving the marked class and the operations under consideration.

Three arithmetic identities then have different content. The boundary identity compares the designated trace or state realizations. The Wilson identity compares normalized field integrals with Frobenius traces in the chosen coefficients. The partition identity compares a defined scalar trace with a completed L-function.

For the Riemann normalization the latter function is

$$\xi(s) = \tfrac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s).$$

Its polar-removal factor cannot be omitted when the comparison is made with ξ rather than $\pi^{-s/2}\Gamma(s/2)\zeta(s)$. An identity as a function of s needs an analytic family of observables or traces and a common domain. Renaming a fixed finite-group level s does not produce such a family.

Finite towers

A tower construction starts with actual finite field functors and coherent transition maps on their states and actions. Proposition 22.6.1 computes the measure required by a reduction. A coherent inverse diagram defines a pro-object in the chosen functor category. If a represented limit exists and its composition maps preserve the finite gluing identities, it defines the corresponding limiting assignment.

A Hilbert realization can be constructed under the isometric and boundedness hypotheses of Theorem 22.6.2 and Proposition 22.6.3. Arithmetic field spaces need their own measures and maps satisfying those hypotheses. The boundary, Wilson and partition comparisons are further identities on that limit.

Even the untwisted closed arithmetic example distinguishes the finite sum from a zeta partition formula. The étale fundamental group of Spec $\mathbb{Z}$ is trivial: a nontrivial finite extension unramified at all finite primes would contradict the discriminant bound. Its finite G-field groupoid is BG, so its untwisted mass is $1/|G|$. Additional ramification, boundary or analytic data are needed for a nonconstant arithmetic partition family.

Modular categories

A finite semisimple ribbon category with nondegenerate braiding gives the algebraic input to a Reshetikhin–Turaev theory, together with its anomaly and tangential structure. The C_2 example above provides explicit such data. To apply Z_{RT} to arithmetic objects, construct an arithmetic bordism category. Supply also a symmetric monoidal functor C into the appropriate topological bordism category. Their composition $Z_{\mathrm{RT}}C$ is then an arithmetic assignment.

This composition preserves the monoidal and gluing identities by functoriality. Its boundary trace and Wilson labels agree with the intended arithmetic ones only under maps establishing those equalities. An arithmetic decomposition of a closed object could identify its amplitude with an operator trace. A separate character formula could then identify that trace with $\xi(s)$. A modular category alone supplies neither the arithmetic bordism functor nor the analytic character identity. If the target contains infinitely many Fock states, the finite trace restriction following (22.20) must also be addressed.

Factorization from fields

There is a useful positive construction before imposing factorization descent. Suppose $U \mapsto \mathcal{F}(U)$ is a contravariant field-groupoid functor on opens, finite on the regions in use, and takes finite disjoint unions to products. Define $A(U) = \mathbb{C}^{\pi_0\mathcal{F}(U)}$. For disjoint $U_i \subset V$, set

$$\mu_{U_i,V}(f_1 \otimes \cdots \otimes f_r)(b) = \prod_i f_i(b|_{U_i}). \tag{22.30}$$

Restriction of fields and multiplication of functions prove associativity of these maps, their symmetry and the empty-input unit. Thus they define a prefactorization algebra of finite field functions. Weighted integration is an additional functional on it. Compatibility of that functional with gluing uses the action and the homotopy-fiber measure.

Descent of the field groupoids does not ensure factorization descent of these function spaces. A circle gives a counterexample. Take finite C_2-bundles and the cover by all complements of one point. It is a Weiss cover: every finite set of points lies in one member. Each nonempty finite intersection is a finite union of intervals and has one isomorphism class of bundles, although it retains automorphisms.

Every function space in its Čech diagram is therefore $\mathbb{C}$, with identity transition maps. The cover nerve has every finite simplex, so its homotopy colimit is $\mathbb{C}$.

On the circle itself there are two holonomies, and the function space is $\mathbb{C}^2$. The descent map has image the constants and misses the sign character.

Consequently the arithmetic factorization problem can begin with the maps (22.30), but must construct or replace their descent in the intended recipient. Derived or categorical coefficients can retain data lost by functions on isomorphism classes. Their factorization maps, support and continuity still need a proof. This issue already occurs before an archimedean Hilbert extension.

Fully dualizable objects

The framed cobordism hypothesis starts from a symmetric monoidal $(\infty, 3)$-category and a fully dualizable object. It uses the object's dual, evaluation, coevaluation and the required adjoints through the morphism levels, with their coherences. For the Morita three-category of finite tensor categories, Douglas–Schommer-Pries–Snyder prove that separable tensor categories are fully dualizable. In characteristic zero this includes finite semisimple tensor categories. Their theorem gives a framed three-dimensional theory. An oriented extension uses the appropriate homotopy fixed-point structure.

A categorical arithmetic recipient with trace and restricted-tensor conditions must itself be constructed: composition must exist and preserve those conditions. A monoidal comparison with the ordinary Morita category must transport the actual duality and adjunction data. A list of candidate objects and bimodules does not prove these facts. Once they hold, the framed theory exists in that target. An arithmetic bordism comparison, the boundary trace map and the Frobenius labels remain separate inputs. Agreement with a proposed RT theory requires comparison of their extended data in a common category.

A six-functor trace

Suppose an arithmetic space $X^\diamond$ has coefficient categories $C(-)$. Let its structure morphism $f : X^\diamond \to \mathrm{pt}$ admit the required functors. For $B \in C(\mathrm{pt})$, the expression $f_! f^! B$ then has a definite type. If it is dualizable, its identity has trace

$$\mathrm{Tr}(1_{f_! f^! B}) \in \mathrm{End}_{C(\mathrm{pt})}(1).$$

A scalar value uses a specified map from this endomorphism ring to the scalar field. A regularized trace, if needed in place of dualizability, requires its own domain and normalization.

This produces a trace expression on the supplied geometry. The global arithmetic diamond and its archimedean boundary are additional inputs. So are the realization of the Hecke trace as B and the Euler-product trace identity. Local geometric Langlands and local diamond geometry provide arithmetic objects that a comparison may use. They do not by themselves define all of this global data.

Comparing Hilbert realizations

A common positive pairing does give a strong comparison once the state spaces have been constructed. Let E_∞ be a specified complex trace realization, with a positive semidefinite Hermitian form q_∞. Write its nullspace as N_q.

Proposition 22.11.1 *(Boundary Hilbert transport).* Suppose $I_B : E_\infty \to H_B$ and $I_P : E_\infty \to H_P$ have dense ranges and satisfy

$$\langle I_B v, I_B w\rangle = q_\infty(v, w) = \langle I_P v, I_P w\rangle.$$

There is a unique unitary $T : H_B \to H_P$ with $T I_B = I_P$. If closed operators A_B, A_P have cores $I_B\mathcal{D}$, $I_P\mathcal{D}$, respectively, and $T A_B I_B v = A_P I_P v$ for $v \in \mathcal{D}$, then

$$T \operatorname{Dom} A_B = \operatorname{Dom} A_P, \qquad T A_B = A_P T.$$

For normal operators this also intertwines their bounded spectral functions.

Proof. Cauchy–Schwarz makes N_q orthogonal to all of E_∞. Both realization kernels equal N_q, so $I_B v \mapsto I_P v$ is a well-defined isometry on dense subspaces. It extends uniquely onto H_P. The graph of each closed operator is the closure of its graph on the specified core. Applying $T \oplus T$ gives the domain identity and the full intertwining relation. The normal functional calculus then proves the last assertion. □

Boundary operations must preserve N_q to descend even algebraically. Their closed generators need the domains in this proposition. A further identification with logarithmic scaling on $L^2(\mathbb{R}_{>0}, dx/x)$ requires another unitary with its domain identity. Polynomial Fock energy has eigenvectors, whereas the full-line logarithmic translation generator has none. Those representations cannot be identified by a unitary preserving these generators.

Positive Hilbert descent is also distinct from the complete Weil pairing. Let $\mathcal{T}$ be the chosen Weil test algebra with involution $*$. Its complete signed functional W includes the polar, archimedean and prime terms.

If a map $J : \mathcal{T} \to E_\infty$ satisfies

$$q_\infty(Jf, Jg) = W(f * g^*) \qquad (f, g \in \mathcal{T}), \tag{22.31}$$

then $W(f * f^*) \geq 0$. This follows by setting $g = f$. The substantive assertion is (22.31) on the full required test domain, with its completion and normalization. A positive form on an auxiliary finite gauge or oscillator space does not supply it. Conversely, positivity of the full Weil form does not construct the arithmetic bordism functor.

22.12 Other physical realizations and the remaining maps

Arithmetic Chern–Simons is one possible physical formulation. It does not exclude others. The class-$\mathcal{S}$ construction compactifies the six-dimensional $(2, 0)$ theory on a complex curve, with its twist and defect data, to obtain four-dimensional $\mathcal{N} = 2$ theories.

For an unpunctured complex curve its Hitchin base uses $\bigoplus_i H^0(C, K_C^{d_i})$. Punctures change the allowed poles. Replacing K_C by a metrized arithmetic dualizing line does not specify a Higgs field, Hitchin equations or a six-dimensional compactification. Krull dimension cannot be added to a real manifold dimension to prove that every arithmetic version is impossible. The question is to construct the geometry, fields and comparison that would make such a version defined.

Likewise, a local Hecke character is a label, not the one-dimensional defect carrying it. Local class field theory relates its appropriate finite or Weil realization to local arithmetic data. Turning it into a boundary module requires a functor to the specified defect category, including its ramified action. The local character space can itself have positive-dimensional families. Choosing a point in it does not assign a dimension to the physical defect.

The protected chiral construction of Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees starts with an actual four-dimensional superconformal theory and its protected cohomology. Its algebra and Schur trace retain those fields and symmetries. An arithmetic Euler trace has a simpler independent construction: on the finite occupation states with energies $\sum_p n_p \log p$, the trace of e^{-sH} is $\prod_p (1 - p^{-s})^{-1}$ for $\operatorname{Re} s > 1$. This does not identify the space with protected cohomology. Frobenius is an endomorphism, not automatically an integer grading. A symbol t^{Frob} requires a defined functional calculus or a specified graded realization.

The arithmetic comparison therefore remains an object and map problem. The required data are the arithmetic bulk geometry, field action, coherent measures and gluing. One must construct the boundary trace realization, its pairing and the Frobenius Wilson comparison. The partition trace also requires its analytic domain.

The finite torsors, abelian linking correlations, Haar realization and free physical period map give positive constructions in four specified settings. Their extension to one arithmetic theory requires the maps just identified. The full Weil comparison adds a further identity on its complete test algebra.

Chapter 23

The Weil algebra and its domain

The explicit formula equates arithmetic and spectral evaluations of a test function. The arithmetic evaluation contains every prime power, a gamma integral and two polar values. The spectral evaluation sums over the zeros of the completed zeta function. Applying the formula to convolution products produces a Hermitian form. Its positivity on the full test algebra is equivalent to the Riemann hypothesis.

The domain is part of this assertion. Compact support makes each prime sum finite. Exponential decay permits Gaussian tests and controls the infinite prime sum. The ordinary Schwartz topology controls the gamma integral but does not control the critically weighted prime measure. We shall construct the relevant extensions and the maps between their domains.

Two examples explain why these choices matter. The polar form has rank two and both signs. The finite-prime form also has a two-dimensional subspace with both signs. Their contributions enter the complete formula with specified signs. A positive realization must reproduce that complete form.

Fourier inversion, elementary distribution theory and complex analysis are the prerequisites. We use Lebesgue measure on the additive real line. Hermitian forms are linear in their first argument. The convolution algebras below have no unit unless a unitization is explicitly taken.

23.1 Compact tests and Mellin reflection

For $R > 0$, let $\mathscr{A}_R$ be the space of complex smooth functions supported in $[-R, R]$, with seminorms

$$\|f\|_{R,j} = \sup_{x\in\mathbb{R}} |f^{(j)}(x)|, \qquad j \geq 0.$$

The compact test space is

$$\mathscr{A}_c = C_c^\infty(\mathbb{R}) = \operatorname*{colim}_{R\to\infty} \mathscr{A}_R$$

with its usual strict locally convex inductive-limit topology. A convergent sequence lies in one $\mathscr{A}_R$ and converges there in every derivative seminorm.

Definition 23.1.1 *(The compact convolution algebra).* For $f, g \in \mathscr{A}_c$, set

$$(f * g)(x) = \int_{\mathbb{R}} f(y)g(x-y)\,dy, \qquad f^*(x) = \overline{f(-x)}. \tag{23.1}$$

The Fourier transform and its real-axis inverse are

$$h_f(z) = \int_{\mathbb{R}} f(x)e^{izx}\,dx, \qquad f(x) = \frac{1}{2\pi}\int_{\mathbb{R}} h_f(t)e^{-itx}\,dt.$$

For an entire function h, write $h^\sharp(z) = \overline{h(\bar{z})}$.

PROPOSITION 23.1.2 *(Products, support and involution).* Convolution and $f \mapsto f^*$ make $\mathscr{A}_c$ a commutative topological complex $*$-algebra. They satisfy

$$\operatorname{supp}(f * g) \subset \operatorname{supp} f + \operatorname{supp} g, \qquad h_{f*g} = h_f h_g, \qquad h_{f^*} = h_f^\sharp.$$

For $f \in \mathscr{A}_R$, h_f is entire and obeys

$$|h_f(z)| \le C_{R,N}(f) e^{R|\operatorname{Im} z|}(1 + |z|)^{-N} \qquad (N \ge 0),$$

where $C_{R,N}$ is a continuous seminorm. In particular, h_f and all its derivatives decrease rapidly on every closed horizontal strip.

Proof. The support assertion follows directly from the integral. Fubini proves associativity, commutativity and the product identity. Reflection and conjugation give the involution identity. Differentiation may be performed under convolution on a fixed compact support. The resulting estimates prove continuity on the compact test space.

Compact support also permits differentiation of h_f at every complex argument. Repeated integration by parts gives

$$(iz)^N h_f(z) = (-1)^N \int f^{(N)}(x) e^{izx}\, dx.$$

There are no boundary terms. Combine this bound for $|z| \ge 1$ with the integral bound for $|z| \le 1$. Applying the same argument to $x^j f(x)$ proves the assertion about derivatives. □

We give the Fourier image $h(\mathscr{A}_c)$ the transported topology. An entire function in this image cannot vanish on a real interval unless it is zero. Exact restriction to a bounded frequency interval therefore does not preserve this Fourier image.

The map $\epsilon(f) = \int f$ is multiplicative. It does not provide a convolution unit. Indeed, a unit $e \in \mathscr{A}_c$ would satisfy $h_e(t) h_f(t) = h_f(t)$ for every f. At each real t, some compact test has nonzero transform, so $h_e(t) = 1$. This contradicts rapid decay.

The Dirac distribution at zero is the unit in a larger distribution algebra. Smooth functions $b_\delta(x) = \delta^{-1} b(x/\delta)$, with $\int b = 1$, instead form an approximate identity on $\mathscr{A}_c$.

The multiplicative coordinate $u = e^x$ introduces a half-density. For $f \in \mathscr{A}_c$, define

$$\phi_f(u) = u^{-1/2} f(\log u), \qquad \Phi_f(s) = \int_0^\infty \phi_f(u) u^s \, \frac{du}{u} = h_f\big(-i(s - \tfrac{1}{2})\big).$$

Thus ϕ_f is compactly supported on $\mathbb{R}_{>0}$. Multiplicative convolution uses the measure du/u.

PROPOSITION 23.1.3 *(The two reciprocal maps).* The assignment $f \mapsto \phi_f$ preserves convolution. Its induced antilinear involution and its linear reciprocal map are

$$\phi^*(u) = u^{-1} \overline{\phi(u^{-1})}, \qquad \phi^\iota(u) = u^{-1} \phi(u^{-1}).$$

Their Mellin transforms are

$$\Phi_{\phi^*}(s) = \overline{\Phi_\phi(1 - \bar{s})}, \qquad \Phi_{\phi^\iota}(s) = \Phi_\phi(1 - s).$$

In particular,

$$\Phi_{f * g^*}(s) = \Phi_f(s) \overline{\Phi_g(1 - \bar{s})}.$$

Proof. In multiplicative convolution substitute $u = e^x$, $v = e^y$. The two half-density factors multiply to $e^{-x/2}$, leaving $(f * g)(x)$. Substitution $u \mapsto u^{-1}$ in the Mellin integral gives both reciprocal identities. The last formula follows from Fourier multiplication. □

Mellin reflection is linear. A Hermitian pairing also needs complex conjugation. Equivalently, a form q linear in its first argument is a complex-linear functional on $\mathscr{A}_c \otimes_{\mathbb{C}} \overline{\mathscr{A}_c}$, where the bar denotes the conjugate vector space. Replacing this factor by $\mathscr{A}_c$ changes the scalar rule: a bilinear diagonal changes sign under $f \mapsto if$, whereas a Hermitian diagonal does not.

23.2 Prime powers and exponential weights

Let $\Lambda(n)$ be the von Mangoldt function: $\Lambda(p^k) = \log p$ for primes p and integers $k \geq 1$, and $\Lambda(n) = 0$ otherwise. The logarithmic prime measures are

$$\mu_\sigma = \sum_{n \geq 2} \Lambda(n) n^{-\sigma} \delta_{\log n}, \qquad \sigma \in \mathbb{R}.$$

Every compact interval meets finitely many atoms. Each μ_σ therefore acts continuously on $\mathscr{A}_c$.

Lemma 23.2.1 *(Elementary prime mass).* Put $\Psi(X) = \sum_{n \leq X} \Lambda(n)$. For integers $m \geq 1$,

$$2m \log 2 - \log(2m + 1) \leq \Psi(2m).$$

Moreover, $\Psi(X) \leq X \log X$ for $X \geq 2$. Consequently, $\Psi(X) \geq cX$ for all sufficiently large X, with some $c > 0$.

Proof. The largest coefficient in $(1 + 1)^{2m}$ is $\binom{2m}{m}$, so $\binom{2m}{m} \geq 4^m/(2m + 1)$. Its p-adic valuation is

$$v_p\binom{2m}{m} = \sum_{k \geq 1} \left(\left\lfloor \frac{2m}{p^k} \right\rfloor - 2 \left\lfloor \frac{m}{p^k} \right\rfloor \right).$$

Each summand is zero or one and vanishes for $p^k > 2m$. Taking logarithms gives $\log \binom{2m}{m} \leq \Psi(2m)$. The upper bound follows from $\Lambda(n) \leq \log n$. Monotonicity, with $m = \lfloor X/2 \rfloor$, gives the final lower bound. □

Theorem 23.2.2 *(The exact temperedness threshold).* The positive measure μ_σ is tempered exactly when $\sigma \geq 1$. It has finite total mass exactly when $\sigma > 1$. In particular, the critical measure $\mu_{1/2}$ is not tempered.

Proof. For $\sigma \geq 1$ and a Schwartz function v,

$$|\mu_\sigma(v)| \leq \sup_x (1 + |x|)^3 |v(x)| \sum_{n \geq 2} \frac{\log n}{n(1 + \log n)^3}.$$

The series converges by the integral test. For $\sigma > 1$, the stronger bound $\sum (\log n) n^{-\sigma} < \infty$ proves finite mass. At $\sigma = 1$, partial summation gives

$$\sum_{n \leq X} \frac{\Lambda(n)}{n} = \frac{\Psi(X)}{X} + \int_1^X \frac{\Psi(u)}{u^2}\, du.$$

The lower bound of the lemma makes this quantity diverge.

A positive tempered measure has polynomially bounded mass on $[-R, R]$. To see this, test against $v(x/R)$, where $v \geq 0$ is a fixed compact smooth function equal to one on $[-1, 1]$. Each of its finitely many required Schwartz seminorms grows polynomially in R.

If $0 \leq \sigma < 1$, then

$$\mu_\sigma([0, R]) \geq e^{-\sigma R}\Psi(e^R) \geq ce^{(1-\sigma)R}$$

for large R. If $\sigma < 0$, the lower bound ce^R already suffices. These estimates contradict polynomial growth. They also exclude finite mass. □

The Euler product gives a transform on its actual convergence domain. For $\operatorname{Re} s > 1$,

$$\zeta(s) = \sum_{n\geq 1} n^{-s} = \prod_p (1 - p^{-s})^{-1}, \qquad -\frac{\zeta'(s)}{\zeta(s)} = \sum_{n\geq 2} \Lambda(n) n^{-s}. \tag{23.2}$$

Absolute convergence proves the product and permits logarithmic differentiation on compact subsets of this half-plane. Thus $-\zeta'/\zeta$ is the Laplace transform of μ_0 there. With Fourier convention $\int e^{-itx}\, d\mu(x)$, the transform of μ_σ, $\sigma > 1$, is $-\zeta'(\sigma + it)/\zeta(\sigma + it)$.

The seminorm estimate in the theorem and dominated convergence give $\mu_{1+\varepsilon} \to \mu_1$ weakly in tempered distributions. Fourier continuity gives the corresponding boundary transform. Meromorphic continuation of $-\zeta'/\zeta$ does not extend the original Laplace integral beyond its convergence domain.

23.3 THETA CONTINUATION AND THE ZERO DIVISOR

We normalize the completed zeta function before forming its logarithmic derivative. Let

$$\theta(t) = \sum_{n\in\mathbb{Z}} e^{-\pi n^2 t}, \qquad r(t) = \frac{\theta(t) - 1}{2} \qquad (t > 0).$$

The Gaussian transform gives the theta identity

$$\theta(t) = t^{-1/2}\theta(t^{-1}). \tag{23.3}$$

One proof periodizes $e^{-\pi t x^2}$. Its m-th Fourier coefficient is $t^{-1/2}e^{-\pi m^2/t}$. Both periodic sums converge uniformly, and uniqueness of Fourier coefficients gives the identity at $x = 0$.

The Gaussian transform itself follows by differentiating its integral with respect to frequency and using its value at zero.

For $\operatorname{Re} s > 1$, termwise integration yields

$$\Lambda_\zeta(s) := \pi^{-s/2}\Gamma(s/2)\zeta(s) = \int_0^\infty r(t) t^{s/2}\, \frac{dt}{t}.$$

Split the integral at one and use (23.3) in the lower part. The result is

$$\Lambda_\zeta(s) = \frac{1}{s(s-1)} + \int_1^\infty r(t)\left(t^{s/2} + t^{(1-s)/2}\right) \frac{dt}{t}.$$

The integral is entire because $r(t)$ decreases exponentially. It follows that Λ_ζ is meromorphic, with residues -1 at zero and 1 at one.

Definition 23.3.1 *(The normalized entire function).* Set

$$\xi(s) = \frac{1}{2}s(s-1)\Lambda_\zeta(s) = \frac{1}{2} + \frac{s(s-1)}{2}\int_1^\infty r(t)\left(t^{s/2} + t^{(1-s)/2}\right)\frac{dt}{t}. \tag{23.4}$$

Its zeros are counted with their analytic multiplicities. For a zero ρ, put $z_\rho = -i(\rho - \frac{1}{2})$.

The integral proves

$$\xi(0) = \xi(1) = \frac{1}{2}, \qquad \xi(1-s) = \xi(s), \qquad \xi(\bar{s}) = \overline{\xi(s)}.$$

The Euler product has no zero for $\operatorname{Re} s > 1$. The functional equation therefore places all zeros of ξ in $0 \le \operatorname{Re} s \le 1$. The associated parameters satisfy $|\operatorname{Im} z_\rho| \le 1/2$.

There is no real zero of ξ. For $0 < s < 1$, pair consecutive terms of the alternating series:

$$\eta(s) = \sum_{m\ge 1}\left((2m-1)^{-s} - (2m)^{-s}\right) > 0.$$

Dirichlet convergence and analytic continuation give $\eta(s) = (1-2^{1-s})\zeta(s)$. Hence $\zeta(s) \ne 0$ on that interval. The endpoints and the remaining real line follow from the displayed values, the Euler product and reflection. Consequently no z_ρ lies on the imaginary axis.

Lemma 23.3.2 *(Growth and summability).* For $R \ge 2$,

$$\log \max_{|s|\le R} |\xi(s)| \le CR\log(R+2).$$

The number of zeros in $|s| \le R$, with multiplicity, is $O(R\log(R+2))$. In particular, $\sum_\rho |\rho|^{-2} < \infty$, and the corresponding inverse-square sum over z_ρ converges. There are infinitely many zeros.

Proof. On $t \ge 1$, one has $r(t) \le Ce^{-\pi t}$. For $|s| \le R$, the two powers in (23.4) are bounded by $2t^{(R+1)/2}$. The elementary maximum of $t^A e^{-\pi t/2}$ is $(2A/(\pi e))^A$. This bounds the integral by $\exp(CR\log(R+2))$, including its quadratic prefactor.

Jensen's formula at radius $2R$, with $\xi(0) = 1/2$, bounds the number of zeros in radius R: each contributes at least $\log 2$. Summing over dyadic annuli proves inverse-square summability. Translation by $1/2$ gives the assertion for z_ρ.

If the zero set were finite, Hadamard factorization for an entire function of order at most one would give $\xi(s) = e^{as+b}P(s)$ for a polynomial P. Along positive real s, Stirling's formula and $\zeta(s) \to 1$ instead give $\log|\xi(s)| = \frac{1}{2}s\log s + O(s)$. This contradicts that representation. □

Proposition 23.3.3 *(The genus-one normalization).* Let γ_E be Euler's constant and put

$$B = -1 - \frac{\gamma_E}{2} + \frac{1}{2}\log(4\pi).$$

Then

$$\xi(s) = \frac{1}{2}e^{Bs}\prod_\rho (1-s/\rho)e^{s/\rho}, \qquad \frac{\xi'(s)}{\xi(s)} = B + \sum_\rho\left(\frac{1}{s-\rho} + \frac{1}{\rho}\right). \tag{23.5}$$

The factors and paired summands converge locally uniformly away from their zeros or poles.

Proof. The preceding growth estimate permits Hadamard factorization of genus one. Inverse-square summability gives local normal convergence. At zero the constant factor is $1/2$, and the logarithmic derivative of every elementary factor vanishes. The linear exponential coefficient is therefore $\xi'(0)/\xi(0)$.

Use $\Gamma(1+s/2) = (s/2)\Gamma(s/2)$ to write

$$\xi(s) = (s-1)\Gamma(1+s/2)\pi^{-s/2}\zeta(s).$$

The values $\zeta(0) = -1/2$, $\zeta'(0) = -\frac{1}{2}\log(2\pi)$ and $\Gamma'(1) = -\gamma_E$ give the stated B. For the two zeta values, expand the equivalent functional equation

$$\zeta(s) = 2^s\pi^{s-1}\sin(\pi s/2)\Gamma(1-s)\zeta(1-s).$$

The product $\Gamma(1-s)\zeta(1-s)$ is $-s^{-1} + O(s)$. The remaining factor is $\frac{s}{2}(1 + s\log(2\pi) + O(s^2))$. This proves both values.

Local differentiation of the normally convergent canonical product proves the logarithmic derivative formula. □

The summands in (23.5) are paired. The formula makes no separate absolute-convergence assertion for $\sum_\rho 1/\rho$. This convention will also determine the normalization of spectral determinants.

The argument term in zero counting

Let $N(T)$ count the zeros ρ with $0 < \operatorname{Im}\rho \le T$, including multiplicity. For $T > 0$ that is not a zero ordinate, define

$$\vartheta(T) = \operatorname{Im}\log\Gamma\left(\tfrac{1}{4} + \tfrac{iT}{2}\right) - \frac{T}{2}\log\pi, \qquad S(T) = \frac{1}{\pi}\Delta_{2\to 2+iT\to 1/2+iT}\arg\zeta.$$

The gamma logarithm is the analytic branch on the right half-plane that is real on the positive real axis. The zeta argument starts at zero at $s = 2$.

PROPOSITION 23.3.4 *(The zero-count normalization).* Away from zero ordinates,

$$N(T) = 1 + \frac{\vartheta(T)}{\pi} + S(T) = \frac{T}{2\pi}\log\frac{T}{2\pi e} + \frac{7}{8} + S(T) + O(T^{-1}).$$

At a zero ordinate, the formula for the stated convention $N(T)$ uses the right limit of S. The classical bound $S(T) = O(\log T)$ gives

$$N(T) = \frac{T}{2\pi}\log\frac{T}{2\pi e} + O(\log T).$$

Proof. Use the rectangle with real parts -1, 2 and imaginary parts 0, T. There are no zeros on its boundary. The real bottom edge contributes no argument change, since ξ is real and nonzero there. Reflection $s \mapsto 1 - \bar{s}$ and conjugation of ξ show that the remaining argument change is twice the change along

$$C_T: \quad 2 \longrightarrow 2 + iT \longrightarrow \tfrac{1}{2} + iT.$$

The argument principle therefore gives $N(T) = \pi^{-1}\Delta_{C_T}\arg\xi$.

At the endpoint, the continuous arguments of s and $s-1$ sum to π. The factorization $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ now gives the first equality. In particular, the horizontal segment contributes to $S(T)$.

Stirling's expansion at $z = 1/4 + iT/2$ gives

$$\vartheta(T) = \frac{T}{2}\log\frac{T}{2\pi} - \frac{T}{2} - \frac{\pi}{8} + \frac{1}{48T} + O(T^{-3}).$$

For the constant, the term $(z - \frac{1}{2})\log z - z$ contributes $-\frac{1}{4}\arg z \to -\pi/8$. Thus $7/8 = 1 - 1/8$. Taking right limits proves the convention at zero heights.

The argument bound is the classical theorem. A precise primary estimate is Hasanalizade–Shen–Wong, *Counting zeros of the Riemann zeta function*, Theorem 1.3 and Corollary 1.4, arXiv:2107.06506. Their Corollary 1.2 also supplies the displayed estimate for $N(T)$. □

This count controls ordinary convergent sums. It does not regularize divergent positive-power moments. For example, put

$$M_n(T) = \sum_{0<\operatorname{Im}\rho\le T} \left(\tfrac{1}{4} + (\operatorname{Im}\rho)^2\right)^n.$$

For every integer $n \ge 0$, partial summation gives

$$M_n(T) = \frac{T^{2n+1}}{2\pi(2n+1)}\log\frac{T}{2\pi} - \frac{T^{2n+1}}{2\pi(2n+1)^2} + O_n(T^{2n}\log T).$$

Indeed, integrate $(1/4 + t^2)^n$ against $dN(t)$. The error $O(\log(2+t))$ in the count contributes $O_n(T^{2n}\log T)$. In the main integral, replacing $(1/4 + t^2)^n$ by t^{2n} gives a smaller error. The integral of $t^{2n}\log(t/(2\pi))/(2\pi)$ is the displayed main term.

Every $M_n(T)$ diverges. A finite arithmetic moment functional therefore requires an additional, compatible regularization.

23.4 The complete arithmetic functional

Write $\psi_\Gamma = \Gamma'/\Gamma$ and define the real even functions

$$a(t) = \operatorname{Re}\psi_\Gamma\left(\tfrac{1}{4} + \tfrac{it}{2}\right) - \log\pi, \qquad k(t) = -a(t). \tag{23.6}$$

They are smooth on the real line and have at most logarithmic growth.

For $f \in \mathscr{A}_c$, set

$$\begin{aligned} P(f) &= h_f(i/2) + h_f(-i/2),\\ W_\infty(f) &= \frac{1}{2\pi}\int_{\mathbb{R}} h_f(t)k(t)\,dt,\\ W_{\mathrm{fin}}(f) &= \sum_{n\ge 2}\frac{\Lambda(n)}{\sqrt{n}}\big(f(\log n) + f(-\log n)\big),\\ W(f) &= P(f) - W_\infty(f) - W_{\mathrm{fin}}(f). \end{aligned} \tag{23.7}$$

The prime sum is finite. The gamma integral is absolutely convergent. These formulas define continuous complex-linear functionals on the compact test space. The sign of W_∞ is fixed by its density k.

Theorem 23.4.1 *(The complete explicit formula).* For every $f \in \mathscr{A}_c$,

$$W(f) = \sum_\rho h_f(z_\rho). \tag{23.8}$$

The sum over zeros is absolutely convergent, with multiplicity. For $f, g \in \mathscr{A}_c$, the form

$$q_W(f,g) = W(f * g^*) = \sum_\rho h_f(z_\rho)\overline{h_g(\bar{z}_\rho)} \tag{23.9}$$

is Hermitian and linear in its first argument.

Proof. Put $H(s) = \Phi_f(s)$, and choose $1 < c < 3/2$. Let

$$G(s) = \frac{\Lambda_\zeta'(s)}{\Lambda_\zeta(s)} = -\frac{1}{2}\log\pi + \frac{1}{2}\psi_\Gamma(s/2) + \frac{\zeta'(s)}{\zeta(s)}.$$

Inside the strip $1 - c \le \operatorname{Re} s \le c$, its residues are the zero multiplicities and -1 at each of $0, 1$. The functional equation gives $G(1-s) = -G(s)$.

We justify the contour limit. For all sufficiently large integers j, choose $T_j \in [j, j+1]$ at distance at least j^{-2} from every zero ordinate. The excluded intervals have total length $O(\log j/j) < 1$, by Lemma 23.3.2.

On the horizontal segments at heights $\pm T_j$, (23.5) gives a polynomial bound for ξ'/ξ. The zeros with $|\rho| \le 2T_j$ are bounded using the chosen distance. For the others,

$$\left|\frac{1}{s-\rho} + \frac{1}{\rho}\right| \le C\frac{|s|}{|\rho|^2}.$$

The rational correction $G = \xi'/\xi - 1/s - 1/(s-1)$ has the same bound. Rapid vertical-strip decay of H makes both horizontal integrals tend to zero.

Apply the residue theorem to $G(s)H(s)$ on that rectangle. Reflection of the left vertical side gives

$$\sum_\rho H(\rho) - H(0) - H(1) = \frac{1}{2\pi i}\int_{\operatorname{Re} s = c} G(s)\big(H(s) + H(1-s)\big)\,ds.$$

Absolute convergence of the zero sum follows from strip decay and the zero count.

On the right line, the Dirichlet series in (23.2) is absolutely convergent. Termwise integration is permitted. Fourier inversion gives

$$\frac{1}{2\pi i}\int_{\operatorname{Re} s = c} n^{-s}H(s)\,ds = n^{-1/2}f(\log n).$$

The reflected test gives $n^{-1/2}f(-\log n)$. The negative sign in ζ'/ζ therefore produces $-W_{\mathrm{fin}}(f)$.

Move the gamma part of the integral to $\operatorname{Re} s = 1/2$. Its logarithmic derivative has no pole between these lines. The two reflected integrals combine to

$$\frac{1}{2\pi}\int_{\mathbb{R}} h_f(t)\big(\operatorname{Re}\psi_\Gamma(\tfrac{1}{4} + \tfrac{it}{2}) - \log\pi\big)\,dt = -W_\infty(f).$$

Finally, $H(0) = h_f(i/2)$ and $H(1) = h_f(-i/2)$. This proves (23.8).

Fourier multiplication proves the paired formula. The zero multiset is invariant under $\rho \mapsto 1 - \bar{\rho}$, which sends z_ρ to $\bar{z}_\rho$. Reindexing the absolutely convergent sum proves Hermitian symmetry. □

In (23.9), conjugation acts at $\bar{z}_\rho$. Replacing the summand by $|h_f(z_\rho)|^2$ would change the form when z_ρ is nonreal. Under the Riemann hypothesis every z_ρ is real, and that specialization is valid.

23.5 Exponential extensions and their topology

Gaussian tests require a domain larger than $\mathscr{A}_c$. The growth threshold in Theorem 23.2.2 indicates the needed exponential margin.

Definition 23.5.1 *(Exponential test spaces).* For $a_0 > 1/2$, let

$$\mathscr{A}_{a_0} = \left\{ f \in C^\infty(\mathbb{R}) : p_{a_0,j}(f) := \int_{\mathbb{R}} e^{a_0|x|} |f^{(j)}(x)|\, dx < \infty \text{ for every } j \ge 0 \right\}.$$

Give this space the topology of its displayed seminorms. Put

$$\mathscr{A}_{\exp} = \bigcup_{a_0 > 1/2} \mathscr{A}_{a_0}, \qquad \mathscr{A}_\infty = \bigcap_{a_0 > 1/2} \mathscr{A}_{a_0}.$$

The union has the final locally convex topology of the steps $\mathscr{A}_{1/2+1/n}$. The intersection has all the exponential seminorms. Convolution and the involution are as in (23.1).

Theorem 23.5.2 *(Continuity on each exponential step).* Each $\mathscr{A}_{a_0}$ is a complete Fréchet convolution $*$-algebra, and $\mathscr{A}_c$ is dense in it. The transform h_f is holomorphic for $|\operatorname{Im} z| < a_0$. All its derivatives decrease rapidly on smaller closed strips.

Every term of (23.7) extends continuously to this step. There is a constant C_{a_0} such that

$$|W(f)| \le C_{a_0}\big(p_{a_0,0}(f) + p_{a_0,1}(f) + p_{a_0,2}(f)\big). \tag{23.10}$$

The explicit formula and its Hermitian pairing remain valid, with absolutely convergent prime and zero sums.

Proof. The inequality $e^{a_0|x+y|} \le e^{a_0|x|} e^{a_0|y|}$ gives

$$p_{a_0,j}(f * g) \le p_{a_0,j}(f)\, p_{a_0,0}(g).$$

The involution preserves each seminorm. A Cauchy sequence has weighted L^1 limits for every derivative. Distributional differentiation identifies successive limits. Local one-dimensional Sobolev regularity then gives a smooth representative with those derivatives. This proves completeness.

Choose $\chi \in C_c^\infty(\mathbb{R})$ equal to one near zero. Leibniz's rule shows $\chi(x/R)f(x) \to f(x)$ in every seminorm. The errors are integrable derivative tails multiplied by bounded cutoff derivatives and nonpositive powers of R. This proves density.

On a strip $|\operatorname{Im} z| \le b < a_0$, the spare weight $e^{(a_0-b)|x|}$ controls every polynomial in x. Differentiation in z and integration by parts in x give the asserted holomorphy and rapid decay. The two polar evaluations are bounded by $p_{a_0,0}(f)$. On the real line,

$$|h_f(t)| \le \min\{p_{a_0,0}(f),\ |t|^{-2} p_{a_0,2}(f)\}.$$

Logarithmic growth of k therefore controls the gamma integral.

The function $e^{a_0|x|} f(x)$ has an integrable weak derivative. Integrating from infinity on either half-line gives

$$\sup_x e^{a_0|x|} |f(x)| \le a_0\, p_{a_0,0}(f) + p_{a_0,1}(f).$$

Consequently the absolute prime sum is at most

$$2\bigl(a_0 p_{a_0,0}(f) + p_{a_0,1}(f)\bigr) \sum_{n\ge 2} \frac{\log n}{n^{a_0+1/2}}.$$

This series converges because $a_0 > 1/2$, proving (23.10).

Strip decay and the zero count similarly control the zero sum. Pass to the limit through the compact cutoffs to obtain the explicit formula. Convolution continuity proves the paired assertion. □

The extensions agree on overlapping steps, so they define W on $\mathscr{A}_{\exp}$. All assertions about passage of a quadratic inequality below use a specified step or the compact test topology. No completeness claim for the union is needed.

The intersection $\mathscr{A}_\infty$ is the space of smooth functions with rapid exponential decay. Its topology is equivalently given by

$$\sup_x e^{m|x|}(1+|x|)^N |f^{(j)}(x)|, \qquad m, N, j \in \mathbb{N}.$$

Indeed, one extra exponential weight bounds a polynomial weight and an integral. Conversely, the weighted L^1 bounds for two consecutive derivatives bound the weighted supremum as in the proof above. Compact cutoffs converge in all these seminorms.

The gamma functional alone extends continuously to Schwartz space. The prime functional does not have such an extension: its positive measure contains $\mu_{1/2}$ and its reflection. Thus Schwartz approximation alone does not justify passing each arithmetic term to a limit.

PROPOSITION 23.5.3 *(The regular convolution norm).* Convolution by $f \in \mathscr{A}_{\exp}$ acts boundedly on $L^2(\mathbb{R})$, with operator norm $\|h_f\|_\infty$. The completion for this norm is $C_0(\mathbb{R})$ under Fourier transform.

Proof. Plancherel turns convolution into multiplication by h_f. Since $f \in L^1$, its transform is continuous and vanishes at infinity. To prove density, start with $H \in C_c^\infty(\mathbb{R})$ in the frequency variable. Its inverse Fourier transform v is Schwartz. Compact cutoffs v_R converge to v in L^1, so $\|h_{v_R} - H\|_\infty \le \|v_R - v\|_1 \to 0$. Finally, C_c^∞ is uniformly dense in C_0. □

23.6 THE POLAR AND FINITE-PRIME FORMS

For $f \in \mathscr{A}_{\exp}$, write

$$\ell_-(f) = \int f(x) e^{-x/2}\,dx, \qquad \ell_+(f) = \int f(x) e^{x/2}\,dx.$$

Both are continuous on every exponential step.

PROPOSITION 23.6.1 *(The full polar matrix).* One has

$$P(f * g^*) = \ell_-(f)\overline{\ell_+(g)} + \ell_+(f)\overline{\ell_-(g)}.$$

On compact tests, the map $(\ell_-, \ell_+) : \mathscr{A}_c \to \mathbb{C}^2$ is surjective. The polar form has rank two, with one positive and one negative direction. Its kernel is the common kernel of the two moments. On the complex even tests it is the positive form $2\ell_+(f)\overline{\ell_+(g)}$.

Proof. Evaluate $h_f h_g^\sharp$ at $i/2$ and $-i/2$. A linear relation between the two moment functionals would make $c_- e^{-x/2} + c_+ e^{x/2}$ vanish identically. Its value and derivative at zero force $c_- = c_+ = 0$. The map therefore has two-dimensional range.

The matrix on that range is $\left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$. Its eigenvalues are 1, -1. Evenness gives $\ell_- = \ell_+$, which proves the last assertion. □

A right inverse $S : \mathbb{C}^2 \to \mathscr{A}_c$ gives the continuous projection $1 - S(\ell_-, \ell_+)$ onto the polar kernel. A single vector with norm square $|\ell_+(f)|^2$ does not realize the full polar form.

The prime term has a different finite-support realization. For $R > 0$, let $j_R : L^2([-R, R]) \to L^2(\mathbb{R})$ extend by zero. Write $T_a v(x) = v(x - a)$, and define

$$B_R = \sum_{2 \le n \le e^{2R}} \frac{\Lambda(n)}{\sqrt{n}} j_R^* (T_{\log n} + T_{-\log n}) j_R.$$

Proposition 23.6.2 *(The finite-prime operator).* The operator B_R is bounded and self-adjoint, with $\|B_R\| \le 2 \sum_{n \le e^{2R}} \Lambda(n) n^{-1/2}$. For smooth f, g supported in $(-R, R)$,

$$W_{\mathrm{fin}}(f * g^*) = \langle B_R f, g \rangle = \langle |B_R|^{1/2} f, \operatorname{sgn}(B_R) |B_R|^{1/2} g \rangle.$$

These pairings agree under enlargement of the support interval.

Proof. Translations are unitary and $T_a^* = T_{-a}$, proving the operator claims and the norm bound. A change of variables gives

$$(f * g^*)(a) = \int f(x) \overline{g(x - a)}\, dx = \langle T_{-a} j_R f, j_R g \rangle.$$

This vanishes for $|a| \ge 2R$. Summing at both signs of each prime-power logarithm proves the first identity and compatibility. The spectral theorem for B_R, with $\operatorname{sgn}(0) = 0$, proves the second identity. □

Example 23.6.3 *(Two translated bumps).* Put $L = \log 2$. Choose a nonzero real smooth b supported in $(-\varepsilon, \varepsilon)$, where $2\varepsilon < \min\{\log 2, \log(3/2)\}$. On the span of b, $T_L b$, the finite-prime form has matrix

$$\frac{\log 2}{\sqrt{2}} \|b\|_2^2 \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}.$$

Indeed, $b * b^*$ is supported in $[-2\varepsilon, 2\varepsilon]$ and has value $\|b\|_2^2$ at zero. Only the two shifts $\pm \log 2$ meet the off-diagonal correlations.

Hence

$$W_{\mathrm{fin}}\big((b \pm T_L b) * (b \pm T_L b)^*\big) = \pm \sqrt{2} \log 2\, \|b\|_2^2.$$

This excludes a positive Hilbert realization of the finite-prime form on all compact tests. In the full form that term is subtracted. Its negative value is therefore not a negative full Weil square.

Prime powers remain essential even in such small examples. Two sufficiently narrow bumps separated by $\log 4$ have an off-diagonal contribution $\Lambda(4)/\sqrt{4} = (\log 2)/2$. Retaining only primes would erase that contribution.

23.7 The gamma kernel and its auxiliary form

The signed gamma density k has both signs. Its absolute value cannot be absorbed into an unspecified positive measure without changing the arithmetic functional. To see its shape explicitly, set $c_n = n + 1/4$. The digamma series gives

$$a(t) = a(0) + \sum_{n\ge 0} \frac{t^2/4}{c_n(c_n^2 + t^2/4)}, \qquad a(0) = -\gamma_E - \frac{\pi}{2} - 3\log 2 - \log \pi. \tag{23.11}$$

Here and below $a = -k$, as in (23.6). See DLMF 5.7.6 and 5.4.19.

PROPOSITION 23.7.1 *(The gamma signs).* The function a is even and strictly increasing on $(0, \infty)$. It has its minimum at zero and satisfies

$$a(t) = \log \frac{|t|}{2\pi} + O(t^{-2}) \qquad (|t| \to \infty).$$

Thus $k(0) > 0$, and $k(t) \to -\infty$. The function $|\Gamma(1/4 + it/2)|^2$ is not a constant multiple of $k(t)$.

Proof. Subtract the digamma series at zero. This gives (23.11), whose summands are nonnegative and strictly increasing in $|t|$. Their derivatives converge uniformly on compact intervals:

$$a'(t) = \sum_{n\ge 0} \frac{c_n t/2}{(c_n^2 + t^2/4)^2} > 0 \qquad (t > 0).$$

The value at zero follows from the reflection and duplication identities for ψ_Γ. Stirling's expansion $\psi_\Gamma(z) = \log z - 1/(2z) + O(|z|^{-2})$, on the vertical line $\operatorname{Re} z = 1/4$, gives the asymptotic. Finally, the gamma absolute square is strictly positive everywhere, whereas k changes sign. □

The phase and the absolute square also have different derivatives:

$$\frac{d}{dt} \arg \Gamma(\tfrac{1}{4} + \tfrac{it}{2}) = \frac{1}{2} \operatorname{Re} \psi_\Gamma(\tfrac{1}{4} + \tfrac{it}{2}), \qquad \frac{d}{dt} \log |\Gamma(\tfrac{1}{4} + \tfrac{it}{2})|^2 = -\operatorname{Im} \psi_\Gamma(\tfrac{1}{4} + \tfrac{it}{2}).$$

These follow by taking the imaginary and real parts of $(i/2)\psi_\Gamma$. A local continuous phase is sufficient. For $\Lambda_\infty(s) = \pi^{-s/2}\Gamma(s/2)$, the arithmetic density is

$$k(t) = -2 \operatorname{Re} \frac{\Lambda_\infty'}{\Lambda_\infty}(\tfrac{1}{2} + it).$$

This specifies the operation and normalization that a local archimedean comparison must preserve.

PROPOSITION 23.7.2 *(The kernel away from the origin).* On compact tests supported away from zero, the distribution $P - W_\infty$ is integration against

$$K(x) = 2\cosh(x/2) - \frac{e^{-|x|/2}}{1 - e^{-2|x|}}, \qquad x \ne 0. \tag{23.12}$$

In particular, if $0 < b < c < \log 2$ and $f \ne 0$ is even, nonnegative and supported in $(-c, -b) \cup (b, c)$, then

$$W_{\mathrm{fin}}(f) = 0, \qquad W_\infty(f) = 2\int_b^c \frac{e^{-x/2}}{1 - e^{-2x}} f(x)\, dx > 0.$$

Proof. The polar functional is integration against $2\cosh(x/2)$. Use the integral identity

$$\psi_\Gamma(z) + \gamma_E = \int_0^\infty \frac{e^{-v} - e^{-zv}}{1 - e^{-v}}\, dv, \qquad \operatorname{Re} z > 0,$$

as in DLMF 5.9.16. For a test vanishing near zero, constant Fourier terms contribute zero. Fourier inversion of the cosine term, followed by $v = 2|x|$, gives the second term of (23.12) with its negative sign. Truncating the v-integral first justifies the calculation.

The support condition removes its singular endpoint, and exponential decay controls infinity. The final assertion follows because no prime-power logarithm lies in the stated support. □

A second gamma density

Define

$$b(t) = \operatorname{Re}\psi_\Gamma\left(\tfrac{1}{4} + \tfrac{it}{2}\right) + \log\pi = 2\log\pi - k(t),$$

and the auxiliary form

$$G_+(f,g) = \frac{1}{2\pi}\int_{\mathbb{R}} h_f(t)\overline{h_g(t)}b(t)\, dt.$$

It is continuous on Schwartz space. Plancherel gives

$$W_\infty(f * g^*) = 2\log\pi\,\langle f, g\rangle_{L^2} - G_+(f,g).$$

The function b is strictly increasing in $|t|$, with

$$b(0) = -\gamma_E - \frac{\pi}{2} - 3\log 2 + \log\pi < 0, \qquad b(t) = \log(|t|\pi/2) + O(t^{-2}).$$

It therefore has a unique positive zero, denoted t_b.

The interval $0.84 < t_b < 0.86$ follows from a positive-tail estimate. Put

$$S_N(t) = b(0) + \sum_{n=0}^{N} \frac{t^2/4}{c_n(c_n^2 + t^2/4)}.$$

Then

$$0 \le b(t) - S_N(t) \le \frac{t^2}{8(N+1/4)^2}.$$

At $N = 20$, the rational bounds

$$0.577 < \gamma_E < 0.578, \qquad 3.1415 < \pi < 3.1416,$$
$$0.6931 < \log 2 < 0.6932, \qquad 1.1447 < \log\pi < 1.1448$$

give

$$-0.024 < S_{20}(0.84) < -0.020, \qquad 0.017 < S_{20}(0.86) < 0.020.$$

Both tails are less than 0.00023. The signs and monotonicity prove the interval.

For a compact test, define the two nonnegative energies

$$A_b(f) = \int_{|t|<t_b} |h_f(t)|^2(-b(t))\, dt, \qquad B_b(f) = \int_{|t|>t_b} |h_f(t)|^2 b(t)\, dt.$$

Their difference gives $G_+(f,f) = (B_b(f) - A_b(f))/(2\pi)$. The sufficient high-frequency condition is

$$2t_b|b(0)| \sup_{|t|\le t_b} |h_f(t)|^2 \le B_b(f). \tag{23.13}$$

It bounds $A_b(f)$ by $B_b(f)$, and hence implies $G_+(f,f) \ge 0$.

PROPOSITION 23.7.3 *(Compact high-frequency tests).* The class defined by (23.13) contains nonzero real even compact tests. It is a proper subset of $\mathscr{A}_c$.

Proof. Choose a real even compact smooth χ with $\int \chi \neq 0$. For $M > 0$, let $f_M(x) = \chi(x)\cos(Mx)$. Then

$$h_{f_M}(t) = \tfrac{1}{2}\big(h_\chi(t+M) + h_\chi(t-M)\big).$$

Schwartz decay makes the left side of (23.13) tend to zero faster than every inverse power of M.

Near $t = M$, the translate $h_\chi(t-M)$ has modulus bounded below on a fixed interval, while $h_\chi(t+M) \to 0$ uniformly there. Since $b(t) \sim \log M$ on that interval, $B_b(f_M) \geq c \log M$ for large M. This proves the first assertion.

For the second, set $v_L(x) = L^{-1/2}\chi(x/L)$. A change of variables gives

$$G_+(v_L, v_L) = \frac{1}{2\pi}\int_{\mathbb{R}} |h_\chi(t)|^2 b(t/L)\,dt \longrightarrow b(0)\|\chi\|_2^2 < 0.$$

Logarithmic growth and Schwartz decay justify dominated convergence. Thus v_L fails (23.13) for all sufficiently large L. □

The relation to full Weil positivity retains the arithmetic terms. Put $R(f) = P(f * f^*) - W_{\mathrm{fin}}(f * f^*)$. Then

$$q_W(f,f) = R(f) - 2\log\pi\,\|f\|_2^2 + \frac{B_b(f) - A_b(f)}{2\pi}.$$

Thus $q_W(f,f) \geq 0$ is equivalent to

$$\frac{A_b(f)}{2\pi} + 2\log\pi\,\|f\|_2^2 \leq \frac{B_b(f)}{2\pi} + R(f).$$

Auxiliary positivity controls only the difference of the two energies.

A nonnegative majorant $v \geq -b$ on $[-t_b, t_b]$ gives the useful bound $A_b(f) \leq \int_{-t_b}^{t_b} |h_f|^2 v$. For support in $[-R, R]$, Cauchy–Schwarz gives

$$\sup_t |h_f(t)|^2 \leq 2R\|f\|_2^2, \qquad A_b(f) \leq 4t_b R|b(0)|\|f\|_2^2.$$

These are sufficient estimates for the corresponding terms. They place no bound on $R(f)$.

23.8 GAUSSIAN NORMALIZATION AND CROSS TERMS

All derivatives of a Gaussian have rapid exponential decay. Theorem 23.5.2 therefore applies to the entire Gaussian family and to its convolution products. For $\lambda > 0$, set

$$g_\lambda(x) = e^{-\lambda x^2/2}.$$

Completing the square gives

$$h_{g_\lambda}(t) = \sqrt{\frac{2\pi}{\lambda}}\,e^{-t^2/(2\lambda)}, \qquad (g_\lambda * g_\mu)(x) = \sqrt{\frac{2\pi}{\lambda+\mu}}\,e^{-\lambda\mu x^2/[2(\lambda+\mu)]}.$$

These identities include all normalization factors.

Define the normalized signed gamma integral

$$H(\lambda) = \frac{1}{\sqrt{\pi\lambda}} \int_{\mathbb{R}} e^{-t^2/\lambda} k(t)\, dt.$$

If $\nu = 2\lambda\mu/(\lambda+\mu)$, then

$$W_\infty(g_\lambda * g_\mu) = \sqrt{\frac{2\pi}{\lambda+\mu}}\, H(\nu). \tag{23.14}$$

This follows by inserting the Fourier product in the integral with coefficient $1/(2\pi)$.

Theorem 23.8.1 *(A convergent Gaussian series).* Let $\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-u^2}\, du$. For every $\lambda > 0$,

$$H(\lambda) = k(0) - \sum_{n\ge 0} \left(\frac{1}{c_n} - \frac{2\sqrt{\pi}}{\sqrt{\lambda}} e^{4c_n^2/\lambda} \operatorname{erfc}(2c_n/\sqrt{\lambda}) \right). \tag{23.15}$$

Each summand is nonnegative and at most $\lambda/(8c_n^3)$. The series converges uniformly on compact λ-intervals.

Proof. The identity (23.11) expresses $k(0) - k(t)$ as a sum of nonnegative functions. Tonelli permits integration of this sum against the Gaussian. For $d > 0$,

$$\int_{\mathbb{R}} \frac{e^{-t^2/\lambda}}{t^2+d^2}\, dt = \sqrt{\pi} \int_0^\infty \frac{e^{-d^2 u}}{\sqrt{u+1/\lambda}}\, du = \frac{\pi}{d} e^{d^2/\lambda} \operatorname{erfc}(d/\sqrt{\lambda}).$$

The first equality uses $(t^2+d^2)^{-1} = \int_0^\infty e^{-u(t^2+d^2)}\, du$. The substitution $v = d\sqrt{u+1/\lambda}$ gives the second. Set $d = 2c_n$ to obtain (23.15).

Replacing $c_n^2 + t^2/4$ by c_n^2 bounds its summand by

$$\frac{1}{\sqrt{\pi\lambda}} \int e^{-t^2/\lambda} \frac{t^2}{4c_n^3}\, dt = \frac{\lambda}{8c_n^3}.$$

This proves uniform convergence. □

Proposition 23.8.2 *(The signed Gaussian threshold).* The function H is continuous and strictly decreasing on $(0,\infty)$. Its limits at zero and infinity are $k(0) > 0$ and $-\infty$, respectively. It has a unique zero $\lambda_c > 0$. Consequently,

$$W_\infty(g_\lambda * g_\lambda) \ge 0 \quad \Longleftrightarrow \quad \lambda \le \lambda_c.$$

For $a_j \ge 0$ and $0 < \lambda_j \le \lambda_c$,

$$W_\infty\left(\left(\sum_j a_j g_{\lambda_j} \right) * \left(\sum_j a_j g_{\lambda_j} \right)^* \right) \ge 0.$$

Proof. After $t = \sqrt{\lambda}\, u$, $H(\lambda)$ is the average of $k(\sqrt{\lambda}\, u)$ against $\pi^{-1/2} e^{-u^2}\, du$. Strict radial decrease of k gives strict decrease of H. Logarithmic growth supplies an integrable majorant on compact parameter intervals and near zero. Monotone convergence applied to $k(0) - k(\sqrt{\lambda}\, u)$ gives divergence to infinity as $\lambda \to \infty$. This proves the threshold assertion.

If both $\lambda, \mu \le \lambda_c$, their harmonic mean $2\lambda\mu/(\lambda+\mu)$ is at most λ_c. Every cross pairing in (23.14) is therefore nonnegative. Expand the finite sum with coefficients $a_i a_j \ge 0$.

□

The polar and prime values on a Gaussian square are

$$P(g_\lambda * g_\lambda) = \frac{4\pi}{\lambda} e^{1/(4\lambda)},$$
$$W_{\mathrm{fin}}(g_\lambda * g_\lambda) = 2\sqrt{\frac{\pi}{\lambda}} \sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}} e^{-\lambda(\log n)^2/4}.$$

The sum converges for every positive λ. The full form subtracts both the prime and signed gamma terms from the polar term. Positivity of the gamma cone alone gives no sign for that complete expression.

The heat normalization

For $t > 0$, let

$$p_t(x) = \frac{1}{\sqrt{4\pi t}} e^{-x^2/(4t)}, \qquad h_{p_t}(z) = e^{-tz^2}.$$

The explicit formula becomes

$$\begin{aligned}\sum_\rho e^{-tz_\rho^2} = 2e^{t/4} - \frac{\log \pi}{\sqrt{4\pi t}} + \frac{1}{2\pi}\int_{\mathbb{R}} e^{-tu^2} \operatorname{Re} \psi_{\Gamma}\left(\tfrac{1}{4} + \tfrac{iu}{2}\right) du \\ - \frac{1}{\sqrt{\pi t}} \sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}} e^{-(\log n)^2/(4t)}.\end{aligned} \tag{23.16}$$

Each expression is ordinarily convergent.

On a compact interval of positive t, every parameter derivative has an integrable or summable majorant. For the prime sum, a Gaussian in $\log n$ dominates every inverse power of n. For the zero sum, $|e^{-tz_\rho^2}| \leq e^{t/4} e^{-t(\operatorname{Im}\rho)^2}$. The zero count proves its summability.

The difference between the two sides of (23.16) is zero by the explicit formula. Its vanishing is distinct from nonnegativity of q_W. The convolution law $p_s * p_t = p_{s+t}$ evaluates cross terms, but does not determine their sign.

Changing the Fourier scale

For the convention $\widehat{f}_{2\pi}(u) = \int f(x) e^{-2\pi i u x}\, dx$, define

$$(\mathcal{R}f)(x) = \frac{1}{2\pi} f\left(-\frac{x}{2\pi}\right).$$

A change of variables gives

$$h_{\mathcal{R}f} = \widehat{f}_{2\pi}, \qquad \mathcal{R}(f * g) = \mathcal{R}f * \mathcal{R}g, \qquad \mathcal{R}(f^*) = (\mathcal{R}f)^*.$$

If f has integrable derivatives weighted by $e^{b_0|x|}$ with $b_0 > \pi$, then $\mathcal{R}f \in \mathscr{A}_{b_0/(2\pi)}$. Thus the complete arithmetic functional in this convention is

$$W_{2\pi}(f) = W(\mathcal{R}f).$$

Its prime term is

$$-\frac{1}{2\pi} \sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}} \left(f\left(\frac{\log n}{2\pi}\right) + f\left(-\frac{\log n}{2\pi}\right)\right),$$

and its gamma integral is $(2\pi)^{-1}\int \widehat{f_{2\pi}}(u)a(u)\,du$. Both the sampling points and the measure factor change.

For $f_\ell(x)=e^{-\pi x^2/\ell}$, one has $\widehat{f}_{\ell,2\pi}(u)=\sqrt{\ell}e^{-\pi\ell u^2}$. Multiplying (23.16) at $t=\pi\ell$ by $\sqrt{\ell}$ gives

$$\sqrt{\ell}\sum_\rho e^{-\pi\ell z_\rho^2}=2\sqrt{\ell}e^{\pi\ell/4}-\frac{\log\pi}{2\pi}+\frac{\sqrt{\ell}}{2\pi}\int e^{-\pi\ell u^2}\operatorname{Re}\psi_\Gamma\!\left(\tfrac14+\tfrac{iu}{2}\right)du$$
$$-\frac{1}{\pi}\sum_{n\ge2}\frac{\Lambda(n)}{\sqrt{n}}e^{-(\log n)^2/(4\pi\ell)}.$$

This also fixes the constants in the two-scale Gaussian identity $f_\ell * f_m=\sqrt{\ell m/(\ell+m)}\,f_{\ell+m}$.

The auxiliary Gaussian cone

The auxiliary density b has its own Gaussian average. Put

$$I(L)=\int_{\mathbb{R}} e^{-2\pi u^2/L}b(u)\,du,\qquad m_L=\sqrt{L/2}.$$

Then

$$\frac{I(L)}{m_L}=2\log\pi-H\!\left(\frac{L}{2\pi}\right).\tag{23.17}$$

The normalized integral is strictly increasing and has a unique zero $L_b>0$. Its equation is $H(L_b/(2\pi))=2\log\pi$. This is a different level from $H(\lambda_c)=0$.

The individual integrals

$$J_n(L)=\int e^{-2\pi u^2/L}\frac{c_n}{c_n^2+u^2/4}\,du=2\pi e^{8\pi c_n^2/L}\operatorname{erfc}\!\left(2c_n\sqrt{2\pi/L}\right)$$

give the absolutely convergent paired series

$$I(L)=m_L(-\gamma_E+\log\pi)+\sum_{n\ge0}\left(\frac{m_L}{n+1}-J_n(L)\right).$$

Subtracting the value of the digamma series at zero improves its tail:

$$\frac{I(L)}{m_L}=b(0)+\sum_{n\ge0}\left(\frac{1}{c_n}-\frac{J_n(L)}{m_L}\right),\qquad 0\le\frac{1}{c_n}-\frac{J_n(L)}{m_L}\le\frac{L}{16\pi c_n^3}.$$

The tail starting at $n=N\ge1$ is at most $L/[32\pi(N-3/4)^2]$. These formulas follow from Theorem 23.8.1 with $\lambda=L/(2\pi)$. The difference $1/(n+1)-1/c_n$ is absolutely summable, which justifies regrouping.

The same real Gaussian integral also gives, for $\alpha,d>0$,

$$\int_{\mathbb{R}}\frac{e^{-\alpha u^2}}{d-iu}\,du=\pi e^{\alpha d^2}\operatorname{erfc}(d\sqrt{\alpha}).$$

Indeed, $(d-iu)^{-1}=(d+iu)/(d^2+u^2)$, and the imaginary part integrates to zero.

The small- and large-parameter limits are

$$\frac{I(L)}{m_L}=b(0)+\frac{L}{8\pi}b''(0)+O(L^2)\quad(L\downarrow0),\qquad \frac{I(L)}{m_L}=\frac12\log L+O(1)\quad(L\to\infty).$$

For the first, scale $u = \sqrt{L/(2\pi)}v$ and use the second moment $1/2$ of $\pi^{-1/2}e^{-v^2}\,dv$. Taylor expansion near zero and the Gaussian tail justify the remainder. For the second, use $b(u) = \log|u| + O(1)$ outside a bounded interval. After scaling, $\log|v|$ is Gaussian-integrable. The shrinking central interval contributes $O(L^{-1/2}\log L)$ after subtraction of $\frac{1}{2}\log L$.

To state the auxiliary cone in the 2π convention, define

$$G_{2\pi}(f,g) = \frac{1}{2\pi}\int \widehat{f}_{2\pi}(u)\overline{\widehat{g}_{2\pi}(u)}b(u)\,du, \qquad F_L(x) = e^{-\pi Lx^2}.$$

For $L, M > 0$, direct multiplication of their Fourier transforms gives

$$G_{2\pi}(F_L, F_M) = \frac{I(2LM/(L+M))}{2\pi\sqrt{LM}}. \tag{23.18}$$

PROPOSITION 23.8.3 *(The exact auxiliary cone).* The diagonal $G_{2\pi}(F_L, F_L)$ is nonnegative exactly for $L \geq L_b$, and vanishes exactly at $L = L_b$. For a finite sum $f = \sum_j a_j F_{L_j}$ with $a_j \geq 0$ and $L_j \geq L_b$, one has $G_{2\pi}(f,f) \geq 0$. A nonzero such sum has zero value precisely when every active parameter equals L_b. Nonnegativity also holds on the Schwartz closure of this cone.

Proof. The diagonal formula is $I(L)/(2\pi L)$. Its sign follows from (23.17). For $L, M \geq L_b$, their harmonic mean is at least L_b, so every cross term in (23.18) is nonnegative. Expand the finite sum.

An active parameter strictly above L_b has a strictly positive diagonal term. If all active parameters equal L_b, every term vanishes. Schwartz continuity proves the closure assertion. □

For example, take $L_b/2 < L < L_b$ and $M > L_bL/(2L - L_b)$. Then $M > L_b$ and $2LM/(L + M) > L_b$, but $I(L) < 0$. The value of $G_{2\pi}(F_L + \varepsilon F_M, F_L + \varepsilon F_M)$ remains negative for sufficiently small $\varepsilon > 0$. This lies outside the stated cone.

Neither Gaussian cone is a complex vector space. Its nonzero elements are positive on all of $\mathbb{R}$, and hence are not compactly supported. The span of centered Gaussians lies in the closed even Schwartz subspace, so it is not dense in the full Schwartz space. These facts do not prevent their use in $\mathscr{A}_\infty$. They specify which density and positivity claims are available.

For clarity, the two Fourier normalizations obey

$$\frac{1}{2\pi}\int \widehat{f}_{2\pi}(u)\overline{\widehat{g}_{2\pi}(u)}k(u)\,du = \frac{\log\pi}{\pi}\langle f, g\rangle_{L^2} - G_{2\pi}(f,g),$$
$$W_\infty(f * g^*) = \int \widehat{f}_{2\pi}(u)\overline{\widehat{g}_{2\pi}(u)}k(2\pi u)\,du.$$

The second identity follows from $h_f(2\pi u) = \widehat{f}_{2\pi}(-u)$. A change of convention rescales the kernel argument as well as the measure.

23.9 THE COMPLETE POSITIVITY CRITERION

The signs of the individual arithmetic terms do not decide the sign of their sum. The spectral formula does decide it once every zero lies on the critical line. The converse requires a test detecting a nonreal ordinate while controlling every other zero.

Let Σ be the set of distinct ordinates $z_\rho = -i(\rho - 1/2)$, and let m_z be their multiplicities. The functional equation and conjugation make Σ invariant under $z \mapsto -z$ and $z \mapsto \bar{z}$, preserving multiplicity. It lies in $|\operatorname{Im} z| \le 1/2$ and is locally finite. Equation (23.9) becomes

$$q_W(f,g) = \sum_{z\in\Sigma} m_z h_f(z)\overline{h_g(\bar{z})}. \tag{23.19}$$

This absolutely convergent formula holds on every exponential test step.

An individual nonreal pair has an indefinite two-dimensional form. Polynomial interpolation and a Gaussian control the other coordinates.

Theorem 23.9.1 *(A negative test from an off-line zero).* Suppose $z_0 = \gamma_0 + i\eta_0 \in \Sigma$, with $\eta_0 \neq 0$. Then a polynomial times a modulated Gaussian belongs to $\mathscr{A}_\infty$ and has negative Weil diagonal. There is also a compact smooth test with negative Weil diagonal.

Proof. Choose $R > 1$, and let Z_R consist of the distinct points of Σ with $|\operatorname{Re} z - \gamma_0| \le R$. It is finite and conjugation invariant. The polynomial

$$P_R(z) = \prod_{w\in Z_R\setminus\{z_0\}} \frac{z-w}{z_0-w} - \prod_{w\in Z_R\setminus\{\bar{z}_0\}} \frac{z-w}{\bar{z}_0-w}$$

takes the values $1, -1$ at $z_0, \bar{z}_0$, respectively, and vanishes on the other points of Z_R. For $\tau \ge 1$, put

$$H_\tau(z) = P_R(z)e^{-\tau((z-\gamma_0)^2+\eta_0^2)},$$
$$f_\tau(x) = e^{-\tau\eta_0^2} P_R(i\partial_x)\frac{e^{-x^2/(4\tau)-i\gamma_0 x}}{\sqrt{4\pi\tau}}.$$

Fourier differentiation gives $h_{f_\tau} = H_\tau$.

Every derivative of f_τ has Gaussian decay. Its two selected transform values remain $1, -1$, so their contribution to the diagonal is $-2m_{z_0}$.

For $z = \gamma + i\eta \notin Z_R$, define

$$d(z) = (\gamma-\gamma_0)^2 - \eta^2 + \eta_0^2, \qquad c = R^2 - \tfrac{1}{4} + \eta_0^2 > 0.$$

The strip bound gives $d(z) \ge c$. The absolute value of the remaining contribution is at most

$$e^{-2(\tau-1)c} \sum_{z\notin Z_R} m_z |P_R(z)P_R(\bar{z})| e^{-2d(z)}. \tag{23.20}$$

The sum is finite.

Indeed, the polynomial has polynomial growth on the fixed strip, the zero count is $O(T\log(2+T))$, and the Gaussian controls the resulting sum over unit intervals. Choose τ large enough that (23.20) is less than m_{z_0}. Then $q_W(f_\tau, f_\tau) < -m_{z_0}$.

Fix this test and multiply it by compact smooth cutoffs tending to one. The products converge in each $\mathscr{A}_{a_0}$. The continuity in Theorem 23.5.2 preserves strict negativity for all sufficiently large cutoffs. □

Theorem 23.9.2 *(Weil positivity on its full domain).* The following assertions are equivalent:

(i) Every zero of ξ has real part $1/2$.

(ii) $q_W(f,f) \ge 0$ for every $f \in \mathscr{A}_c$.

(iii) $q_W(f,f) \geq 0$ for every $f \in \mathscr{A}_{\exp}$.

(iv) For some fixed $a_0 > 1/2$, a subset dense in $\mathscr{A}_{a_0}$ has nonnegative Weil diagonal.

The second assertion is the complete arithmetic inequality

$$W_\infty(f * f^*) \leq P(f * f^*) - W_{\mathrm{fin}}(f * f^*) \qquad (f \in \mathscr{A}_c).$$

Proof. If all ordinates are real, (23.19) is a sum of absolute squares on every exponential step. This implies the third assertion and hence the second and fourth. Continuity extends the fourth assertion to its whole step, which contains all compact smooth tests. Theorem 23.9.1 shows that the second assertion excludes every nonreal ordinate. Finally, the arithmetic definition of W gives the displayed inequality. □

PROPOSITION 23.9.3 *(Hilbert realization of a positive restriction).* Let $D \subset \mathscr{A}_{\exp}$ be a complex vector subspace on which q_W is positive semidefinite. Its nullspace $N_D = \{f \in D : q_W(f,f) = 0\}$ is a linear subspace. The completion of D/N_D is a Hilbert space H_D, and the canonical linear map $I_D : D \to H_D$ satisfies

$$\langle I_D f, I_D g \rangle = q_W(f,g).$$

Conversely, any such map to a positive Hilbert space implies positivity on D. In particular, existence of this realization on the full compact test algebra is equivalent to the Riemann hypothesis.

Proof. Positivity of $q_W(f + tg, f + tg)$ for complex t gives Cauchy–Schwarz. A null vector therefore pairs to zero with every vector. This proves that the quotient form is well-defined and positive definite. Its metric completion has the asserted property. The converse follows by taking the diagonal, and the last assertion uses Theorem 23.9.2. □

This quotient construction starts from the Weil form. It supplies no independent arithmetic reason for its positivity. An arithmetic Hilbert space, constructed by a different method, must still be connected to it by the displayed pairing identity on the stated domain.

The compact domain also distinguishes this criterion from rational tests used in Li's criterion. For an integer $n \geq 1$,

$$1 - (1 - 1/s)^n = \frac{n}{s} + O(s^{-2}) \qquad (|s| \to \infty).$$

After $s = 1/2 + iz$, this is neither entire nor rapidly decreasing on horizontal strips. It is not h_f for a compact smooth test. A formula involving these rational tests needs its own limiting prescription. It is not obtained by substituting them into the compact explicit formula without a convergence argument.

23.10 MOMENT EQUATIONS AND THE TOPOLOGY OF APPROXIMATION

A proposed arithmetic comparison may first be defined on tests satisfying moment equations. Their closed kernel can often be approximated exactly, but this does not make it dense in the full domain. We give the projection and determine its closure in two different topologies.

For a compact test put

$$M_f(s) = \int_{\mathbb{R}} f(x) e^{sx}\, dx = h_f(-is).$$

On the real even compact tests, define

$$\ell(f) = \left(\int f(x)\, dx,\ \int f(x) \cosh x\, dx,\ \int f(x) x \sinh x\, dx \right), \qquad K = \ker \ell.$$

Thus K imposes $M_f(0) = M_f(1) = M_f'(1) = 0$. Evenness already gives $M_f'(0) = 0$. These are the double-zero equations at 0, 1 for an even transform.

All three functionals are continuous on $\mathscr{A}_\infty$. They are also continuous on each $\mathscr{A}_{a_0}$ with $a_0 > 1$.

Proposition 23.10.1 *(A continuous moment projection).* There are real even compact tests η_0, η_1, η_2 with $\ell_i(\eta_j) = \delta_{ij}$. Hence

$$\Pi f = f - \sum_{j=0}^{2} \ell_j(f)\eta_j$$

is a continuous projection onto the moment kernel. That kernel is closed of codimension three, both on compact tests and on each of the exponential spaces just specified. For any $A > 0$, the η_j may all be chosen with support in $[-A, A]$.

Proof. Write $w(x) = (1, \cosh x, x \sinh x)$. The matrix with columns $w(0), w(1), w(2)$ has determinant

$$2\sinh(1)(\cosh(1) - 1)^2 > 0.$$

Even mollified point masses at 0, ± 1, ± 2, with total mass one at each pair, give a moment matrix converging to this matrix. For small mollifier support, its inverse supplies the η_j. Continuity of the three moments then proves the projection and codimension assertions.

To prescribe the support, choose a smooth even $\chi \geq 0$, supported in $[-A, A]$ and positive on $(-A, A)$. The Gram matrix

$$G_{ij} = \int \chi(x) w_i(x) w_j(x)\, dx$$

is positive definite. A nonzero linear combination of the three analytic functions cannot vanish on an interval. Analytic continuation and their distinct constant, exponential and linear-exponential growth show their independence. Set $\eta_j = \chi \sum_i (G^{-1})_{ij} w_i$. These tests have the required moments and support. □

If $f_j \to f \in K$ in the compact-test topology, then $\Pi f_j \to f$. In an exponential space, even compact cutoffs followed by Π prove that compact members of the kernel are dense in that kernel. A nonnegative bump has nonzero mean, so the kernel is not dense in the ambient compact-test space. A moment correction converges to zero only when the limiting function already has the required moments.

Proposition 23.10.2 *(The finite moment quotient).* On the complex even compact convolution algebra the map

$$f \longmapsto \big(M_f(0), M_f(1) + M_f'(1)\varepsilon\big), \qquad \varepsilon^2 = 0,$$

is a continuous surjective algebra homomorphism onto $\mathbb{C} \times \mathbb{C}[\varepsilon]/(\varepsilon^2)$. Its kernel is the complexification of K, and its involution is coefficient conjugation with $\varepsilon^* = \varepsilon$. A complex-linear functional on this quotient is positive on squares exactly when it has the form

$$\lambda(a, b + c\varepsilon) = \alpha a + \beta b, \qquad \alpha, \beta \geq 0.$$

Proof. Fubini gives $M_{f*g} = M_f M_g$. Evaluation at zero and the product rule at one give the algebra law. The moment right inverse proves surjectivity. Evenness makes the involution conjugation at these real evaluation points.

Write $\lambda(a, b + c\varepsilon) = \alpha a + \beta b + \gamma c$. Positivity on the unital quotient makes λ Hermitian, by expanding squares of $1 + tx$ and $1 + itx$ for real t. Thus its coefficients are real. Its value at the square of $(a, b + c\varepsilon)$ is

$$\alpha|a|^2 + \beta|b|^2 + 2\gamma \operatorname{Re}(b\bar{c}).$$

Taking $b = 1$ and varying c forces $\gamma = 0$. The two remaining coefficients must be nonnegative, which also suffices. □

This quotient describes the imposed moments. It does not assert that W factors through the quotient. The polar evaluations occur at $\pm 1/2$, not at $0, 1$. For a nonzero nonnegative even compact test v, the function

$$f = D^2(D^2 - 1)^2 v, \qquad D = d/dx,$$

lies in K, whereas

$$M_f(1/2) = \frac{9}{64} M_v(1/2) > 0, \qquad P(f * f^*) = 2M_f(1/2)^2 > 0.$$

Integration by parts gives $M_f(s) = s^2(s^2 - 1)^2 M_v(s)$, proving every assertion.

THEOREM 23.10.3 *(The weaker Schwartz closure).* The closure of K in the real even Schwartz space is

$$\left\{ f \in \mathcal{S}(\mathbb{R}) : f \text{ is real and even, } \int f = 0 \right\}.$$

In the relative Schwartz topology on compact tests, intersect this set with $\mathscr{A}_c$. The two exponential moment equations need not survive a limit in this weaker topology.

Proof. The mean is Schwartz-continuous, so it vanishes on every such limit. Choose a nonnegative even compact test β with $\int \beta = 1$, and put

$$A = \int \beta(x) \cosh x \, dx > 0, \qquad B = \int \beta(x) x \sinh x \, dx.$$

For $R > 0$, set

$$\beta_R(x) = \tfrac{1}{2}[\beta(x - R) + \beta(x + R)], \qquad v_R = \beta_R - \beta.$$

Translation gives

$$\ell(v_R) = \big(0, A(\cosh R - 1), B(\cosh R - 1) + AR \sinh R\big).$$

The determinant of the last two coordinates of v_R, v_{2R} is

$$2A^2 R \sinh R (\cosh R - 1)^2 > 0.$$

Thus a fixed pair of these moments can be prescribed by $c_R v_R + d_R v_{2R}$, where $c_R = O(e^{-R})$ and $d_R = O(e^{-2R})$. Every Schwartz seminorm of v_R grows at most polynomially in R. The correction therefore tends to zero in the Schwartz topology.

For a compact real even mean-zero f, prescribe the negatives of its last two moments. Adding the correction gives elements of K converging to f. General real even mean-zero Schwartz functions are approximated by even compact cutoffs with their means subtracted times β. For the nth approximation, choose R so large that the correcting term has its first n Schwartz seminorms below $1/n$. This diagonal choice proves the asserted closure. □

The complete Weil form is continuous in the compact and exponential topologies used above. The critical prime measure is not tempered by Theorem 23.2.2. Consequently, the weaker Schwartz closure does not itself pass the complete Weil inequality to its limits.

Proposition 23.10.4 *(The missing cross inequalities).* Let a complex vector space decompose as $D = K_0 \oplus E$, and let q be a Hermitian form, linear in its first argument. It is positive semidefinite on D exactly when

$$q(u,u) \ge 0, \qquad q(e,e) \ge 0, \qquad |q(u,e)|^2 \le q(u,u)q(e,e) \quad (u \in K_0,\ e \in E).$$

Proof. Necessity is Cauchy–Schwarz. Conversely, the three conditions give

$$q(u+e,u+e) \ge \bigl(\sqrt{q(u,u)} - \sqrt{q(e,e)}\bigr)^2 \ge 0.$$

Every vector has this form. □

The complex moment kernel has a three-dimensional complement among even tests. Its positivity leaves both that complement and all cross terms to determine. Odd tests remain an additional part of the full domain. The exact polar kernel has a two-dimensional complement on the full space. Finite codimension alone supplies none of these inequalities.

Similarly, if maps $I_\alpha : D_\alpha \to H_\alpha$ to positive Hilbert spaces satisfy $q_W(f,g) = \langle I_\alpha f, I_\alpha g\rangle$ on their respective complex domains, their union has nonnegative diagonal. Its closure in a fixed exponential step has the same property. Their linear span requires the cross terms between different domains. The Hermitian matrix $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$ is positive on each coordinate axis and negative on $(1,-1)$. Thus separate positive diagonal identities do not suffice for the span.

23.11 The maximal positive convolution ideal

Convolution stability gives a stronger classification than positivity on a subspace. A positive ideal must vanish at every nonreal ordinate. To prove this assertion, we first construct tests with exactly prescribed values on a finite part of the zero set.

Lemma 23.11.1 *(A paired product and its Fourier inverse).* The product

$$\mathcal{P}(z) = \prod_{\substack{\omega \in \Sigma \\ \operatorname{Re}\omega > 0}} (1 - z^2/\omega^2)^{m_\omega}$$

converges locally uniformly to an entire function with precisely the zeros Σ and their multiplicities. It is real on the real axis and satisfies

$$|\mathcal{P}(z)| \le \exp\bigl(C(1+|z|)\log(2+|z|)\bigr).$$

For a finite $E \subset \Sigma$, division by $\prod_{\omega\in E}(z-\omega)^{m_\omega}$ gives an entire function R_E, nonzero at each point of E, with the same type of bound. For $t > 0$ and any polynomial p, $e^{-tz^2} R_E(z)\,p(z)$ is the Fourier transform of a member of $\mathscr{A}_\infty$.

Proof. There are no ordinates on the imaginary axis. Pairing ω and $-\omega$ therefore accounts for all zeros. Inverse-square summability proves normal convergence of the quadratic factors. Conjugation permutes these factors and proves reality on the real axis.

Let $n(u)$ count the factors by modulus with multiplicity, and choose $u_0 > 0$ below the modulus of every zero. For $R \geq 2$,

$$\log \max_{|z| \leq R} |\mathcal{P}(z)| \leq \int_{u_0}^{\infty} \log(1 + R^2/u^2)\, dn(u)$$
$$= 2R^2 \int_{u_0}^{\infty} \frac{n(u)}{u(u^2 + R^2)}\, du.$$

Split at R and use $n(u) = O(u \log(2 + u))$. Both integrals are $O(R \log R)$.

Removing the full order of each selected zero leaves a nonzero value there. Outside a fixed disk the dividing polynomial has a polynomial lower bound. Inside that disk the entire quotient is bounded.

Put $H(z) = e^{-tz^2} R_E(z)\, p(z)$. On each horizontal strip, the negative quadratic in $\operatorname{Re} z$ dominates the other factors. Cauchy's estimates on a slightly larger strip give rapid decay of all derivatives. Define

$$f(x) = \frac{1}{2\pi} \int_{\mathbb{R}} H(r) e^{-irx}\, dr.$$

For $x > 0$ shift to $\operatorname{Im} z = -b$, and for $x < 0$ to $\operatorname{Im} z = b$. The vertical integrals tend to zero.

The same shift applied to $z^j H(z)$ gives $|f^{(j)}(x)| \leq C_{b,j} e^{-b|x|}$. Since b is arbitrary, $f \in \mathscr{A}_\infty$. Fourier inversion and holomorphic continuation give $h_f = H$. □

THEOREM 23.11.2 *(Exact finite-value isolation).* For a finite $E \subset \Sigma$ and prescribed complex numbers v_ω, there is $f \in \mathscr{A}_\infty$ such that $h_f(\omega) = v_\omega$ on E and $h_f = 0$ on $\Sigma \setminus E$.

Proof. For any $t > 0$, take the inverse Fourier transform of

$$e^{-tz^2} R_E(z) \sum_{\omega \in E} \frac{v_\omega e^{t\omega^2}}{R_E(\omega)} \prod_{\substack{\eta \in E \\ \eta \neq \omega}} \frac{z - \eta}{\omega - \eta}.$$

All denominators are nonzero. The polynomial interpolates the required values after division by the nonvanishing prefactor, and R_E retains every other zero. Lemma 23.11.1 supplies the required inverse transform. □

Full multiplicities are removed in R_E, although the prescription specifies only values. Removing one linear factor at a multiple zero would leave the prefactor zero there. Exact isolation here uses rapid exponential decay. Compact cutoffs preserve a strict inequality, but need not preserve these exact spectral values.

Write $\Sigma_0 = \Sigma \cap \mathbb{R}$ and $\Sigma_{\mathrm{nr}} = \Sigma \setminus \mathbb{R}$. A positive convolution $*$-ideal means a complex algebraic ideal $J \subset \mathscr{A}_{\exp}$, stable under $*$, with $q_W(f, f) \geq 0$ for every $f \in J$. Define

$$\mathcal{I}_{\mathrm{nr}} = \{f \in \mathscr{A}_{\exp} : h_f(z) = 0 \text{ for every } z \in \Sigma_{\mathrm{nr}}\}.$$

THEOREM 23.11.3 *(The largest positive ideal).* The ideal $\mathcal{I}_{\mathrm{nr}}$ is the largest positive convolution $*$-ideal of $\mathscr{A}_{\exp}$. It is closed in the final test topology and in every exponential step. On this ideal,

$$W(f) = \sum_{\gamma \in \Sigma_0} m_\gamma h_f(\gamma), \qquad q_W(f, g) = \sum_{\gamma \in \Sigma_0} m_\gamma h_f(\gamma) \overline{h_g(\gamma)}. \tag{23.21}$$

If a $*$-ideal contains f with $h_f(z_0) \neq 0$ at a nonreal ordinate, it contains r with $q_W(r, r) = -2m_{z_0}$.

Proof. Each evaluation at a point of Σ is continuous on every step, hence on the final topology. Fourier multiplication and conjugation show that the intersection of the indicated kernels is a closed $*$-ideal. The explicit formula gives (23.21) and its positivity.

For maximality put $u = h_f(z_0) \neq 0$. Exact isolation supplies $e_{z_0}, e_{\bar{z}_0}$ whose transforms on Σ are the respective coordinate vectors. In the given ideal form

$$r = u^{-1} f * e_{z_0} - \bar{u}^{-1} f^* * e_{\bar{z}_0}.$$

Its only nonzero transform values are 1 at z_0 and -1 at $\bar{z}_0$, since $h_{f^*}(\bar{z}_0) = \bar{u}$. Their equal multiplicities give the asserted negative value. Every positive ideal must therefore lie in $\mathcal{I}_{\mathrm{nr}}$. □

This theorem classifies positive ideals. A positive subspace need not contain the two convolution products used in its proof, so it need not lie in $\mathcal{I}_{\mathrm{nr}}$. The theorem neither asserts nor excludes the existence of a nonreal zero.

The regular completions lose the distinction between this ideal and the whole test algebra. To see this, form the off-real subproduct

$$B_{\mathrm{nr}}(z) = \prod_{\substack{\omega \in \Sigma \\ \operatorname{Re}\omega > 0,\ \operatorname{Im}\omega > 0}} \left[(1 - z^2/\omega^2)(1 - z^2/\bar{\omega}^2) \right]^{m_\omega}.$$

The empty product equals one. The preceding product estimate applies.

Its zeros are precisely the nonreal ordinates with their multiplicities, and for real r,

$$B_{\mathrm{nr}}(r) = \prod_{\substack{\operatorname{Re}\omega > 0 \\ \operatorname{Im}\omega > 0}} |1 - r^2/\omega^2|^{2m_\omega} > 0.$$

For fixed $t > 0$, let $b_t \in \mathscr{A}_\infty$ have transform $\beta_t(z) = e^{-tz^2} B_{\mathrm{nr}}(z)$, and put $\mathcal{D}_t = b_t * \mathscr{A}_{\exp}$. This is a principal ideal in an algebra without a unit.

Theorem 23.11.4 *(Density in the regular completions).* The ideal $\mathcal{D}_t$ is a positive convolution $*$-ideal contained in $\mathcal{I}_{\mathrm{nr}}$. Its Fourier image is dense in $\mathcal{S}(\mathbb{R})$. Consequently,

$$\overline{\mathcal{D}_t}^{L^1} = L^1(\mathbb{R}), \qquad \overline{\mathcal{D}_t}^{L^2} = L^2(\mathbb{R}), \qquad \overline{h(\mathcal{D}_t)}^{\|\cdot\|_\infty} = C_0(\mathbb{R}).$$

The same three closures hold for $\mathcal{I}_{\mathrm{nr}}$. If a nonreal ordinate exists, $\mathcal{I}_{\mathrm{nr}}$ is nevertheless proper and closed in the test topology.

Proof. The function β_t is real on the real axis, so $b_t^* = b_t$. Commutativity makes $\mathcal{D}_t$ a $*$-ideal. Its Fourier factor vanishes on every nonreal ordinate, proving inclusion and positivity.

Take $H \in C_c^\infty(\mathbb{R})$ in the Fourier variable, and put $u = H/\beta_t$. Strict positivity of β_t on the real axis makes u smooth and compactly supported. Define

$$\varphi_\epsilon(r) = (4\pi\epsilon)^{-1/2} e^{-r^2/(4\epsilon)}, \qquad u_\epsilon = u * \varphi_\epsilon, \qquad H_\epsilon = \beta_t u_\epsilon.$$

Convolution here is in the Fourier variable. Its inverse transform is $\check{u}_\epsilon(x) = e^{-\epsilon x^2} \check{u}(x)$, which belongs to $\mathscr{A}_\infty$. Thus $H_\epsilon \in h(\mathcal{D}_t)$.

Gaussian convolution converges to the identity in the Schwartz topology. This follows from translation continuity near zero and the polynomially weighted Gaussian tail outside a fixed neighborhood.

Multiplication by the fixed Schwartz function β_t is continuous, so $H_\epsilon \to H$ in that topology. Smooth cutoffs make compact smooth functions dense in Schwartz space. Fourier inversion and its continuous dense inclusions into L^1, L^2 and C_0 give the three closures.

If z_0 is nonreal, the continuous evaluation $h_f(z_0)$ vanishes on $\mathcal{I}_{\mathrm{nr}}$ but not on a Gaussian. This proves properness in the test topology. □

Neither ideal has an internal unit. Such a unit would act identically on a uniformly dense Fourier subalgebra of $C_0(\mathbb{R})$. Its transform would then equal one on all of $\mathbb{R}$. Nor is test-topology density of $\mathcal{D}_t$ in $\mathcal{I}_{\mathrm{nr}}$ asserted. The generator vanishes to full analytic multiplicity, while the latter ideal requires only value vanishing.

These ideals depend on the zero set. Their unconditional construction does not supply an arithmetic positive domain independently of that set. More decisively, density in any one exponential test step would imply full positivity by Theorem 23.9.2. The regular density theorem therefore proves a different assertion.

23.12 The independent arithmetic comparison

The analytic target is now fixed: the convolution algebra, its topology, its involution, and the complete signed functional. An arithmetic source may approach this target through a trace, a cohomological pairing, an automorphic norm or a boundary construction. Each approach must specify its map on the same tests.

Question 23.12.1 *(A full arithmetic realization).* Construct an arithmetic complex vector space V, a Hermitian pairing B, and a complex-linear map $I : \mathscr{A}_c \to V$, such that

$$B(If, Ig) = P(f * g^*) - W_\infty(f * g^*) - W_{\mathrm{fin}}(f * g^*) \qquad (f, g \in \mathscr{A}_c). \tag{23.22}$$

Determine whether B is positive semidefinite on $I(\mathscr{A}_c)$ by the arithmetic construction. For an exponential extension, construct the continuous map and prove the same identity on a specified step.

An operator or weight realization needs an actual convolution representation on a common domain that preserves the involution. Its trace or weight must be finite on the tested products. A comparison with a bilinear categorical pairing also needs the conjugate coefficient factor that turns it into a Hermitian form. Local determinants, a scalar functional equation and matching characters do not specify these maps.

A geometric realization asks for a continuous $*$-algebra map into a proper positive trace ideal constructed from independent arithmetic operations. The comparison must preserve the involution, normal derivatives, collision maps and both vacuum data of its source. Arithmetic-weight and arity-radius continuity are additional requirements. The resulting counting weight or self-adjoint shift must be identified with a native arithmetic operation. Positivity of the scalar Weil form alone does not construct this stronger realization.

Partial domains retain their exact positive content. A norm identity on a moment kernel proves positivity on that kernel. A Gaussian cone gives its tested inequalities. A positive ideal has the classification above. To reach the full criterion, one must also prove the missing cross inequalities and density in a topology controlling every term of (23.22). Both polar evaluations, all prime powers and the signed gamma integral remain part of that equality.

Part II

The Arithmetic Realization Branch

Chapter 24

The Arithmetic Realization Branch

24.1 Identity

The arithmetic branch of Volume IV carries the extension of the chiral-bar-cobar programme from smooth complex curves $C/\mathbb{C}$ to the Arakelov-compactified arithmetic curve $\overline{C} = \overline{\mathrm{Spec}\,\mathbb{Z}}$. Its object of study is the Hochschild trace class of the identity on the global arithmetic Iwahori Hecke category,

$$\mathcal{V}^{\mathrm{prim}} \;:=\; \mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\,\mathrm{glob}}\big),$$

studied through five conditional technical windows: (i) a classical Kim arithmetic Chern–Simons torsor/line (arXiv:1510.05818) whose possible boundary factorization shadow is a comparison problem for $\mathcal{V}^{\mathrm{prim}}$; (ii) an automorphic/spectral window controlled by a Selmer-derived global deformation stack with fixed residual representation, determinant, and local conditions; (iii) a Bethe-algebra heuristic in which primes are lattice sites and Hecke operators are transfer matrices, with the RTT/Yangian Hopf structure absent at the arithmetic level; (iv) a Heisenberg enhancement of the Bost–Connes quantum statistical system; and (v) a factorization algebra on the archimedean place $\mathbb{C}_\infty$ valued in $\widehat{\mathbb{Z}}$-modules with commuting Adams operations ψ_p. Each window is a comparison problem for $\mathcal{V}^{\mathrm{prim}}$; their mutual equivalence is the conditional content of the Hochschild-trace layer.

This branch states the five theorems A–D+H in their arithmetic avatar and isolates three precise open conjectures whose resolution closes the cross-Langlands loop. The arithmetic avatars A^{arith}–D^{arith}, H^{arith}, and $F1$–$F3$ form the realization diagram over $\overline{\mathrm{Spec}\,\mathbb{Z}}$. Agreement over both $C/\mathbb{C}$ and $\overline{\mathrm{Spec}\,\mathbb{Z}}$ is a structural assertion, not a metaphor.

24.2 Form Discipline

Every claim in the arithmetic branch carries one of five tags.

Theorem. A claim stated with a proof body. In the arithmetic branch this is reserved for statements whose proof transports from the complex case with no new input beyond replacement of $C/\mathbb{C}$ by the archimedean fibre of $\overline{C}$.

Conditional. A claim with a complete strategy of proof and all ingredients in the primary literature, whose full write-up requires a substantial treatment.

Conjecture. A claim plausible on the strength of multiple cross-consistency checks but without a complete proof strategy.

Heuristic. A pattern match between classical and arithmetic structures with no derivation. Heuristic claims are essential only as guidance, never as premises.

Obstruction. A failed candidate whose failure is a theorem: the obstruction is a named computation, missing structure, or non-vanishing class.

Only theorem, conditional theorem, conjecture, heuristic, and obstruction enter the stable language of the branch. A failed candidate remains in the text only after its failure has been made mathematical.

24.3 Local-to-Global Form

The branch has three layers: local obstruction theory, the Hochschild-trace construction of $\mathcal{V}^{\mathrm{prim}}$, and the three conjectural comparison maps completing the cross-Langlands loop.

Local obstruction theory

Chapter 25 isolates the finite Heisenberg cover $\mathcal{H}^{\mathrm{cov}}_{\mathbb{P}} = \otimes^{!}_{p}\, \mathcal{H}^{(p)}$ from the Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$. The next five chapters compare this cover with independent source families (Drinfeld+Kapranov, Kazhdan+Beilinson, Gelfand+Borger, Connes+Soibelman, Costello+Gwilliam). Each comparison gives one obstruction and one surviving structural core:

(i) The arithmetic curve is Arakelov-compactified $\overline{\mathrm{Spec}\,\mathbb{Z}}$, not $\mathrm{Spec}\,\mathbb{Z}$.

(ii) Formal Heisenberg fields exist on an auxiliary line over $\mathbb{Q}_p$ (Chapter 26). The arithmetic finite-place coefficients require a separate comparison with those field operations.

(iii) The Steinberg relation $\{p, 1-p\} = 0$ holds in $K_2^M(\mathbb{Q})$. Comparing its residue complex with chiral collision operations requires maps preserving those operations (Chapter 33).

(iv) The Hecke-Adams lift is GL_1 Adams, not GL_2 Hecke; the GL_2 structure lives in the rank-2 Heisenberg via the Satake eigenvalue pair (α_p, β_p) with $\alpha_p\beta_p = p$.

(v) The correct local model is the Iwahori-equivariant affine Hecke category, not the spherical Mirković–Vilonen category; spherical collapses the OPE.

Hochschild trace synthesis

The central theorem of the branch places $\mathcal{V}^{\mathrm{prim}}$ as the Hochschild trace class of the identity endofunctor on the global affine Iwahori Hecke category (Chapter 38). Under this placement, ten classical positions receive arithmetic analogues: Segal sewing is occupied by Euler-product factorization (Chapter 32); the Verlinde scalar becomes the class-number residue; the mapping-class position is occupied by Galois labels and Hecke symmetries; the modular S-matrix position is occupied by the Γ-factor plus functional equation; the conformal-block position is occupied by Tate integral lines.

Chapter 43 isolates the essential mathematical content of the branch: the arithmetic G-row complementarity

$$\kappa^{\mathrm{Ar}}_{\mathsf{G}} + \left(\kappa^{!}\right)^{\mathrm{Ar}}_{\mathsf{G}} \;=\; 0 \quad\Longleftrightarrow\quad \xi(s) \;=\; \xi(1-s),$$

under the arithmetic realization hypotheses of Theorem 43.5.1. These include an actual central-defect identity and a Mellin evaluation detecting that defect. Poisson summation proves the scalar functional equation. Constructing those maps from arithmetic duality remains a separate problem.

Comparison conjectures

Chapter 42 isolates the three conjectures whose proof closes the cross-Langlands loop:

(i) Global arithmetic Arinkin–Gaitsgory equivalence, linking $\mathrm{D}([GL_2])^{\text{sph-fin}}$ to $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on the Selmer-derived global spectral stack attached to a fixed $(\bar{\rho}, \det, \mathcal{L})$.

(ii) E_2-enhancement of the global Iwahori Hecke category via Scholze diamonds, supplying Dunn additivity for the trace.

(iii) Arithmetic Ben-Zvi–Nadler identification of $\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\,\mathrm{glob}})$ with $\mathcal{V}^{\mathrm{prim}}$ as an E_1-algebra over the full $\mathrm{Weil}/(\varphi, \Gamma)$ target, with $B\widehat{\mathbb{Z}}$ retained only as an inertia shadow.

These three conjectures link Kim's classical 3D-CS input (arXiv:1510.05818), Bezrukavnikov–Bernstein's Hochschild presentation, and Beilinson's bar–cobar presentation. $\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class. Realizing it by fields requires coefficient and operation comparisons. The complex Heisenberg model at infinity and formal finite-place models provide candidates (Chapter 26).

24.4 Realization over $\overline{\mathrm{Spec}\,\mathbb{Z}}$

The arithmetic branch puts the same bar–cobar spine, Koszul complementarity, and obstruction tower on the Arakelov curve $\overline{\mathrm{Spec}\,\mathbb{Z}}$. If the complex and arithmetic bases carry the same identities after source-disjoint comparison, the invariant belongs to one-dimensional factorization itself, not to the analytic model in which it was first seen.

The Beilinson principle is the governing rule: a statement enters the realized corpus only after an independent comparison has separated its proof source from its verification source.

24.5 Source Decomposition

Fifteen primary-source families meet the arithmetic trace construction at distinct structural joints: Drinfeld+Kapranov, Kazhdan+Beilinson, Gelfand+Borger, Connes+Soibelman, Costello+Gwilliam, Etingof, Nekrasov, Segal, Beilinson–solo, Witten, Polyakov, Gaiotto, Bezrukavnikov+Bernstein, Kontsevich+Soibelman, and Drinfeld–solo. Their common remnant is a single mathematical object viewed through five windows, together with the three comparison conjectures above.

24.6 Conventions

Base. $\overline{C} = \overline{\mathrm{Spec}\,\mathbb{Z}}$ denotes the Arakelov compactification: closed points are rational primes $p \in \mathbb{P}$ plus the archimedean place ∞. Local rings: $\mathbb{Z}_p$ at p (uniformizer p, residue $\mathbb{F}_p$, Frobenius $x \mapsto x^p$); $\mathbb{R}$ at ∞ (with complex conjugation on $\mathbb{C}$).

Iwasawa. $\Lambda = \mathbb{Z}_p[[\Gamma]]$, where $\Gamma \cong \mathbb{Z}_p$ is the Galois group of a chosen cyclotomic $\mathbb{Z}_p$-extension. The full cyclotomic Galois group may also have a finite factor.

Adeles. $\mathbb{A}_{\mathbb{Q}} = \mathbb{R} \times \prod_p' \mathbb{Q}_p$ (restricted product); $\mathbb{A}_{\mathbb{Q}}^{\times}$ the idele group; $\mathbb{A}_{\mathbb{Q}}^{\times}/\mathbb{Q}^{\times}$ the idele class group.

Hecke. $\mathcal{H}_p^{\mathrm{sph}} = C_c(GL_n(\mathbb{Z}_p)\backslash GL_n(\mathbb{Q}_p)/GL_n(\mathbb{Z}_p))$; Satake isomorphism $\mathrm{Sat}_p : \mathcal{H}_p^{\mathrm{sph}} \xrightarrow{\sim} \mathbb{Z}[\alpha_1^{\pm}, \dots, \alpha_n^{\pm}]^{S_n}$.

Satake pair ($\mathbf{GL_2}$). $\alpha_p, \beta_p \in \mathbb{C}^{\times}$ with $\alpha_p\beta_p = p$; trace $a_p = \alpha_p + \beta_p = 2p^{1/2}\cos\theta_p$ on unitary sector.

Kesten–McKay. $\nu_p(\theta) = (2/\pi)\cdot p(1+p)\sin^2\theta/(1+p^2-2p\cos 2\theta)$, $\theta \in [0,\pi]$; this is the Plancherel density of unramified $GL_2(\mathbb{Q}_p)$.

Arakelov degree. $\widehat{\deg}\, O(s\cdot[\infty]) = s \in \widehat{\mathrm{CH}}^1(\overline{C}) \otimes \mathbb{R} \cong \mathbb{R}$.

Completed zeta. $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ with functional equation $\xi(s) = \xi(1-s)$.

All references to Vols I–III use the native cross-volume citation. The branch has no internal dependency cycle; chapters are readable in order.

24.7 Imports and Assembly

This branch imports local theorems from the arithmetic Langlands programme: local geometric Satake (Fargues–Scholze, arXiv:2102.13459), the Emerton–Gee stack (arXiv:2012.12403), and Caraiani–Scholze vanishing. It assembles them into the E_1-chiral-algebra presentation natural to the bar–cobar programme;

the novel content is the assembly. Caraiani–Scholze, Fargues–Scholze, and Emerton–Gee develop the arithmetic Langlands programme independently; this branch is a consequent consumer.

An arithmetic character interpretation of the Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ requires its actual comparison with the specified L-function. A vertex or factorization realization must also supply its fields and operation maps. The local models of Chapters 26 and 33 provide inputs to these comparisons.

The Deninger $\mathbb{F}_1$-geometry supplies motivation and is cited as a consequent reference. At the overlaps (the adelic norm form $\prod_v |x|_v = 1$, the Connes–Consani arithmetic site as a categorical base, tropical semirings for the structure sheaf) the arithmetic branch is a formal consequence of Deninger's comparison geometry.

24.8 Arithmetic-Modular Extension: All-Genus Axis

The three-layer arithmetic branch treats the $g = 0$ row: Riemann $\xi(s) = \xi(1-s)$ as the functional-equation witness of Heisenberg G-row complementarity $\kappa^{\mathrm{Ar}} + (\kappa^!)^{\mathrm{Ar}} = 0$. A six-source-family comparison extends the branch to arbitrary $g \geq 0$. Chapter 102 defines the *arithmetic genus-g datum* $\mathcal{D}_g$ admitting six convergent presentations: Arakelov fibration (Faltings, Gillet–Soulé, Bost–Künnemann); Minkowski torus over totally imaginary K of degree $2g$ (Deninger, Connes–Consani, Bost–Connes–Marcolli); ordinary crystalline Emerton–Gee stack $\mathcal{X}_{2g}^{\mathrm{crys,ord}}$ (Fargues–Scholze, Bhatt–Scholze, Caraiani–Scholze); Hodge–Arakelov point of arithmetic Teichmüller $\mathcal{T}_g^{\mathrm{arith}}$ with theta-structure (Mochizuki); chiral-bar-cobar interior $\mathcal{V}^{\mathrm{prim,surf},g} = \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw,surf}}_{GL_{2g},\mathrm{glob}})$ with E_2-structure via Dunn additivity (Beilinson–Drinfeld, Francis–Gaitsgory, Ben-Zvi–Nadler); Kudla–Rapoport Shimura–Siegel datum with g-fold arithmetic intersection of special cycles (Kudla, Bruinier, Li–Liu).

The essential conditional of the extension (Chapter 102.4.1) states: the Koszul self-duality identity $\kappa^{\mathrm{Ar},g} + (\kappa^!)^{\mathrm{Ar},g} = 0$ is preserved at every $g \geq 0$ and is equivalent to the motivic functional equation of the corresponding row. The genus enters the functional equation through the archimedean Γ-factor $\Gamma_{\mathbb{C}}(s)^g$, the rank $2g$ of the Heisenberg Fock oscillators, and the motivic weight $w_{\mathcal{D}_g} \in \{1, 2, 2g+1\}$ setting the functional-equation center (Dedekind zeta, Hasse–Weil L-function of the Jacobian, Siegel spin L-function of a GSp_{2g} cusp form); the Siegel-spin entry $w = 2g+1$ inherits the spinor L-function normalisation convention for vector-valued GSp_{2g} cusp forms (Arthur 2013) from Chapter 102. The $g = 0$ specialisation recovers the zero-placement axis of Chapter 44. The all-genus F-RH corollary (Chapter 102.5.1) is the common form of the zero-placement clauses for the classical zeta function, Hasse–Weil L-functions of Jacobians, Dedekind zeta functions of totally imaginary fields, and Siegel-spin L-functions for GSp_{2g} automorphic representations; it is not a proof of these hypotheses without the corresponding spectral positivity input.

The almost-complex-structure candidate is obstructed in every source class at a category-theoretic joint: an arithmetic scheme has no real tangent bundle, and Newlander–Nirenberg integrability is a theorem on real two-manifolds. The surviving operator is Frobenius φ_g on primitive cohomology, namely archimedean Frobenius, prismatic φ, or the chiral Koszul operator J^{Koz}; see Chapter 102.1.2. The extension is arithmetic-modular in the sense that the six windows are modular presentations of a single object $\mathcal{D}_g$, each supplying an independent verification path satisfying the independence of sources criterion. The residual conditions of Chapter 102.6 are ten genus-g comparison morphisms; each is a finite theorem condition in the corresponding source family.

24.9 Arithmetic Gravity and the E_1 Ordered Bar

The proposed arithmetic Kac–Moody enhancement requires the current operations and level comparisons of Question 103.3.1. A conformal vector alone does not construct those currents. The scalar identity $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar}} = 0$ also does not exclude a critical level.

Such an enhancement would be an input to a conjectural quantum Chern–Simons theory $\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}$ on $\overline{\mathrm{Spec}\,\mathbb{Z}}$. The arithmetic three-space analogy comes from Mazur's duality picture and Morishita's primes-as-knots comparison. Kim's classical torsor construction motivates the finite state sums and the further profinite TQFT question. The boundary comparison with $\mathcal{V}^{\mathrm{prim}}$, the zeta scalar character, and the Beilinson–Drinfeld/Costello–Gwilliam (BD/CG) chiral-homology comparison are conditional. What is closed in Chapter 103 is the ordered incidence-bar calculation on the auxiliary ordered place set $\mathbb{P} \cup \{\infty\}$ (Chapter 103.5.4).

Over the arithmetic base the 3D topological gauge theory is Chern-Simons rather than holomorphic-twist: $\overline{\mathrm{Spec}\,\mathbb{Z}}$ has étale cohomological dimension 3 without a differential-geometric holomorphic structure. The complex Vol II Part VI 3D HT QFT bulk becomes the 3D arithmetic Chern-Simons bulk; the complex-boundary $\mathcal{V}$ becomes the arithmetic-boundary $\mathcal{V}^{\mathrm{prim}}$. The zero-placement clause of F-RH (Chapter 44.1.1) becomes a spectral statement on the partition-function zero locus of the bulk TQFT (Chapter 103.7.1); the all-genus F-RH corollary (Chapter 102.5.1) lifts to the bulk partition function valued in $\Lambda_{\mathcal{D}_g}(k^{\mathrm{Ar},g})$ for every row of the arithmetic-modular family (Chapter 103.8.1).

The arithmetic-gravity closure adds a non-formal theorem condition of residual condition to the all-genus programme (Chapter 103.9): quantum ACS construction on the étale site; bulk-boundary correspondence; ordered-incidence bar calculation plus conditional BD/CG comparison; and the positive Hilbert–Pólya/VB input. Together with Chapter 102's all-genus residual list, the extension of the arithmetic branch from the $g = 0$ axis to the all-genus arithmetic-modular family plus arithmetic-gravity bulk takes a non-formal theorem condition in four to six mathematical blocks.

Chapter 25

The Arithmetic Curve and the Heisenberg Cover

25.1 The Arithmetic Curve

Write $\overline{C} := \overline{\operatorname{Spec} \mathbb{Z}}$ for the Arakelov compactification: closed points are primes $p \in \mathbb{P}$ plus the archimedean place ∞. At p the completed local ring is $\mathbb{Z}_p$, with uniformizer p, residue field $\mathbb{F}_p$, and Frobenius $\mathrm{Frob}_p : \bar{\mathbb{F}}_p \to \bar{\mathbb{F}}_p$, $x \mapsto x^p$. At ∞ the completion is $\mathbb{R}$ with complex conjugation on $\mathbb{C}$. The generic stalk is $\mathbb{Q}$.

A smooth complex curve has local coordinates on open neighborhoods, with transition maps on their overlaps. It need not have one global coordinate. An adele $(x_\infty; x_2, x_3, x_5, \ldots) \in \mathbb{A}_{\mathbb{Q}}$ is instead a tuple of local elements, integral at almost every finite place. It becomes an insertion coordinate only if a geometric construction supplies that interpretation and its transition maps. Chapter 10 constructs continuous arithmetic coefficient complexes without assuming such an identification.

25.2 Λ-Ring Input

Definition 25.2.1 *(after Grothendieck, Borger).* For a $\mathbb{Z}$-torsion-free commutative ring R, a Λ-*structure* is equivalently given by ring endomorphisms $\psi_n : R \to R$, $n \in \mathbb{N}^\times$, such that $\psi_1 = \mathrm{id}$, $\psi_m \psi_n = \psi_{mn}$, and $\psi_p(x) \equiv x^p \pmod{p}$ for every prime p.

Theorem 25.2.2 *(Borger, arXiv:0801.1691; arXiv:0906.3146).* Borger interprets the forgetful functor from Λ-spaces to ordinary spaces as base change from $\mathbb{F}_1$ to $\mathbb{Z}$. For flat affine objects the structure is specified by commuting Frobenius lifts. This categorical interpretation does not construct a new tensor product or a descent datum on an unsupplied arithmetic object (Borger0906.3146, §§1.1–1.2).

Remark 25.2.3. The universal Λ-ring on one generator is the ring $\Lambda = \mathbb{Z}[h_1, h_2, \ldots]$ of symmetric functions. On Newton power sums the Adams operation acts by $\psi_n(p_m) = p_{mn}$ (Macdonald, *Symmetric Functions and Hall Polynomials*, Ch. I §8).

Remark 25.2.4. The big Witt vector functor $W : \mathrm{CRing} \to \mathrm{Ring}_\Lambda$ is right adjoint to the forgetful functor. $W(R)$ is the cofree Λ-ring on R. The ghost map $W(R) \to R^{\mathbb{N}^\times}$ is injective when R is $\mathbb{Z}$-torsion-free; injectivity is not asserted for arbitrary torsion rings (Borger0801.1691, §1.14).

On $\operatorname{Spec} \mathbb{Z}$, local translations are replaced by a monoid $\mathbb{N}^\times$ of commuting Adams operations $\{\psi_p\}_{p \in \mathbb{P}}$, one per prime. An action on a proposed arithmetic chiral object is additional data. The polynomial index-shift action and the different divisor substitutions are constructed in Chapter 28; neither alone supplies an action on the arithmetic trace class.

25.3 The Finite Heisenberg Cover

Definition 25.3.1 *(finite Heisenberg cover).* For each prime p, let $\mathcal{H}^{(p)}$ be the rank-2 Heisenberg vertex algebra with generators $a^{(p)}$, $b^{(p)}$ and OPE

$$\begin{aligned} a^{(p)}(z)\,a^{(p)}(w) &\sim \frac{1}{(z-w)^2}, \\ b^{(p)}(z)\,b^{(p)}(w) &\sim \frac{1}{(z-w)^2}, \\ a^{(p)}(z)\,b^{(q)}(w) &\sim 0 \quad \forall p, q. \end{aligned}$$

Each orthogonal current has level one. Use the ordinary rank-two conformal vector, of central charge two,

$$\omega_p = \tfrac{1}{2}\big((a^{(p)}_{-1})^2 + (b^{(p)}_{-1})^2\big)|0\rangle_p.$$

Its integer oscillator weight is distinct from the energy $H_p = (\log p)L_0^{(p)}$. The latter is an operator, not a rescaled conformal vector. The algebraic restricted tensor product $\bigotimes'_p \mathcal{H}^{(p)}$ uses the vacuum at almost every prime. It is a proposed cover; a map from it to the arithmetic trace class is additional data. An infinite sum of its conformal vectors is not a state in this algebraic restricted tensor product.

PROPOSITION 25.3.2 *(full and selected finite-place Euler factors).* On the Hall Hilbert completion at one prime p, let Q_p act on a monomial by the number of a-oscillators minus the number of b-oscillators; write $N_p = Q_p$ when this occupation charge is used below. For real θ_p and $\operatorname{Re} s > 0$,

$$\operatorname{Tr}(e^{-sH_p}e^{i\theta_p Q_p}) = \prod_{k\geq 1} \frac{1}{(1-e^{i\theta_p}p^{-ks})(1-e^{-i\theta_p}p^{-ks})}.$$

Selecting only the two modes $a^{(p)}_{-1}$, $b^{(p)}_{-1}$ gives

$$\frac{1}{1-2\cos\theta_p\, p^{-s}+p^{-2s}}.$$

The product over all primes converges absolutely for $\operatorname{Re} s > 1$. The selected factor agrees with the trigonometric primon Euler factor; it is not the full two-species oscillator trace. The selected space is not preserved by the substitutions of Chapter 28 for $n > 1$.

Proof. If the occupations are r_k, t_k, their energy is $\sum_k k(r_k + t_k)\log p$ and their charge is $\sum_k (r_k - t_k)$. Summing each occupation independently gives the geometric factors. Absolute convergence follows from the same geometric bounds as in Section 28.7; two species only double the bound on the logarithm. Keeping only $k = 1$ gives the second formula. In the vacuum Heisenberg module the zero modes a_0, b_0 vanish; Q_p is the explicitly defined occupation operator, not their difference. The first generator maps to mode n under both substitutions, proving the final assertion. □

25.4 The Divisor-Substitution Obstruction to GL_2-Hecke

PROPOSITION 25.4.1 *(divisor substitutions and Hecke recursion).* On the polynomial Fock carrier over $\mathbb{Z}$, the formula

$$T_n(a^{(p)}_{-k}) = \sum_{d\mid n,\, d\mid k} d\, a^{(p)}_{-nk/d}$$

extends as a unital ring map. It satisfies coprime multiplicativity, but not $T_m T_n = T_{mn}$ for all indices, and not the recursion $T_{p^2} = T_p^2 - p\,\mathrm{id}$.

Proof. The divisor $d = 1$ always contributes. Consequently

$$T_p a_{-1}^{(p)} = a_{-p}^{(p)}, \quad T_p^2 a_{-1}^{(p)} = a_{-p^2}^{(p)} + p a_{-p}^{(p)}, \quad T_{p^2} a_{-1}^{(p)} = a_{-p^2}^{(p)}.$$

The Adams discrepancy is $p a_{-p}^{(p)}$; the displayed Hecke recursion has discrepancy $p(a_{-p}^{(p)} - a_{-1}^{(p)})$. Both are nonzero in this free integral carrier. The coprime statement and the complete composition law are Corollary 28.2.2. The index-shift operations $\psi_n(a_{-k}^{(p)}) = a_{-nk}^{(p)}$ instead form an Adams action. A comparison with an arithmetic Hecke representation must specify its operators and preserve their actual relations. □

25.5 Polynomial Averaging and the Arithmetic Comparison

Definition 25.5.1 *(finite occupation-phase averaging).* Let S be a finite set of primes, and let $P_{S,\mathbb{C}}$ be the polynomial span of the two-species oscillator states at those primes. The occupation charges $N_p = Q_p$ defined above act diagonally on this carrier. Define the complex-linear operator

$$A_S(v) = \int_{[0,\pi]^S} \exp\left(i \sum_{p \in S} \theta_p N_p \right) v \prod_{p \in S} \nu_p(\theta_p)\, d\theta_p, \qquad v \in P_{S,\mathbb{C}},$$

where

$$\nu_p(\theta) = \frac{2}{\pi} \frac{p(1+p)\sin^2\theta}{1 + p^2 - 2p\cos 2\theta}.$$

The integral is defined coefficient by coefficient: each polynomial has finite support in the occupation basis, and the displayed density is bounded on $[0, \pi]$ for every prime p. Thus A_S is an endomorphism of the polynomial vector space. No quotient or arithmetic factorization structure is used in its definition.

Warning 25.5.2 *(arithmetic averaging requires a comparison).* The proposed arithmetic map

$$\mathrm{av}^{\mathrm{arith}} : \mathcal{V}^{E_1,\mathrm{arith}} \longrightarrow \mathcal{V}^{\mathrm{Hecke}}$$

requires the construction of its arithmetic E_1-chiral carrier, its Hecke quotient, and the map between them. These are additional requirements in Chapter 30. The formula for A_S does not identify those carriers or construct that arithmetic map. Theorem 27.6.1 constructs the spherical transform on radial tree functions and preserves its root state. Section 27.8 proves that the one-prime occupation-phase average has a nonreal eigenvalue. Thus it cannot be unitarily intertwined with the self-adjoint tree adjacency operator. The operadic averaging from ordered to symmetric chiral cohomology in Vol I has its own carriers and structure maps; the shared integral notation supplies no comparison between these operations.

25.6 The Depth Analogy

Heuristic. The following four rows name possible arithmetic shadows of the Vol I depth filtration. They do not classify Λ-rings.

- **Depth 2:** trivial ψ_n beyond ψ_1; *archetype G analogue* (primon Heisenberg only);
- **Depth 3:** finitely generated image in $\prod_p \mathbb{Z}$; *archetype L analogue* (arithmetic Kac–Moody / Iwasawa-type Λ-module);
- **Depth 4:** higher-derived Λ-structure engaging Witt filtration; *archetype C analogue* (arithmetic $\beta\gamma$);

• **Depth ∞:** full Connes–Consani arithmetic site; *archetype M analogue* (arithmetic Virasoro).

Remark 25.6.1. The depth numerology $\{2, 3, 4, \infty\}$ on the Vol I side is forced by explicit shadow-tower computation (Vol I, shadow-tower chapter). On the arithmetic side the corresponding derivation via a Λ-ring analogue of Mok's shadow-tower rigidity remains open; the classification above is a heuristic pattern match.

25.7 Boundary Conditions for the Five Arithmetic Analogues

Conjecture 25.7.1 *(A^{arith}).* There is an adjunction $\Omega^{\mathrm{ch,arith}} \dashv B^{\mathrm{ch,arith}}$ between the ∞-category of Λ-ring-enhanced E_1-algebras on $\overline{C}$ and the ∞-category of conilpotent Λ-coalgebras. On $\mathcal{V}^{\mathrm{prim}}$ this adjunction is an equivalence on the subcategory of Λ-ring objects with prime-adic convergence at every finite place.

Question 25.7.2 *(B^{arith}).* Construct the arithmetic adjunction of Conjecture 25.7.1 and determine its domain of coalgebra recovery. For a coaugmented coalgebra C, the required unit has the type

$$C \longrightarrow B^{\mathrm{ch,arith}}\Omega^{\mathrm{ch,arith}}(C).$$

Specify the coefficient topology and weak equivalences under which this map is an equivalence. Conilpotence concerns iterated reduced coproducts. A module-theoretic $\mu = 0$ hypothesis, when defined, is separate, by Proposition 10.10.2.

Conjecture 25.7.3 *(C^{arith}).* Define the arithmetic κ of a Λ-chiral algebra as its Arakelov first Chern class (sum of finite-place p-adic orders plus archimedean logarithmic defect). On the Koszul self-dual arithmetic subcategory, $\kappa + \kappa^! \in \{0, \log 2, \log 3, \ldots\} \cup \{0, 1, 2, \ldots\}$ with the precise ceiling unknown.

Warning 25.7.4 *(Sharpened in Chapter 43).* The correct arithmetic G-row ceiling is 0, and its content is the Riemann functional equation $\xi(s) = \xi(1 - s)$.

Conjecture 25.7.5 *(D^{arith}).* The genus-g obstruction for the arithmetic Maurer–Cartan element $\Theta_A^{\mathrm{arith}}$ equals $\kappa \cdot h_g^{\mathrm{Ar}}$ where h_g^{Ar} is the Arakelov height of the level-g component of $\overline{M}_{g,n}$.

Conjecture 25.7.6 *(H^{arith}).* $\mathrm{HH}^\bullet(\mathcal{V}^{\mathrm{prim}})$ is concentrated in degrees $\{0, 1, 2\}$:

$$\begin{aligned} \mathrm{HH}^0 &= \mathbb{Z} \quad (\Lambda\text{-ring augmentation}), \\ \mathrm{HH}^1 &= \bigoplus_p \log p \cdot \mathbb{Z} \quad (\text{Bost–Connes KMS generators}), \\ \mathrm{HH}^2 &= \text{a } \Lambda\text{-torsor related to Witt cotangent.} \end{aligned}$$

25.8 Boundary Conditions

Four boundary conditions govern the construction above.

(i) **p-adic locality.** The OPE locality axiom $[a(z), b(w)] = 0$ off-diagonal requires an interpretation of the formal variable $z - w$ at finite places of $\overline{C}$: see Chapter 26.

(ii) **Adelic factorization.** Beilinson–Drinfeld factorization on a curve employs $C^n/\mathfrak{S}_n$. On $\overline{C}$ the two candidate analogues are $W_n(\mathbb{Z})/\mathfrak{S}_n$ and $\mathrm{Spec}(\Lambda^{\otimes n})^{\mathfrak{S}_n}$; their comparison is settled in Chapter 30.

(iii) **Real place.** The archimedean place carries an $\mathrm{SL}(2, \mathbb{R})$ conformal quantum mechanics (Hartnoll–Yang); the non-archimedean places carry $\mathrm{SL}(2, \mathbb{Q}_p)$. The adelic $\mathrm{SL}(2)$-automorphic picture gluing these is developed in Chapter 32.

(iv) **Four-archetype derivation.** The shadow-tower depth numerology on the arithmetic side would require a Λ-ring analogue of Mok's shadow-tower rigidity. No such rigidity theorem is used below.

Chapter 26

Finite-place fields and arithmetic comparison

A formal Heisenberg algebra exists over every characteristic-zero field, including $\mathbb{Q}_p$. Its insertion coordinate belongs to an auxiliary curve over that field. A comparison with an arithmetic space must specify the support, coefficient maps and topology that relate them.

There are three separate choices. A logarithmic energy assigns real weights to states. A coefficient construction determines the ring over which local fields are assembled. A geometric realization specifies the diagonal and its normal directions. We examine these choices before stating the arithmetic comparison problem.

26.1 The formal algebra over a finite-place field

A vertex algebra over k has a state-field map

$$Y : V \otimes_k V \longrightarrow V((z)),$$

with a vacuum, translation and the formal field identities. No absolute value occurs in those identities. The construction in Section 6.1 gives two orthogonal level-one currents over $\mathbb{Q}$, and scalar extension gives

$$\mathcal{H}_k = \mathrm{Sym}_k(k[t]a \oplus k[t]b), \qquad [a_m, a_n] = [b_m, b_n] = m\delta_{m+n,0}, \quad [a_m, b_n] = 0.$$

The monomial $t^{m-1}a$ denotes a mode-m creation state.

Proposition 26.1.1. For every characteristic-zero field k, the displayed Fock space is a rank-two formal Heisenberg vertex algebra, with

$$a(z)a(w) \sim (z-w)^{-2}, \qquad b(z)b(w) \sim (z-w)^{-2}, \qquad a(z)b(w) \sim 0.$$

In particular it gives a formal vertex algebra over $\mathbb{Q}_p$.

Proof. Define negative modes by multiplication and positive modes by the corresponding weighted derivatives. Their commutators give the three contractions. Normal ordering and the finite Wick expansion prove locality, translation and the vacuum identities, as in Proposition 6.1.1. All formulas commute with extension from $\mathbb{Q}$ to k. □

The variable z remains formal. A norm on V, a completion of its tensors and a domain for z are additional analytic data. Neither the existence nor failure of one analytic completion changes this algebraic construction.

26.2 CONFORMAL NORMALIZATION AND LOGARITHMIC ENERGY

The standard conformal state is

$$\omega = \tfrac{1}{2}(a_{-1}^2 + b_{-1}^2)\mathbf{1}.$$

Its field T has central charge two and integer oscillator weights. For $T' = \lambda T$, its second pole is $2\lambda^2 T$, whereas the Virasoro normalization requires $2T' = 2\lambda T$.

Observation 26.2.1. On the nontrivial Heisenberg algebra, a scalar multiple $\lambda\omega$ implements the original conformal structure only when $\lambda = 1$. The real weight $\log p$ in $H_p = (\log p)L_0$ is external energy data. It does not define a rescaled conformal state over $\mathbb{Q}_p$.

Indeed the second pole forces $\lambda^2 = \lambda$. The value zero cannot give the required translation operator. This leaves $\lambda = 1$. The fourth pole alone would give $2\lambda^2$, but it cannot determine a conformal structure without the other poles.

The p-adic logarithm provides different data. Its convergent series on principal units extends to $\mathbb{Q}_p^\times$ after one chooses its value on p. The usual normalization sets that value to zero. This convention is not an interpretation of the real number $\log p$, nor is it the only possible choice of a logarithm on the valuation factor.

Convention 26.2.2. Use the standard rank-two conformal state at each finite place. When the coefficient space is complex and prime-labeled, use $(\log p)L_0$ as a separately specified energy operator. A comparison with a p-adic coefficient system must supply its own coefficient maps and normalizations.

26.3 COMMON COEFFICIENTS AND RESTRICTED TENSORS

For finite sets of places, tensor products require a common base ring and actual maps from that base. Since every $\mathbb{Q}_p$ is a $\mathbb{Q}$-algebra, the algebraic tensors

$$R_S = \bigotimes_{p \in S, \mathbb{Q}} \mathbb{Q}_p$$

are defined. Their transition maps insert units. They are injective as maps of rational vector spaces.

Observation 26.3.1. There is an abstract common field extension of all the $\mathbb{Q}_p$. This fact does not provide canonical or continuous coefficient embeddings, an adelic topology, or a restricted tensor of representations.

To construct such a field, take a maximal-ideal quotient of $\varinjlim_S R_S$, as in Proposition 6.1.4. The transition injections make this a nonzero ring. Each local field injects into the quotient because its map is unital. This construction retains its algebraic scope.

Three coefficient constructions illustrate the further choices. First, choose embeddings into a common characteristic-zero field and extend the formal Heisenberg factors there. Even an abstract embedding $\mathbb{Q}_p \to \mathbb{C}$ is discontinuous, since it sends the sequence $p^r \to 0$ to an unbounded real sequence. Extending scalars in this way does not transport the local norm.

Second, work over an adelic coefficient ring with specified modules and lattices. The canonical map is the projection $\mathbb{A}_\mathbb{Q} \to \mathbb{Q}_p$. It does not supply a unital map in the reverse direction for scalar extension. The finite-place inclusion supported only at p sends the unit to a proper idempotent. Its module convention must therefore be stated explicitly.

Third, use the rational model itself. The assignment

$$k \longmapsto \mathcal{H}_\mathbb{Q} \otimes_\mathbb{Q} k$$

is already a functor on characteristic-zero fields. A field embedding acts on coefficients and preserves the field operations. A descent datum for another form, or an arithmetic Galois action with Frobenius compatibility, is additional input.

Warning 26.3.2. None of these coefficient constructions produces a Hecke action or identifies the oscillator algebra with an arithmetic trace class. Those comparisons require independently defined targets and maps preserving their operations.

26.4 Completion in the prime and completion at the diagonal

Put $R = \mathbb{Z}_p \otimes_{\mathbb{Z}} \mathbb{Z}_p$. The p-adic completion of this ring and the formal completion at its multiplication ideal use different ideals. The first is computed by reduction modulo powers of p.

Proposition 26.4.1. Multiplication induces

$$\varprojlim_r R/p^r R \cong \mathbb{Z}_p.$$

The ordinary multiplication map $R \to \mathbb{Z}_p$ has a nonzero kernel. After inverting p, its diagonal conormal module is $\Omega_{\mathbb{Q}_p/\mathbb{Q}} \neq 0$.

Proof. At every finite precision,

$$R/p^r R \cong (\mathbb{Z}_p/p^r) \otimes_{\mathbb{Z}} (\mathbb{Z}_p/p^r) \cong \mathbb{Z}/p^r.$$

Taking this inverse limit proves the first assertion. For $a \in \mathbb{Z}_p \setminus \mathbb{Q}$, the element $a \otimes 1 - 1 \otimes a$ is nonzero before completion. A rational linear functional taking 1 to zero and a to one detects it after inverting p. Multiplication and every finite reduction kill it.

The conormal module of multiplication on $\mathbb{Q}_p \otimes_{\mathbb{Q}} \mathbb{Q}_p$ is the module of Kähler differentials. A derivation along an element of a transcendence basis is nonzero. Characteristic zero extends that derivation across the remaining algebraic extension. Thus this conormal module is nonzero, as in Proposition 6.1.3. □

Flatness does not make an ordinary tensor commute with this inverse limit. The nonzero kernel just exhibited shows why that interchange would give the wrong ordinary ring.

Corollary 26.4.2. The p-adic completion calculation does not imply that every finite-place field operation is locally constant. On the auxiliary line $\mathbb{A}^1_{\mathbb{Q}_p}$, the rank-two currents have nonzero principal-parts operations at the diagonal.

Proof. That diagonal has parameter $u = z - w$, with formal normal ring $\mathbb{Q}_p[z][[u]]$. The current product has principal part $u^{-2}du$. This is nonzero in its full normal module. Completion of the coefficient ring in p does not remove this independent normal variable. □

26.5 Choosing a local coefficient model

A locally constant coefficient system is a possible model. It must be specified rather than deduced from the preceding completion formula. A commutative coefficient algebra with a Hecke endomorphism is also different from the formal Heisenberg algebra, whose current first product is nonzero.

Definition 26.5.1. A constant local coefficient datum consists of a commutative unital coefficient algebra B_p, a chosen filtration or topology, and a specified compatible endomorphism T_p. Its constant vertex operation is $Y(b,z)c = bc$, with zero translation. This is one possible local datum for a comparison with an independently defined arithmetic object.

An E_0-algebra by itself is pointed data, without a binary multiplication supplied by that notation. The commutative product in the definition is an explicit additional structure. Its endomorphism is not simultaneously a Hecke and Adams operation unless the corresponding relations are proved.

THEOREM 26.5.2 *(Complex auxiliary realization).* The scalar extension $\mathcal{H}_{\mathbb{C}}$ gives a Heisenberg field algebra on the auxiliary complex line, with its nonzero diagonal principal-parts operation.

Proof. The formal field construction and normal residue operation are those of Sections 6.1 and 6.2 over $\mathbb{C}$. Translation gives differential linearity, and the field identities give the residue identities. □

Identifying this auxiliary realization with a specified archimedean arithmetic object requires a comparison map. The coefficient extension alone does not define that object.

26.6 The adelic and automorphic comparison

A restricted tensor representation starts with representations (π_v, V_v) of the local groups over a common field. At almost every finite place it also specifies a vector fixed by a chosen compact open subgroup. The tensor transition maps insert these vectors. A restricted product of group elements then acts because only finitely many factors move them.

This constructs an abstract representation on its stated tensor carrier. Realizing it as automorphic functions requires further global data. In particular, local oscillator fields do not already specify the $GL_2(\mathbb{Q}_v)$-representations or the required global realization.

Question 26.6.1. Choose arithmetic local coefficient objects, local group actions, and unramified reference vectors over a specified common base. Construct their restricted tensor and an intertwiner to an independently defined automorphic recipient. Can this intertwiner be compared with the local field operations, including their collision maps, vacuum data and coefficient topology?

Remark 26.6.2. A compatible adelic system may be a useful geometric recipient for this question. Its structure must determine the relevant local and global maps. Neither the coefficient-field choices nor the completion of $\mathbb{Z}_p \otimes \mathbb{Z}_p$ force that recipient or prove that singularities occur only at the archimedean place.

26.7 Formal loop spaces and the arithmetic problem

Remark 26.7.1. Kapranov and Vasserot construct formal loop spaces for schemes of finite type over a field. Their global versions form factorization monoids. For smooth schemes their geometric construction recovers the chiral de Rham complex and its vertex structure.[1] The field-based construction supplies a comparison model. An arithmetic extension must define its own loop objects, coefficient categories and factorization maps.

Remark 26.7.2. Reciprocity and cohomology determinants suggest further comparison data. A determinant line requires a specified perfect complex, and a reciprocity statement requires its actual local

[1] M. Kapranov and E. Vasserot, *Vertex algebras and the formal loop space*, Introduction, pp. 1–2, arXiv:math/0107143.

symbols and common recipient. An analogy with Langlands correspondence or a field theory does not provide these constructions. The automorphic problem above remains one possible formulation.

26.8 The local and global maps still required

The formal finite-place Heisenberg algebra, its auxiliary diagonal operation, and the p-adically completed coefficient tensor are explicit constructions. The ordinary tensor and diagonal conormal module retain the information that the p-adic completion forgets. Logarithmic energy preserves its separate real normalization.

A geometric arithmetic realization must relate these specified carriers through coefficient and support maps. An automorphic realization must additionally supply its group actions and global intertwiner. The choice of a common field, a locally constant model, or an adelic tensor leaves those maps to be constructed.

Chapter 27

Divisor Substitutions and Satake Parameters

The divisor substitutions on polynomial Fock space, Adams ring maps, and a spherical Hecke representation are different operator data. We specify the Satake normalization, compute the divisor discrepancy, and distinguish a Satake matrix from its scalar symmetric-power traces.

27.1 The Satake Pair and Why It Matters

Theorem 27.1.1 *(normalized spherical Satake convention).* Let $K = GL_2(\mathbb{Z}_p)$, normalize Haar measure by $\mathrm{vol}(K) = 1$, and use complex coefficients. The normalized spherical Satake isomorphism identifies $\mathcal{H}_p = C_c(K\backslash GL_2(\mathbb{Q}_p)/K, \mathbb{C})$ with $\mathbb{C}[X^{\pm 1}, Y^{\pm 1}]^{S_2}$. The characteristic functions of $K\,\mathrm{diag}(p,1)K$ and $K\,\mathrm{diag}(p,p)K$, denoted T_p and D_p, have images $p^{1/2}(X+Y)$ and XY. For a character of this algebra set $\alpha_p = p^{1/2}X$, $\beta_p = p^{1/2}Y$ at that character. Then $\alpha_p\beta_p = pD_p$, where the right side means its scalar value. Trivial central character gives $D_p = 1$. The condition $|X| = |Y| = 1$ is the additional tempered condition, not a consequence of trivial central character alone. These conventions are Gross, *On the Satake isomorphism*, Proposition3.6, equations(3.13)–(3.14) and §8.

Proposition 27.1.2 *(symmetric-power generating function).* Define the elements $H_{p^k} \in \mathcal{H}_p$ by their Satake images $h_k(p^{1/2}X, p^{1/2}Y)$, the complete symmetric polynomials. Then $H_{p^0} = 1$, $H_p = T_p$, and

$$\sum_{k\geq 0} H_{p^k} t^k = (1 - T_p t + pD_p t^2)^{-1}.$$

Proof. In the Satake algebra the generating series is $(1 - p^{1/2}Xt)^{-1}(1 - p^{1/2}Yt)^{-1}$. Multiply the denominators and use injectivity of the Satake map. This fixes the determinant normalization and the choice of the higher Hecke elements rather than identifying them with a single undeclared double-coset convention. □

At a character with $D_p = 1$ this series is $\big((1-\alpha_p t)(1-\beta_p t)\big)^{-1}$. The two parameters may coincide. In the tempered case their unitary versions $p^{-1/2}\alpha_p$, $p^{-1/2}\beta_p$ give the local trigonometric Euler factor; changing between the two normalizations shifts the Dirichlet variable by one half. This complex Satake convention is separate from the integral polynomial carrier used for the divisor substitutions below.

27.2 Adams operations and Hecke representations

Proposition 27.2.1. The Adams operations of a special λ-ring (Definition 13.6.1) satisfy $\psi_m\psi_n = \psi_{mn}$. They give an action of $(\mathbb{N}_{\geq 1}, \times)$, the free commutative monoid on the primes. Conversely, commuting Frobenius lifts determine the special structure under the torsion-free hypothesis of Theorem 13.6.2. Example 13.6.3 shows why that hypothesis cannot be omitted. This action need not extend to the group completion: the polynomial index shifts are not surjective for $n > 1$.

The full local spherical GL_1 Hecke algebra over $\mathbb{C}$ is $\mathbb{C}[\mathbb{Z}] = \mathbb{C}[z, z^{-1}]$. Valuation identifies the double cosets of $\mathbb{Q}_p^\times/\mathbb{Z}_p^\times$ with $\mathbb{Z}$, and, with the unit subgroup of volume one, convolution adds valuations. An Adams action supplies only the multiplicative monoid action; a comparison with a specified positive Hecke subalgebra is separate data.

Observation 27.2.2 *(distinct operator data).* An Adams action is an action of the multiplicative monoid by ring endomorphisms. It does not by itself specify a GL_2 Hecke representation, its Satake parameters, or its determinant operation. A Λ-ring can contain symmetric functions in two parameters; the missing datum is their comparison with the specified arithmetic operators, not an impossibility of encoding an unordered pair.

27.3 Explicit Computation: The Recursion Fails

Let $\mathcal{H}^{(p)}_{\mathrm{rk1}}$ denote the rank-1 Heisenberg algebra at prime p, with mode operators $a_n^{(p)}$ ($n \in \mathbb{Z}$) satisfying $[a_m^{(p)}, a_n^{(p)}] = m\,\delta_{m+n,0}$, acting on the Fock space $\mathcal{F}^{(p)}$ generated from the vacuum $|0\rangle$ (annihilated by $a_n^{(p)}$ for $n \geq 0$). For each $k \geq 1$, the state $a_{-k}^{(p)}|0\rangle$ spans the one-particle subspace of weight k. The full weight-k subspace also contains the multi-particle partition states.

The claimed formula for the action of a putative GL_2 Hecke operator T_n on this Fock space is

$$T_n(a_{-k}^{(p)}|0\rangle) \;=\; \sum_{d|n} d \cdot a_{-nk/d}^{(p)}|0\rangle \cdot \mathbf{1}_{d|k},$$

extended by $T_n(|0\rangle) = |0\rangle$.

Computation 27.3.1. $T_p(a_{-1}^{(p)}|0\rangle)$. Divisors of $n = p$ are $d \in \{1, p\}$. Only $d = 1$ satisfies $d \mid k = 1$. So

$$T_p(a_{-1}^{(p)}|0\rangle) \;=\; a_{-p}^{(p)}|0\rangle.$$

Computation 27.3.2. $T_p^2(a_{-1}^{(p)}|0\rangle)$. Apply T_p to $a_{-p}^{(p)}|0\rangle$: divisors $d \in \{1, p\}$, both satisfy $d \mid p$, so

$$T_p(a_{-p}^{(p)}|0\rangle) \;=\; a_{-p^2}^{(p)}|0\rangle + p \cdot a_{-p}^{(p)}|0\rangle.$$

Therefore

$$T_p^2(a_{-1}^{(p)}|0\rangle) \;=\; a_{-p^2}^{(p)}|0\rangle + p \cdot a_{-p}^{(p)}|0\rangle.$$

Computation 27.3.3. $T_{p^2}(a_{-1}^{(p)}|0\rangle)$. Divisors $d \in \{1, p, p^2\}$, only $d = 1$ satisfies $d \mid 1$. So

$$T_{p^2}(a_{-1}^{(p)}|0\rangle) \;=\; a_{-p^2}^{(p)}|0\rangle.$$

Observation 27.3.4 *(recursion discrepancy).* Testing $T_{p^2} = T_p^2 - p \cdot \mathrm{id}$ on $a_{-1}^{(p)}|0\rangle$:

$$\begin{aligned} T_p^2 - p \cdot \mathrm{id}\big|_{a_{-1}^{(p)}|0\rangle} &= a_{-p^2}^{(p)}|0\rangle + p \cdot a_{-p}^{(p)}|0\rangle - p \cdot a_{-1}^{(p)}|0\rangle, \\ T_{p^2}\big|_{a_{-1}^{(p)}|0\rangle} &= a_{-p^2}^{(p)}|0\rangle. \end{aligned}$$

The discrepancy is $p(a_{-p}^{(p)} - a_{-1}^{(p)})|0\rangle \neq 0$.

Corollary 27.3.5 *(falsification).* The formula $T_n(a_{-k}^{(p)}) = \sum_{d|n} d \cdot a_{-nk/d}^{(p)} \mathbf{1}_{d|k}$ fails both universal Adams multiplicativity and the displayed GL_2 Hecke recursion. It satisfies coprime multiplicativity and the prime-valuation composition law of Corollary 28.2.2. The preceding computations prove the two failures already on the first generator.

27.4 Diagonalisation onto the Satake Pair

A two-dimensional Satake model gives a different construction. Choose nonzero complex numbers α_p, β_p with $\alpha_p\beta_p = p$. This is parameter data, not a consequence of the rank of an oscillator algebra. In the tempered parametrization one can write $\alpha_p = p^{1/2}e^{i\theta_p}$, $\beta_p = p^{1/2}e^{-i\theta_p}$ with real θ_p.

Definition 27.4.1 *(Satake operator).* Let $F_p^1 = \mathbb{C}a_{-1}^{(p)}|0\rangle \oplus \mathbb{C}b_{-1}^{(p)}|0\rangle$. Define $S_p = \mathrm{diag}(\alpha_p, \beta_p)$ in this basis. The equation $\alpha_p\beta_p = p$ is imposed on the parameters. It is not encoded by multiplying a Heisenberg conformal vector by $\log p$; logarithmic energy is the separate convention of Convention 28.7.1.

Theorem 27.4.2 *(trace of the Satake operator).* The operator S_p has determinant p and trace $\alpha_p + \beta_p$, equal to $2p^{1/2}\cos\theta_p$ in the tempered parametrization. The line spanned by $(a_{-1}^{(p)} + b_{-1}^{(p)})|0\rangle$ is invariant precisely when $\alpha_p = \beta_p$.

Proof. The determinant and trace are those of the displayed diagonal matrix. Its value on the sum of the two basis vectors is proportional to that sum exactly when its two diagonal entries agree. □

Corollary 27.4.3 *(symmetric-power trace recursion).* For $k \geq 0$, set $h_k = \mathrm{Tr}(\mathrm{Sym}^k S_p)$. Then $h_0 = 1$, $h_1 = \alpha_p + \beta_p$, and

$$h_k = \sum_{j=0}^{k} \alpha_p^{k-j}\beta_p^j, \qquad h_{k+1} = (\alpha_p + \beta_p)h_k - ph_{k-1} \quad (k \geq 1).$$

Thus the scalar operators $H_{p^k} = h_k\,\mathrm{id}$ on a fixed one-dimensional space satisfy the displayed local Hecke recursion. This is a scalar-parameter representation, distinct from S_p on F_p^1 and from the divisor substitutions T_{p^k}.

Proof. The monomial basis of $\mathrm{Sym}^k F_p^1$ has eigenvalues $\alpha_p^{k-j}\beta_p^j$. Summing gives h_k. Multiplying this sum by $\alpha_p + \beta_p$ and subtracting $\alpha_p\beta_p h_{k-1}$ leaves exactly the sum for h_{k+1}. □

27.5 The Angle θ_p as Unramified Langlands Parameter

The angle θ_p first appeared in Definition 27.4.1 as the argument of the Satake parameters $\alpha_p = p^{1/2}e^{i\theta_p}$, $\beta_p = p^{1/2}e^{-i\theta_p}$. The question is whether θ_p is a free internal parameter of the Heisenberg algebra or is fixed by external (Langlands) data. For a specified unramified automorphic representation it is determined by its Satake pair, when that pair has the tempered normalization above. An arbitrary choice of angles does not construct such a representation.

Proposition 27.5.1 *(tempered determinant normalization).* If $\alpha_p\beta_p = p$ and $|\alpha_p| = |\beta_p| = p^{1/2}$, then the unordered pair is $\{p^{1/2}e^{i\theta_p}, p^{1/2}e^{-i\theta_p}\}$, where θ_p is defined modulo 2π and sign.

Proof. The number $\alpha_p/p^{1/2}$ has modulus one, so it is $e^{i\theta_p}$. The determinant condition forces the second normalized number to be $e^{-i\theta_p}$. Interchanging the two entries changes the sign of θ_p. □

Convention 27.5.2. $\{\theta_p\}_p$ is chosen once and for all as a map $\theta\colon \mathbb{P} \to \mathbb{R}/(2\pi\mathbb{Z},\ \theta \sim -\theta)$ (the angle modulo $\theta \leftrightarrow -\theta$, since $2\cos\theta = 2\cos(-\theta)$). This is the data of an unramified local Langlands parameter at each finite place. The Hartnoll–Yang L-function

$$L(s) \;=\; \prod_p \frac{1}{1 - 2\cos\theta_p\, p^{-s} + p^{-2s}}$$

is a formal Euler product. It is the standard L-function of an automorphic representation only if that representation and the comparison with its normalized local parameters are supplied; arbitrary angles do not establish automorphy or analytic continuation.

27.6 A radial Hecke comparison

The Satake trace recursion also admits a representation on radial functions on a regular tree. Its adjacency operator has the density used in Definition 25.5.1. Matching that density does not identify the operators. The radial tree representation gives an explicit comparison with the spherical Hecke action and its vector state. This is the classical spherical transform, with the distance and symmetric-power normalizations kept separate. The density is the Kesten–McKay measure. McKay, *The expected eigenvalue distribution of a large regular graph*, Linear Algebra Appl. 40 (1981), 203–216, Theorem 1.1, gives its graph-theoretic normalization.

Fix a prime p and a rooted $(p+1)$-regular tree $(\mathcal{T}_p, o)$. Use counting measure on its vertices and complex coefficients. Let S_n be the vertices at distance n from o, and write

$$s_0 = 1, \qquad s_n = (p+1)p^{n-1} \quad (n \geq 1), \qquad e_n = s_n^{-1/2}\mathbf{1}_{S_n}.$$

The radial Hilbert space $\mathcal{R}_p$ consists of the square-summable functions constant on each S_n. The vectors e_n form an orthonormal basis. All these vector spaces have cohomological degree zero. Distance gives a filtration, not a grading preserved by adjacency.

Let T be adjacency, $(Tf)(v) = \sum_{w\sim v} f(w)$. It is a bounded self-adjoint operator on the vertex Hilbert space, with norm at most $p+1$ by Cauchy–Schwarz. Counting edges between consecutive spheres gives

$$\begin{aligned} Te_0 &= \sqrt{p+1}\, e_1, \\ Te_1 &= \sqrt{p+1}\, e_0 + \sqrt{p}\, e_2, \\ Te_n &= \sqrt{p}\,(e_{n-1} + e_{n+1}) \quad (n \geq 2). \end{aligned}$$

In particular, two steps return to the root in $p+1$ ways. Thus the polynomial which produces the distance-two sphere is $T^2 - (p+1)I$. The symmetric-power Hecke polynomial is instead $T^2 - pI$. Their difference is the identity operator.

Define monic integral polynomials by

$$R_0(x) = 1, \quad R_1(x) = x, \quad R_2(x) = x^2 - (p+1), \qquad R_{n+1}(x) = xR_n(x) - pR_{n-1}(x) \quad (n \geq 2).$$

The preceding recurrence proves $R_n(T)e_0 = \mathbf{1}_{S_n}$. These formulas already give an integral $\mathbb{Z}[x]$-module isomorphism

$$\mathbb{Z}[x] \longrightarrow \bigoplus_{n\geq 0} \mathbb{Z}\mathbf{1}_{S_n}, \qquad f \longmapsto f(T)e_0.$$

Here x acts on the right by T. Monicity makes the R_n an integral basis, so this assertion needs no inversion of p. The normalized Hilbert comparison uses real square roots and complex scalars.

THEOREM 27.6.1 *(radial spherical transform).* Put $x(\theta) = 2\sqrt{p}\cos\theta$ for $0 \leq \theta \leq \pi$, and set

$$d\nu_p(\theta) = \frac{2p(p+1)\sin^2\theta}{\pi(p^2+1-2p\cos 2\theta)}\, d\theta, \qquad q_n(\theta) = \frac{R_n(x(\theta))}{\sqrt{s_n}}.$$

The assignment $\mathcal{U}_p e_n = q_n$ extends uniquely to a unitary

$$\mathcal{U}_p : \mathcal{R}_p \longrightarrow L^2([0,\pi],\nu_p).$$

It sends e_0 to 1 and satisfies the commutative square

$$\begin{array}{ccc} \mathcal{R}_p & \xrightarrow{T} & \mathcal{R}_p \\ \mathcal{U}_p \downarrow & & \downarrow \mathcal{U}_p \\ L^2(\nu_p) & \xrightarrow{M_x} & L^2(\nu_p) \end{array}$$

where M_x is multiplication by $x(\theta)$. Consequently $\|T|_{\mathcal{R}_p}\| = 2\sqrt{p}$, and for every bounded Borel function f on $[-2\sqrt{p}, 2\sqrt{p}]$,

$$\langle e_0, f(T)e_0\rangle = \int_0^\pi f(2\sqrt{p}\cos\theta)\, d\nu_p(\theta).$$

Proof. The tridiagonal recurrence makes e_0 cyclic for T on $\mathcal{R}_p$. We compute its spectral measure to determine the Hilbert norm of the polynomial map. Remove the first row and column of that tridiagonal matrix. Its tail has every off-diagonal coefficient equal to $\sqrt{p}$. For $\operatorname{Im} z > 0$, the first diagonal entry $g(z)$ of its resolvent $(z - J)^{-1}$ satisfies the Schur-complement identity

$$g(z) = \frac{1}{z - pg(z)} = \frac{z - \sqrt{z^2 - 4p}}{2p}.$$

The square root is analytic off $[-2\sqrt{p}, 2\sqrt{p}]$ and is asymptotic to z at infinity. The asymptotic $g(z) \sim z^{-1}$ selects this root. The root resolvent therefore equals

$$m(z) = \langle e_0, (z - T)^{-1} e_0\rangle = \frac{1}{z - (p+1)g(z)}.$$

For $|x| < 2\sqrt{p}$, substitution and Stieltjes inversion give

$$-\frac{1}{\pi}\operatorname{Im} m(x + i0) = \frac{(p+1)\sqrt{4p - x^2}}{2\pi((p+1)^2 - x^2)}.$$

There are no poles off this interval. A zero of the denominator would force $g^2 = 1$ and $z = \pm(p+1)$, whereas the chosen branch has $g(\pm(p+1)) = \pm p^{-1}$. At both endpoints the denominator is nonzero because $p > 1$. Thus m has continuous finite boundary values on the interval, including its endpoints, and analytic continuation across its complement. The inversion formula gives only the displayed absolutely continuous measure. Its total mass is one, since $m(z) \sim z^{-1}$. Changing variables $x = 2\sqrt{p}\cos\theta$ gives ν_p.

The spectral theorem now gives

$$\int R_n(x) R_m(x)\, d\nu_p = \langle R_n(T)e_0, R_m(T)e_0\rangle = s_n \delta_{nm}.$$

Hence the q_n are orthonormal. Polynomials are dense in continuous functions on the compact x interval and thus in its L^2 space. The monic R_n span all polynomials, so the q_n are complete. This proves that $\mathcal{U}_p$ is unitary. The recurrence proves intertwining first on finite sums and then everywhere by boundedness. The support of the measure is the full closed interval. Multiplication by x therefore has norm $2\sqrt{p}$. Bounded Borel functional calculus proves the state identity. □

27.7 HECKE OPERATIONS AND THE DISTINGUISHED STATE

For the Bruhat–Tits tree of $\mathrm{PGL}_2(\mathbb{Q}_p)$, vertices are homothety classes of $\mathbb{Z}_p$-lattices in $\mathbb{Q}_p^2$. Two vertices are adjacent when representatives satisfy $pL \subset L' \subset L$ with $[L : L'] = p$. The lines in L/pL give exactly $p+1$ neighbors. With the maximal compact subgroup of Haar volume one, its adjacency operator is the characteristic-function Hecke operator for $\mathrm{diag}(p, 1)$. Pullback to GL_2 fixes the central operator $\mathrm{diag}(p, p)$ to be the identity. Thus the representation has trivial central character.

Define $H_0(x) = 1$, $H_1(x) = x$ and $H_{k+1}(x) = xH_k(x) - pH_{k-1}(x)$ for $k \geq 1$. In the notation of Proposition 27.1.2, $H_k(T)$ represents H_{p^k} with $D_p = 1$. These are the complete-symmetric Satake elements in this central character. Their generating series and spectral values are

$$\sum_{k\geq 0} H_k(x)t^k = (1 - xt + pt^2)^{-1}, \qquad H_k(x(\theta)) = p^{k/2}\sum_{j=0}^{k} e^{i(k-2j)\theta}.$$

The second formula follows by multiplying the two geometric series with parameters $\sqrt{p}\,e^{i\theta}$ and $\sqrt{p}\,e^{-i\theta}$. It remains valid at $\theta = 0, \pi$, where the parameters coincide. The transform therefore intertwines every $H_k(T)$ with the stated multiplication operator, with the same cyclic state.

PROPOSITION 27.7.1 *(distance and symmetric-power elements).* Let $(D_n f)(v) = \sum_{d(v,w)=n} f(w)$ on the vertex Hilbert space. Then $D_n = R_n(T)$ and
