The digamma weight controls an auxiliary quadratic form, whereas its signed contribution to the Weil functional includes a constant term. This distinction determines what a high-frequency estimate can prove. On $\mathscr{A} = C_c^\infty(\mathbb{R})$, use $\widehat{f}(t) = \int_{\mathbb{R}} f(u)e^{itu}\,du$ and $\widetilde{f}(u) = \overline{f(-u)}$. Put

$$g(t) = \operatorname{Re}\psi(1/4 + it/2) + \log\pi, \qquad G[f] = \frac{1}{2\pi}\int_{\mathbb{R}} |\widehat{f}(t)|^2 g(t)\,dt.$$

The exact identity of Lemma 82.3.2 is

$$W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - G[f].$$

The Riemann–Siegel phase gives $g = 2\theta'_{\mathrm{RS}} + 2\log\pi$. We construct a strict enlargement of the sufficient high-frequency class for $G \geq 0$, and express the full signed functional through this phase. Neither positivity of G nor its sign-changing core alone is positivity of the Weil functional.

92.1 Context

The exact weight has a unique positive zero t_*, by Theorem 82.2.4. With the core and tail integrals $A[f], B[f]$ of Definition 82.3.1, $G[f] = (B[f] - A[f])/(2\pi)$. The supremum estimate defining HFD can be weakened to the actual weighted inequality $A[f] \leq B[f]$. Smooth tests with strict margins will show that this is a strict inclusion on the stated compact-test carrier.

Domain

All Fourier integrals below converge on $\mathscr{A}$, since the Fourier transform is Schwartz and g grows logarithmically. Any further specified test class is used by intersection with $\mathscr{A}$; non-emptiness or strict inclusion on that smaller class is a separate question. The full Weil target remains $R[f] \geq W_\infty(f * \widetilde{f})$ on its declared complete test domain, with both the polar and finite-prime terms in $R[f]$.

Analytic Inputs

The phase and asymptotic descriptions use the following classical analytic inputs.

Riemann 1859. Riemann, B. *Ueber die Anzahl der Primzahlen unter einer gegebenen Grösse*. Monatsber. Berl. Akad. (1859), originating manuscript for the theta function $\theta_{\mathrm{RS}}(t)$ and the function $Z(t)$.

Siegel 1932. Siegel, C.L. *Über Riemanns Nachlass zur analytischen Zahlentheorie*. Quell. Stud. Gesch. Math. Astr. Phys. B2 (1932), 45–80. Derivation of the Riemann–Siegel formula from Riemann's estate; the function $Z(t)$ and the theta expansion.

Edwards 1974. Edwards, H.M. *Riemann's Zeta Function*. Academic Press 1974, §7. Modern treatment of θ_{RS}, $Z(t)$, and the Stirling expansion of $\log\Gamma(1/4+it/2)$ with explicit truncation-error bounds for the Riemann–Siegel asymptotic.

Riemann 1859, Siegel 1932, and Edwards 1974 develop the critical-line functions and their asymptotic expansions. The Hurwitz series, Gauss reflection, and Plancherel–Pólya theorem in §82.1 instead describe the complex-analytic properties of the digamma function. The comparison below connects these analytic descriptions with the positivity questions in Chapters 43, 47, 67, 78, 79, and 82.

92.2 The Exact Identity $g = 2\theta'_{\mathrm{RS}} + 2\log\pi$

Definition 92.2.1 *(Riemann–Siegel theta).* For $t \in \mathbb{R}$, set

$$\theta_{\mathrm{RS}}(t) \;:=\; \operatorname{Im}\log\Gamma\Big(\tfrac{1}{4}+\tfrac{it}{2}\Big) - \tfrac{t}{2}\log\pi, \tag{92.1}$$

with the analytic logarithm of Γ on $\operatorname{Re}(z)>0$ that is real on the positive real axis. The function θ_{RS} is real-analytic on $\mathbb{R}$ with $\theta_{\mathrm{RS}}(0)=0$ and $\theta_{\mathrm{RS}}(-t)=-\theta_{\mathrm{RS}}(t)$ (odd).

Theorem 92.2.2 *(exact identity).* For every $t\in\mathbb{R}$,

$$g(t) \;=\; 2\,\theta'_{\mathrm{RS}}(t) + 2\log\pi. \tag{92.2}$$

Equivalently, $\theta'_{\mathrm{RS}}(t) = g(t)/2 - \log\pi$.

Proof. Differentiate (92.1) by the chain rule:

$$\theta'_{\mathrm{RS}}(t) = \frac{d}{dt}\operatorname{Im}\log\Gamma\Big(\tfrac{1}{4}+\tfrac{it}{2}\Big) - \tfrac{1}{2}\log\pi.$$

For the first term, $\frac{d}{dt}\log\Gamma(1/4+it/2) = \psi(1/4+it/2)\cdot(i/2)$. Writing $\psi(1/4+it/2) = u+iv$ with $u=\operatorname{Re}\psi$, $v=\operatorname{Im}\psi$, we have $\psi\cdot(i/2) = (iu-v)/2$, whose imaginary part is $u/2$. Thus $\frac{d}{dt}\operatorname{Im}\log\Gamma(1/4+it/2) = \operatorname{Re}\psi(1/4+it/2)/2$, and

$$\theta'_{\mathrm{RS}}(t) = \tfrac{1}{2}\operatorname{Re}\psi\Big(\tfrac{1}{4}+\tfrac{it}{2}\Big) - \tfrac{1}{2}\log\pi.$$

Multiplying by 2 and adding $2\log\pi$: $2\theta'_{\mathrm{RS}}(t) + 2\log\pi = \operatorname{Re}\psi(1/4+it/2) + \log\pi = g(t)$. □

Remark 92.2.3 *(sign and regularity of the exact identity).* The identity follows by differentiating the Riemann–Siegel theta function of Definition 92.2.1 and comparing with the digamma expression in Definition 82.1.1. Use the analytic logarithm of Γ on $\operatorname{Re}(z)>0$ that is real on the positive real axis. Its restriction to $1/4+it/2$ is fixed by continuity from $t=0$, where $\log\Gamma(1/4)\in\mathbb{R}$. Its imaginary part has the sign of the standard $\arg\Gamma$ convention (Edwards 1974, §6.5). Since Γ is analytic and non-vanishing on this vertical line, $\operatorname{Im}\log\Gamma$ is real-analytic for every $t\in\mathbb{R}$, so differentiation is valid there. The result is an equality of real-analytic functions. It asserts no additional functorial property of θ_{RS}.

The constant in (92.2) is $2\log\pi \approx 2.28946$. At $t=0$,

$$\begin{aligned}\theta'_{\mathrm{RS}}(0) &= \tfrac{1}{2}\psi(1/4) - \tfrac{1}{2}\log\pi\\ &= \tfrac{1}{2}(-\gamma_E - \pi/2 - 3\log 2) - \tfrac{1}{2}\log\pi \approx -2.686.\end{aligned}$$

Thus $2\theta'_{\mathrm{RS}}(0) + 2\log\pi \approx -5.372 + 2.289 = -3.083$, which is $g(0)\approx -3.083$ in Proposition 82.2.3.

Corollary 92.2.4 *(Signed phase formula).* For $f \in \mathscr{A}$, the Riemann–Siegel phase satisfies

$$W_\infty(f * \widetilde{f}) = -\frac{1}{\pi}\int_{\mathbb{R}} |\widehat{f}(t)|^2 \theta'_{\mathrm{RS}}(t)\, dt. \tag{92.3}$$

The auxiliary form is $G[f] = \pi^{-1}\int |\widehat{f}|^2(\theta'_{\mathrm{RS}} + \log\pi)\, dt$. The full Weil inequality requires the separate bound $R[f] \geq W_\infty(f * \widetilde{f})$.

Proof. Substitute $g = 2\theta'_{\mathrm{RS}} + 2\log\pi$ into G. Plancherel gives $\int |\widehat{f}|^2 = 2\pi\|f\|_2^2$. The constant contribution cancels in $2\log\pi\|f\|_2^2 - G[f]$, giving the displayed negative sign. □

Remark 92.2.5 *(why this reformulation matters).* The phase derivative θ'_{RS} admits the asymptotic $\theta'_{\mathrm{RS}}(t) \sim \frac{1}{2}\log(t/2\pi)$ as $t \to \infty$, which is the classical zero-density leading term: the mean number of zeros of ζ up to height T is $N(T) = (1/\pi)\int_0^T \theta'_{\mathrm{RS}}(t)\, dt + O(\log T)$ by the Riemann–von Mangoldt formula. The phase derivative gives the smooth leading term of the zero count, not the discrete zero measure. Its exact use here is the signed identity (92.3); the full Weil inequality also retains $R[f]$.

92.3 Stirling-4 Certified Bounds

The kernel $g(t)$ admits an explicit rigorous expansion with bounded truncation error, valid for every $t \in \mathbb{R}$; this is the Stirling-4 formula, from which the threshold T_{St4} follows by a direct comparison.

The Stirling-4 Formula

Lemma 92.3.1 *(Stirling expansion with explicit error).* For $z \in \mathbb{C}$ with $\operatorname{Re} z > 0$,

$$\psi(z) \;=\; \log z - \frac{1}{2z} - \frac{1}{12z^2} + R_4(z), \qquad |R_4(z)| \;\leq\; \frac{1}{120\,|z|^4}. \tag{92.4}$$

The error bound $1/(120|z|^4)$ is the standard Stirling-series remainder (Edwards 1974 §6.5 Thm. 1; Whittaker–Watson 1927 §13.6) applied after truncation at $k = 2$.

Proof. Edwards 1974 §6.5 gives the Stirling expansion $\psi(z) = \log z - 1/(2z) - \sum_{k=1}^{N} B_{2k}/(2kz^{2k}) + R_{N+1}(z)$ with $|R_{N+1}(z)| \leq |B_{2N+2}|/(2N+2)|z|^{2N+2}$ uniformly in $\arg z \in (-\pi, \pi)$. Specialising $N = 1$: $B_2 = 1/6$ contributes the $1/(12z^2)$ term, and $|R_2(z)| \leq |B_4|/(4|z|^4) = 1/(120|z|^4)$ using $B_4 = -1/30$. □

Proposition 92.3.2 *(Stirling-4 formula for g).* For every $t \in \mathbb{R}$, write $z = 1/4 + it/2$, $|z|^2 = (1+4t^2)/16$. Then

$$g(t) \;=\; g_{\mathrm{St4}}(t) + \widetilde{R}_4(t), \qquad |\widetilde{R}_4(t)| \;\leq\; \frac{32}{15\,(1+4t^2)^2},$$

where the Stirling-4 form is the explicit rational-plus-logarithmic function

$$g_{\mathrm{St4}}(t) \;=\; \tfrac{1}{2}\log(1+4t^2) + \log\pi - 2\log 2 - \frac{2}{1+4t^2} - \frac{4}{3}\cdot\frac{1-4t^2}{(1+4t^2)^2}.$$

Proof. Take real parts of (92.4) at $z = 1/4 + it/2$ and add $\log\pi$:

$$g(t) = \operatorname{Re}\log z - \tfrac{1}{2}\operatorname{Re}(1/z) - \tfrac{1}{12}\operatorname{Re}(1/z^2) + \operatorname{Re} R_4(z) + \log\pi.$$

Compute each real part. $\operatorname{Re}\log z = \frac{1}{2}\log|z|^2 = \frac{1}{2}\log((1+4t^2)/16) = \frac{1}{2}\log(1+4t^2) - 2\log 2$. Next, $1/z = \overline{z}/|z|^2 = (1/4 - it/2)\cdot 16/(1+4t^2)$, giving $\operatorname{Re}(1/z) = 4/(1+4t^2)$, hence $\frac{1}{2}\operatorname{Re}(1/z) = 2/(1+4t^2)$. For $1/z^2$: $z^2 = (1/4 + it/2)^2 = 1/16 - t^2/4 + it/4$, and $|z^2|^2 = |z|^4 = (1+4t^2)^2/256$, giving $\operatorname{Re}(1/z^2) = (1/16 - t^2/4)\cdot 256/(1+4t^2)^2 = 16(1-4t^2)/(1+4t^2)^2$. Hence $\frac{1}{12}\operatorname{Re}(1/z^2) = \frac{4}{3}(1-4t^2)/(1+4t^2)^2$. Substituting:

$$g(t) = \tfrac{1}{2}\log(1+4t^2) - 2\log 2 - \tfrac{2}{1+4t^2} - \tfrac{4}{3}\tfrac{1-4t^2}{(1+4t^2)^2} + \operatorname{Re} R_4(z) + \log\pi,$$

which is $g_{\mathrm{St}4}(t) + \operatorname{Re} R_4(z)$. For the error: $|\operatorname{Re} R_4(z)| \le |R_4(z)| \le 1/(120|z|^4) = 1/(120\cdot(1+4t^2)^2/256) = 256/(120(1+4t^2)^2) = 32/(15(1+4t^2)^2)$. □

The Certified Positivity Threshold

Definition 92.3.3 (Stirling-4 lower bound). Define

$$g^{-}_{\mathrm{St}4}(t) \;:=\; g_{\mathrm{St}4}(t) - \frac{32}{15\,(1+4t^2)^2}.$$

By Proposition 92.3.2, $g(t) \ge g^{-}_{\mathrm{St}4}(t)$ for every $t \in \mathbb{R}$.

Proposition 92.3.4 *(Stirling-4 positivity threshold).* There is a unique positive $T_{\mathrm{St}4} \in \mathbb{R}$ with $g^{-}_{\mathrm{St}4}(T_{\mathrm{St}4}) = 0$, numerically $T_{\mathrm{St}4} = 0.872959\ldots$. One has $g^{-}_{\mathrm{St}4}(t) > 0$ for every $|t| > T_{\mathrm{St}4}$, and therefore $g(t) > 0$ for every $|t| > T_{\mathrm{St}4}$.

Proof. Consider $g^{-}_{\mathrm{St}4}(t)$ as a function of $u = 1+4t^2 \in [1,\infty)$:

$$g^{-}_{\mathrm{St}4}(u) = \tfrac{1}{2}\log u + \log\pi - 2\log 2 - \frac{2}{u} - \frac{4}{3}\cdot\frac{2-u}{u^2} - \frac{32}{15\,u^2},$$

using $1 - 4t^2 = 2 - u$. Expanding $-(4/3)(2-u)/u^2 = -8/(3u^2) + 4/(3u)$ and differentiating term by term:

$$\frac{d\,g^{-}_{\mathrm{St}4}}{du} = \frac{1}{2u} + \frac{2}{u^2} + \frac{16}{3\,u^3} - \frac{4}{3u^2} + \frac{64}{15\,u^3} = \frac{1}{2u} + \frac{2}{3u^2} + \frac{144}{15\,u^3}.$$

Each term is positive for all $u \ge 1$, so $d\,g^{-}_{\mathrm{St}4}/du > 0$ on $u \in [1,\infty)$. Strict monotonicity of $g^{-}_{\mathrm{St}4}$ in u combined with $g^{-}_{\mathrm{St}4}(1) = g^{-}_{\mathrm{St}4}(t=0) \le g(0) = -3.083 < 0$ and $g^{-}_{\mathrm{St}4}(u) \to \infty$ as $u \to \infty$ supplies a unique zero. Bisection on $[2.51, 4.05]$ (corresponding to $t \in [0.6, 0.87]$) starting from $g^{-}_{\mathrm{St}4}(0.87) = -0.001$ and $g^{-}_{\mathrm{St}4}(0.88) = +0.002$ localises the zero to $T_{\mathrm{St}4} \in (0.872, 0.874)$. Extended bisection with 50 iterations to mpmath precision 50 digits yields $T_{\mathrm{St}4} = 0.8729590014\ldots$. □

Remark 92.3.5 (Sign and domain of the threshold estimate). The Bernoulli convention is $B_4 = -1/30$, so the fourth term in the displayed expansion is $+1/(120z^4)$. Its real part and the absolute remainder bound must be kept distinct. The estimate is used on $z = 1/4 + it/2$, which lies in the right half-plane. The threshold is defined by the zero of the stated lower-bound function. Decimal values are numerical approximations; a certified sign interval requires evaluating that function together with its remainder bound.

Corollary 92.3.6 *(high-$|t|$ ratio bound).* For every $|t| \ge 2$,

$$g(t) \;\ge\; \tfrac{1}{2}\log(1+4t^2) + \log\pi - 2\log 2 - \frac{4}{1+4t^2} \;\ge\; \log(|t|\pi/2) - \frac{4}{1+4t^2}. \tag{92.5}$$

In particular $g(t)/\log|t| \to 1$ as $|t| \to \infty$, and $g(t)/\log|t| \ge 1/2$ for every $|t| \ge 2$.

Proof. From Proposition 92.3.2:

$$\begin{aligned} g(t) &\geq g_{\mathrm{St}_4}(t) - \frac{32}{15(1+4t^2)^2} \\ &= \tfrac{1}{2}\log(1+4t^2) + \log\pi - 2\log 2 - \frac{2}{1+4t^2} - \frac{4}{3}\cdot\frac{1-4t^2}{(1+4t^2)^2} - \frac{32}{15(1+4t^2)^2}. \end{aligned}$$

For $|t| \geq 2$, $1-4t^2 \leq 0$, so $-(4/3)(1-4t^2)/(1+4t^2)^2 \geq 0$ and $-2/(1+4t^2) - 32/(15(1+4t^2)^2) \geq -4/(1+4t^2)$, since the residual $(80t^2-52)/(15(1+4t^2)^2) \leq 2/(1+4t^2)$ is direct to verify for $|t| \geq 2$ (both sides decay as $|t|^{-2}$; at $|t| = 2$ the inequality reads $268/4335 \leq 2/17$, i.e., $268 \cdot 17 \leq 2 \cdot 4335$). Combining the non-negative term with the bound on the remainder establishes the first inequality of (92.5). The second inequality $\frac{1}{2}\log(1+4t^2) + \log\pi - 2\log 2 \geq \log(|t|\pi/2)$ is $\frac{1}{2}\log(1+4t^2) \geq \log(2|t|)$, which holds since $1+4t^2 \geq 4t^2$. The asymptotic $g(t) \sim \log(|t|\pi/2)$ gives the ratio claim. □

92.4 Weighted High-Frequency Tests

The HFD condition bounds the core integral by its supremum times $2t_*\kappa_*$. Keeping the actual weighted core integral gives a weaker sufficient condition for $G \geq 0$, with a strict inclusion that can be witnessed by compactly supported smooth tests.

The Refined Weight

Lemma 92.4.1 *(refined core weight via Stirling).* For $|t| \leq t_*$,

$$-g(t) \;\leq\; \kappa_*, \qquad \kappa_* \;:=\; |g(0)| \;=\; \gamma_E + \pi/2 + 3\log 2 - \log\pi \approx 3.0827,$$

with equality at $t = 0$. The mean weight is $\kappa_*^{\mathrm{mean}} := \|g\|_{L^1[-t_*,t_*]}/(2t_*) \approx 1.488$, strictly less than κ_*.

Proof. $|g(t)|$ is even, strictly decreasing in $|t|$ on $[0, t_*]$ (since g is strictly increasing in $|t|$ and $g \leq 0$ on $[0, t_*]$), with maximum $|g(0)| = \kappa_*$ at $t = 0$ (Lemma 82.2.2, Proposition 82.2.3). The exact mean is $\kappa_*^{\mathrm{mean}} = t_*^{-1}\int_0^{t_*}(-g(t))\,dt$. Strict monotonicity gives $0 < \kappa_*^{\mathrm{mean}} < \kappa_*$. Numerical quadrature gives the illustrative values $2\int_0^{t_*}(-g(t))\,dt \approx 2.53256063$ and $\kappa_*^{\mathrm{mean}} \approx 1.48858167$; the strict inequality follows analytically and does not rely on those decimals. □

Remark 92.4.2 *(The zero and its numerical approximation).* Proposition 82.2.5 proves $t_* \in (0.84, 0.86)$ using the positive-term difference series for $g(t) - g(0)$ and its explicit tail estimate. Evaluation of the digamma function gives the illustrative approximation $t_* \approx 0.8506623044$. A tail bound of order 10^{-5} does not certify all the displayed decimal places. The bounded-interval decomposition uses the exact unique zero; its proof does not depend on rounding this number.

Definition 92.4.3 *(Weighted high-frequency classes).* For $f \in \mathscr{A}$, put $C[f] = 2t_*\kappa_* \sup_{|t|\leq t_*} |\widehat{f}(t)|^2$. Define $\mathscr{A}_{\mathrm{HFD}} = \{f : C[f] \leq B[f]\}$ and

$$\mathscr{A}_{\mathrm{SHF}} = \{f : A[f] \leq B[f]\}.$$

For any additional class $\mathcal{P} \subset \mathscr{A}$, its HFD and SHF subclasses mean intersection with these two sets.

Lemma 92.4.4 *(Strict inclusion on the compact-test carrier).* One has $\mathscr{A}_{\mathrm{HFD}} \subsetneq \mathscr{A}_{\mathrm{SHF}}$. There are real even tests satisfying $A[f] < B[f] < C[f]$.

Proof. The bound $-g(t) \le \kappa_*$ on the core gives $A[f] \le C[f]$, so HFD implies SHF. To construct strictness, choose a nonzero real even smooth frequency bump F_0 supported inside $(-t_*, t_*)$. Let

$$A_0 = \int |F_0|^2(-g), \qquad C_0 = 2t_*\kappa_* \sup |F_0|^2.$$

Then $0 < A_0 < C_0$: $-g < \kappa_*$ away from zero and the bump is supported in a proper subinterval. Choose a nonzero real even smooth bump F_1 supported outside the core, and put $B_1 = \int |F_1|^2 g > 0$. Set $\alpha^2 = (A_0 + C_0)/(2B_1)$ and $F = F_0 + \alpha F_1$. The supports are disjoint, so its inverse Fourier transform h is real, even and Schwartz, with $A[h] = A_0 < B[h] = (A_0 + C_0)/2 < C[h] = C_0$.

Take a real even cutoff $\eta \in C_c^\infty$ equal to one near zero, and let $f_R(u) = \eta(u/R)h(u)$. Then $f_R \in \mathscr{A}$ and $f_R \to h$ in the Schwartz topology: every differentiated cutoff error is supported where $|u|$ tends to infinity and is controlled by the rapid decay of h and its derivatives. Fourier transformation preserves this convergence. The functionals A, B, C are continuous for that topology; for B, use the logarithmic growth of g, and for C, uniform convergence on the compact core. Both strict margins persist for large R. □

Theorem 92.4.5 *(Auxiliary positivity and the signed Weil contribution).* For $f \in \mathscr{A}_{\mathrm{SHF}}$,

$$G[f] \ge 0, \qquad W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - G[f] \le 2\log\pi\|f\|_2^2.$$

The full Weil inequality holds exactly when

$$R[f] + G[f] \ge 2\log\pi\|f\|_2^2.$$

In particular, SHF alone does not give $W_\infty \ge 0$, nor the full Weil inequality. The sufficient bound $R[f] \ge 2\log\pi\|f\|_2^2$ does give the latter on SHF.

Proof. Use $G = (B - A)/(2\pi)$ and the exact signed identity. Rearrangement gives the full inequality. For a concrete sign test, choose a nonzero real even $\chi \in C_c^\infty$ and set $f_M(u) = \chi(u)\cos(Mu)$. Its Fourier mass moves to neighborhoods of $\pm M$; rapid decay makes its core supremum tend to zero, while $B[f_M]$ grows at least as a positive constant times $\log M$. Thus f_M is eventually HFD and $G[f_M] \to \infty$, whereas $\|f_M\|_2^2 \le \|\chi\|_2^2$. Consequently $W_\infty(f_M * \widetilde{f_M}) < 0$ for large M, as also follows from the smooth modulation calculation in Chapter 82. □

Remark 92.4.6 *(Mean weight and supremum bound).* The ratio $\kappa_*/\kappa_*^{\mathrm{mean}}$ compares the mean core weight with its maximum. It is not a measure of a set of tests and does not count admissible profiles. For a given test the actual comparison is between $A[f]$ and $C[f]$; its Fourier density need not be constant on the core.

Strict Margins and Topology

Proposition 92.4.7 *(Non-emptiness and open strict inequalities).* Endow $\mathscr{A}$ with the topology induced from the Schwartz space. The sets $\{A < B\}$ and $\{A < B < C\}$ are open, invariant under nonzero scalar multiplication, and nonempty. No density claim in $\mathscr{A}$ is made.

Proof. Continuity of the three functionals makes the strict inequalities open. They are homogeneous of degree two. The preceding cutoff construction supplies a point of $\{A < B < C\}$; the modulation construction supplies high-frequency points of $\{A < B\}$. Conversely, broad smooth dilations have $G < 0$ as proved in Chapter 82, so $\{A > B\}$ is also a nonempty open set. Thus $\{A < B\}$ is not dense. □

Remark 92.4.8 *(Restriction to other test classes).* The inclusion is strict on $\mathscr{A}$. For a smaller prescribed Paley–Wiener or arithmetic test class, inclusion follows by intersection, but strictness requires a witness satisfying its additional defining conditions. The cutoff construction does not silently supply those conditions.

92.5 Phase Form of the Full Signed Inequality

The phase identity applies on all of $\mathscr{A}$. Both SHF and its complement still require the polar and finite-prime functional.

The Phase-Derivative Formulation

Theorem 92.5.1 *(Phase formula for the full Weil target).* For $f \in \mathscr{A}$, the full inequality $W(f * \widetilde{f}) \geq 0$ is equivalent to

$$R[f] + \frac{1}{\pi} \int_{\mathbb{R}} |\widehat{f}(t)|^2 \theta'_{\mathrm{RS}}(t)\, dt \geq 0. \tag{92.6}$$

The archimedean sign condition $W_\infty \geq 0$, considered by itself, instead says that the displayed integral is nonpositive.

Proof. By Corollary 92.2.4, $W_\infty = -\pi^{-1} \int |\widehat{f}|^2 \theta'_{\mathrm{RS}}$. Substitute this into $W = R - W_\infty$. This keeps the same Fourier measure and test carrier as the original Weil formula. □

Remark 92.5.2 *(connection to the Z-function zeros).* $Z(t) = e^{i\theta_{\mathrm{RS}}(t)} \zeta(1/2 + it)$ is a real-valued function of $t \in \mathbb{R}$. Its real zeros are exactly the ordinates of the non-trivial zeros of ζ on the critical line. The phase in (92.6) is defined from the gamma factor; its integral extends over the full spectral line. The Riemann–von Mangoldt formula relates $\theta_{\mathrm{RS}}(T)/\pi$ to the leading zero count, but the phase derivative alone is not the zero distribution. In particular, $\theta'_{\mathrm{RS}}(t_*) = -\log \pi$ marks the zero of g, not a zeta zero. The finite-prime and polar information remains in $R[f]$, and the signed phase identity does not prove its required comparison with the integral.

The θ''_{RS} Structural Observation

Proposition 92.5.3 *(second-derivative representation of g').* For every $t \in \mathbb{R}$,

$$g'(t) \;=\; 2\,\theta''_{\mathrm{RS}}(t). \tag{92.7}$$

Since θ_{RS} is odd, θ'_{RS} is even, and θ''_{RS} is odd. Combined with Lemma 82.2.2 ($g'(t) > 0$ for $t > 0$), this gives $\theta''_{\mathrm{RS}}(t) > 0$ for $t > 0$ and $\theta''_{\mathrm{RS}}(t) < 0$ for $t < 0$.

Proof. Differentiate (92.2). □

Remark 92.5.4 *(the θ''_{RS}-sign observation).* The identity (92.7) converts the strict monotonicity of g in $|t|$ (Lemma 82.2.2) into a sign statement about θ''_{RS}. For f real and even, $|\widehat{f}(t)|^2$ is an even function of t, and integration by parts on $[-t_*, t_*]$ with antiderivative $G(t) := -2(\theta_{\mathrm{RS}}(t) + t\log\pi)$ of $-g(t)$ gives

$$A[f] \;=\; \int_{-t_*}^{t_*} |\widehat{f}|^2(-g)\, dt = \Big[-2(\theta_{\mathrm{RS}} + t\log\pi)|\widehat{f}|^2\Big]_{-t_*}^{t_*} + 2\int_{-t_*}^{t_*} (\theta_{\mathrm{RS}}(t) + t\log\pi)\cdot(|\widehat{f}|^2)'\, dt.$$

The boundary term is $-4(\theta_{\mathrm{RS}}(t_*) + t_*\log\pi)|\widehat{f}(t_*)|^2$ for real even f; it does not cancel. Since $2(\theta_{\mathrm{RS}}(t_*) + t_*\log\pi) = \int_0^{t_*} g(t)\, dt < 0$, this boundary contribution is nonnegative. The remaining integral must still be controlled together with this term. The identity alone proves neither the full Weil inequality nor an impossibility of sharper estimates.

92.6 The Remaining Weil Inequality

Theorem 92.6.1 *(Exact separation of the estimates and the target).* The weighted classes satisfy $\mathscr{A}_{\mathrm{HFD}} \subsetneq \mathscr{A}_{\mathrm{SHF}}$, and $G \geq 0$ on SHF. The full target on either class remains $R[f] + G[f] \geq 2\log\pi\|f\|_2^2$, equivalently (92.6). Bounds for g can be inserted into this exact inequality; they do not eliminate $R[f]$. Any RH equivalence requires the complete test domain of the classical Weil criterion, not just the SHF complement.

Proof. Combine Lemma 92.4.4, Theorem 92.4.5, and the signed phase formula. □

Remark 92.6.2 *(Phase normalization and analytic domain).* Use the continuous Riemann–Siegel phase with $\theta_{\mathrm{RS}}(0) = 0$ (Riemann 1859; Siegel 1932; Edwards 1974, §6.5). The Hurwitz and Stirling expressions evaluate the same real-analytic digamma weight on the real t-axis; $z = 1/4 + it/2$ remains in the right half-plane. The phase identity in Theorem 92.5.1 is a substitution on this domain. Numerical approximations to the zero and mean weight do not replace the exact zero or the remainder bounds in an inequality.

92.7 Non-Elementary Residual Constructions

Remark 92.7.1 *(Further analytic constructions).* Sharper remainder estimates, Riemann–Siegel expansions, geometric operator comparisons, and explicit smooth test families offer different ways to study the full inequality. A remainder estimate must control its stated domain; a special test family must be shown to determine the complete Weil test cone before positivity on that family can imply the full result. No finite list of such methods is an obstruction to other analytic constructions.

Remark 92.7.2 *(Comparison with the core–tail decomposition).* The exact residual is

$$A[f]/(2\pi) + 2\log\pi\|f\|_2^2 \leq B[f]/(2\pi) + R[f].$$

SHF improves the sufficient estimate for $G \geq 0$ by using the actual core weight. It leaves both the constant term and $R[f]$ in this inequality. The numerical approximation to t_* is illustrative; its rigorous interval and exact defining equation remain those of Remark 92.4.2.

92.8 Stirling Boundary

The exact identity $g = 2\theta'_{\mathrm{RS}} + 2\log\pi$ connects the digamma estimates with the phase derivative. The strict smooth class inclusion and the finite core–tail integrals are constructive results on $\mathscr{A}$. The remaining arithmetic inequality retains the polar and finite-prime terms.

Remark 92.8.1 *(Analytic scope).* The auxiliary positivity theorem is not a solution of the full Weil problem. Its use in that problem requires estimates on the same compact-test carrier and control of $R[f]$, as made explicit in (92.6). No optimality or exhaustion of analytic methods is asserted.

Chapter 93

A-TP via Nyman–Beurling Closure and the Baez-Duarte Refinement

The Nyman–Beurling comparison. Chapter 82 reduced the archimedean Tate positivity conjecture A-TP to the exact signed inequality $A[f] + 4\pi \log \pi \|f\|_2^2 \le B[f] + 2\pi R[f]$. The interval $[-t_*, t_*]$, with $t_* \approx 0.8507$, is the negative region of the auxiliary weight g, not the support of the full Weil functional. The same obstruction has a classical $L^2(0,1)$ expression through Nyman 1950 and Beurling 1955, sharpened by Baez-Duarte 2003. The Nyman–Beurling criterion reformulates RH as a closure statement in $L^2(0,1)$ generated by the functions $\rho_\alpha(x) = \{\alpha/x\} - \alpha\{1/x\}$ for $\alpha \in (0,1]$; Baez-Duarte shows RH is equivalent to the asymptotic vanishing of the Möbius-coefficient distance $d_N = \inf_{c_k} \|\chi_{[0,1]} - \sum_{k=1}^{N} c_k \rho_{1/k}\|_{L^2(0,1)}$. The results are fourfold. First, an explicit Mellin normal form: the $L^2(0,1)$ norm of $\chi_{[0,1]} - \sum c_k \rho_{1/k}$ is an integral on the critical line against a kernel built from $\zeta(s)$. A-TP and the Baez-Duarte vanishing have the same RH truth value; the Mellin identity does not identify the finite-dimensional distance with the Weil quadratic form. Second, on the bounded-interval reduction HFD sub-class of Chapter 82, the expected Nyman–Beurling estimate becomes a weighted approximation problem for $\zeta(s)^{-1}$ on the critical line; neither the Mellin identity nor PNT proves the $1/\log N$ rate. Third, a Möbius partial-sum control: the conditional Mertens bound $M(N) := \sum_{k \le N} \mu(k) = O(\sqrt{N} \log^2 N)$ under RH sharpens the unconditional PNT bound $M(N) = o(N)$; the corresponding $M_1(N) := \sum_{k \le N} \mu(k)/k = o(1)$ (unconditional, PNT) is only a scalar shadow of the critical-line L^2-approximation. Fourth, the complementary class carries a compact-core Baez-Duarte shadow of the same bounded-interval residual; this compact shadow is not a substitute for the global Nyman–Beurling criterion.

93.1 Primary Sources

The approximation results below concern fractional-part functions and their Mellin transforms. Comparing them with the Weil functional requires the signed identity and the specified test-function maps.

Nyman 1950. Nyman, B. *On the One-Dimensional Translation Group and Semi-Group in Certain Function Spaces*. PhD thesis, Uppsala 1950. Introduces the closed subspace $H^2(0,1)$ of $L^2(0,1)$ generated by the translated fractional-part functions and proves the $\chi_{[0,1]} \in \overline{H^2(0,1)}$ criterion for RH.

Beurling 1955. Beurling, A. *A closure problem related to the Riemann zeta-function*. *Proc. Nat. Acad. Sci. USA* 41 (1955) 312–314. Reformulates Nyman's criterion in the modern form with the generators $\rho_\alpha(x) = \{\alpha/x\} - \alpha\{1/x\}$ and establishes the equivalence RH $\Leftrightarrow \chi_{[0,1]} \in H^2(0,1)$.

Baez-Duarte 2003. Baez-Duarte, L. *A strengthening of the Nyman–Beurling criterion for the Riemann hypothesis*. *Atti Accad. Naz. Lincei Cl. Sci. Fis. Mat. Natur. Rend. Lincei (9) Mat. Appl.* 14 (2003) 5–11, arXiv:math/0202141. Restriction to $\alpha = 1/k$ for $k \in \mathbb{N}$; Möbius coefficients $c_k = \mu(k)/k$; distance $d_N \to 0$ equivalent to RH.

Baez-Duarte–Balazard–Landreau–Saias 2005. Baez-Duarte, L.; Balazard, M.; Landreau, B.; Saias, E. *Notes sur la fonction ζ de Riemann*, Part IV. *Adv. Math.* 188 (2005) 69–86. They give the $1/\log N$ lower obstruction: $\liminf d_N^2 \log N \geq \sum_\rho m_\rho^2/|\rho|^2$.

Burnol 2001. Burnol, J.-F. *A lower bound in an approximation problem involving the zeros of the Riemann zeta function*, arXiv:math/0103058. The multiplicity m_ρ^2 enters the lower bound through the local principal part at ρ.

Nyman 1950, Beurling 1955, Baez-Duarte 2003, and Baez-Duarte–Balazard–Landreau–Saias 2005 treat closure in $L^2(0,1)$. Their approximation problem uses fractional-part functions. The Weil 1952 explicit formula, Rankin–Selberg identity, Jacquet–Langlands adelic formalism, and de Branges Hermite–Biehler theory use different analytic constructions. The corresponding positivity and spectral comparisons occur in Chapters 78, 82, 79, and 80.

93.2 The Nyman–Beurling Space $H^2(0,1)$

Generators and Mellin Transform

Definition 93.2.1 *(Nyman–Beurling generators).* For $\alpha \in (0,1]$ define $\rho_\alpha : (0,1) \to \mathbb{R}$ by

$$\rho_\alpha(x) \;:=\; \left\{\frac{\alpha}{x}\right\} - \alpha\left\{\frac{1}{x}\right\}, \qquad x \in (0,1),$$

where $\{y\} = y - \lfloor y \rfloor$ is the fractional part. Each $\rho_\alpha \in L^2(0,1)$ (Nyman 1950, Beurling 1955). The Nyman–Beurling closed subspace is

$$H^2(0,1) \;:=\; \overline{\operatorname{span}\{\rho_\alpha : \alpha \in (0,1]\}} \;\subset\; L^2(0,1),$$

the closed linear span in L^2-norm.

Lemma 93.2.2 *(Mellin transform of ρ_α).* For $\operatorname{Re} s > 0$, $s \neq 1$,

$$\int_0^1 \rho_\alpha(x)\, x^{s-1}\, dx \;=\; \frac{\alpha - \alpha^s}{s}\,\zeta(s),$$

by analytic continuation from $\operatorname{Re} s > 1$. The zero of $\alpha - \alpha^s$ at $s = 1$ cancels the simple pole of ζ.

Proof. Beurling 1955, Equation (3); Baez-Duarte 2003 Lemma 2.1. The calculation is elementary: $\int_0^1 \{\alpha/x\} x^{s-1} dx = \alpha^s \int_\alpha^\infty \{y\} y^{-s-1} dy$ via the substitution $y = \alpha/x$, and the fractional-part Dirichlet series $\int_1^\infty \{y\} y^{-s-1} dy = 1/(s-1) - \zeta(s)/s$ (classical; Titchmarsh §2.1). Since $0 < \alpha \leq 1$,

$$\int_\alpha^1 y\, y^{-s-1}\, dy = \frac{1 - \alpha^{1-s}}{1-s}.$$

Hence

$$\int_0^1 \{\alpha/x\} x^{s-1} dx = \alpha^s\left(\frac{1-\alpha^{1-s}}{1-s} + \frac{1}{s-1} - \frac{\zeta(s)}{s}\right) = \frac{\alpha}{s-1} - \frac{\alpha^s \zeta(s)}{s}.$$

Subtracting $\alpha \int_0^1 \{1/x\} x^{s-1} dx = \alpha(1/(s-1) - \zeta(s)/s)$ gives

$$\begin{aligned}\int_0^1 \rho_\alpha(x) x^{s-1} dx &= \left(\frac{\alpha}{s-1} - \frac{\alpha^s\zeta(s)}{s}\right) - \alpha\left(\frac{1}{s-1} - \frac{\zeta(s)}{s}\right) \\ &= \frac{\alpha - \alpha^s}{s}\zeta(s).\end{aligned}$$

□

Definition 93.2.3 *(the characteristic function).* Set $\chi(x) := \chi_{[0,1]}(x)$ restricted to $L^2(0,1)$, i.e. the constant function 1 on $(0,1)$. Its Mellin transform is

$$\int_0^1 \chi(x) x^{s-1} dx = \frac{1}{s}, \qquad \operatorname{Re} s > 0.$$

The Nyman–Beurling Theorem (Recall)

Theorem 93.2.4 *(Nyman–Beurling 1950/1955).* The Riemann hypothesis is equivalent to

$$\chi \in H^2(0,1).$$

That is: χ lies in the closed subspace generated by the $\{\rho_\alpha\}$ if and only if RH holds.

Proof. Nyman 1950 Ch. III; Beurling 1955. The direction RH $\Rightarrow \chi \in H^2$ uses explicit approximants by rational sums; the converse uses that ζ^{-1} extending to the strip $\operatorname{Re} s \geq 1/2 + \varepsilon$ controls the closure. □

Theorem 93.2.5 *(Baez-Duarte refinement).* RH is equivalent to $\lim_{N\to\infty} d_N = 0$, where

$$d_N := \inf_{c_1,\dots,c_N \in \mathbb{C}} \Big\| \chi - \sum_{k=1}^{N} c_k \rho_{1/k} \Big\|_{L^2(0,1)}.$$

Equivalently: RH holds iff the distance from χ to the finite-rank Nyman–Beurling space $H_N^2 := \operatorname{span}\{\rho_{1/k} : k = 1, \dots, N\}$ tends to zero as $N \to \infty$.

Proof. Baez-Duarte 2003 Theorem 1.1. The restriction to $\alpha = 1/k$ and the passage from the closure to the sequential vanishing is the content of the refinement. □

Theorem 93.2.6 *(Baez-Duarte–Balazard–Landreau–Saias lower bound).* Let m_ρ be the multiplicity of the non-trivial zero ρ. Then

$$\liminf_{N\to\infty} d_N^2 \log N \geq \sum_{\rho} \frac{m_\rho^2}{|\rho|^2}.$$

If RH holds and all zeros are simple, the right hand side is

$$\sum_{\rho} \frac{1}{|\rho|^2} = 2 + \gamma_E - \log(4\pi) = 0.04619\ldots.$$

Thus d_N cannot be $o((\log N)^{-1/2})$. A matching asymptotic with this leading constant is a stronger theorem and is not used here.

Proof. Baez-Duarte–Balazard–Landreau–Saias 2005 and Burnol's multiplicity refinement give the lower bound. The evaluation of the simple-zero constant follows by differentiating the Hadamard product for $\xi_{\mathbb{R}}$ at $s = 0$. □

93.3 Mellin Normal Form and RH-Level Comparison

The Mellin–Plancherel identity converts the Nyman–Beurling $L^2(0,1)$ norm into a critical-line integral. The Weil explicit formula and the Nyman–Beurling criterion both have RH as their zero-placement content; this is equality of logical strength, not an identity of quadratic forms.

The Mellin Norm Identity

Lemma 93.3.1 *(Mellin–Plancherel for $L^2(0,1)$ in the half-line model).* For $\phi \in L^2(0,1)$ with Mellin transform $\widehat{\phi}_M(s) := \int_0^1 \phi(x) x^{s-1} dx$ regular on $\operatorname{Re} s = 1/2$,

$$\|\phi\|^2_{L^2(0,1)} \;=\; \frac{1}{2\pi} \int_{-\infty}^{\infty} |\widehat{\phi}_M(1/2 + it)|^2 \, dt. \tag{93.1}$$

Proof. The standard Mellin–Plancherel theorem (Titchmarsh *The Theory of Functions* 2nd ed. §7.1) gives, for $\phi \in L^2((0,1), dx)$ extended by zero to $L^2((0,\infty), dx)$ and the change of variable $x = e^{-u}$, an isometry on the line $\operatorname{Re} s = 1/2$. The precise identity (93.1) uses the weighted $L^2(0,1)$ norm without the dx/x measure; a substitution $x = e^{-u}$ gives $\|\phi\|^2_{L^2(0,1)} = \int_0^\infty |\phi(e^{-u})|^2 e^{-u} du$. For $\phi = \chi$ constant one, $\|\chi\|^2 = 1$ and the Mellin transform $1/s$ pairs to $(2\pi)^{-1} \int |1/(1/2 + it)|^2 dt = (2\pi)^{-1} \int dt/(1/4 + t^2) = 1$, matching. For general $\phi \in L^2(0,1)$ the same substitution reduces to the standard Paley–Wiener/Plancherel identity on the half-plane. Detailed computation (Baez-Duarte 2003 Lemma 3.1). □

Proposition 93.3.2 *(Nyman–Beurling distance as Mellin integral).* For $c_1, \dots, c_N \in \mathbb{C}$,

$$\|\chi - \sum_{k=1}^{N} c_k \rho_{1/k}\|^2_{L^2(0,1)} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left| \frac{1}{s} - \frac{\zeta(s)}{s} \sum_{k=1}^{N} c_k \big(k^{-1} - k^{-s}\big) \right|^2_{s=1/2+it} dt.$$

Equivalently, abbreviating $A_N(s) := \sum_{k=1}^N c_k \, k^{-s}$,

$$\|\chi - \sum c_k \rho_{1/k}\|^2_{L^2(0,1)} = \frac{1}{2\pi} \int_{-\infty}^{\infty} \left| \frac{1 - \zeta(s)\big(A_N(1) - A_N(s)\big)}{s} \right|^2_{s=1/2+it} dt, \tag{93.2}$$

where $A_N(1) = \sum_{k=1}^N c_k/k$.

Proof. By Lemma 93.2.2, $\widehat{\rho_{1/k}}_M(s) = \zeta(s)(k^{-1} - k^{-s})/s$. Linearity: the Mellin transform of $\chi - \sum c_k \rho_{1/k}$ is $1/s - \zeta(s) s^{-1} \sum c_k (k^{-1} - k^{-s})$. Apply Lemma 93.3.1 on $\operatorname{Re} s = 1/2$. □

Remark 93.3.3 *(Möbius choice and the missing $(s-1)^{-1}$ pole).* Setting $c_k = \mu(k)/k$ gives $A_N(s) = \sum_{k=1}^N \mu(k) k^{-s-1}$, so $A_N(1) = \sum_{k=1}^N \mu(k)/k^2 \to 6/\pi^2$ as $N \to \infty$ (absolutely convergent, unconditional). There is no $(s-1)^{-1}$-term in (93.2). The main term is the critical-line factor $\big(1 - \zeta(s)(A_N(1) - A_N(s))\big)/s$, and it is not controlled by the scalar $M_1(N) = \sum_{k \le N} \mu(k)/k$ alone.

The Weil-Type Insertion

Theorem 93.3.4 *(A-TP and Nyman–Beurling have the same RH content).* The archimedean Tate positivity A-TP of Conjecture 78.2.3 is equivalent to the Nyman–Beurling closure $\chi \in H^2(0,1)$; equivalently to the Baez-Duarte vanishing $\lim_{N\to\infty} d_N = 0$.

Proof. Both conditions are equivalent to RH. A-TP $\Leftrightarrow$ RH by Theorem 78.2.4. RH $\Leftrightarrow$ $\chi \in H^2(0,1)$ by Theorem 93.2.4. RH $\Leftrightarrow$ $d_N \to 0$ by Theorem 93.2.5. Transitivity closes the reformulation. The two equivalent RH formulations are related by an *explicit* Mellin-Plancherel integral identity. □

Remark 93.3.5 *(the Mellin identity is not a zero-square identity).* Beyond the tautological RH-equivalence, the Nyman–Beurling side gives the exact Mellin-Plancherel identity

$$\|\chi - \sum_{k=1}^{N} c_k \rho_{1/k}\|^2_{L^2(0,1)} \;=\; \frac{1}{2\pi} \int_{-\infty}^{\infty} \left| \frac{1 - \zeta(s)\big(A_N(1) - A_N(s)\big)}{s} \right|^2_{s=1/2+it} dt, \tag{93.3}$$

with $A_N(s) = \sum c_k k^{-s}$. No formula with $|\xi_{\mathbb{R}}(\rho)|^{-2}$ at non-trivial zeros can be correct, since $\xi_{\mathbb{R}}(\rho) = 0$. Passing from (93.3) to a zero expansion is exactly the Baez–Duarte theorem; it is not an elementary residue computation inside the Mellin identity.

93.4 Restricted-Class Estimate on HFD

On $\mathscr{A} = C_c^\infty(\mathbb{R})$, the quantitative HFD condition of Definition 82.4.1 implies $G[f] = (B[f] - A[f])/(2\pi) \geq 0$, hence $W_\infty(f * \widetilde{f}) \leq 2\log\pi\|f\|_2^2$. It does not imply $W_\infty \geq 0$: the smooth modulated tests of Theorem 92.4.5 give the opposite sign. On any further specified arithmetic test class, HFD means intersection with this quantitative class. Neither that intersection nor HFD itself supplies a weighted Baez-Duarte estimate.

HFD-Adapted Nyman–Beurling Distance

Definition 93.4.1 *(HFD-restricted Nyman–Beurling distance).* For $f \in \mathrm{PW}_F^{\mathrm{hol,HFD}}$ together with a specified unitary Mellin transform $\mathcal{M}_{\mathrm{add}\to\mathrm{mult}}$ from the additive Paley–Wiener model to the critical-line Mellin model, set $\widehat{f}_M = \mathcal{M}_{\mathrm{add}\to\mathrm{mult}}(\widehat{f})$ and define

$$d_N^{\mathrm{HFD}}(f) := \inf_{c_k} \left\| \widehat{f}_M(1/2+it) \cdot \left[\frac{1 - \zeta(s)\sum_{k=1}^N c_k(k^{-1} - k^{-s})}{s} \right]_{s=1/2+it} \right\|_{L^2(\mathbb{R})}.$$

This is the Mellin-weighted Nyman–Beurling distance tested against the spectral profile of f. Without the displayed unitary transform, $\widehat{f}_M$ is not determined by the additive test function.

Theorem 93.4.2 *(weighted HFD Nyman–Beurling bound is an open estimate).* The estimate

$$d_N^{\mathrm{HFD}}(f)^2 \leq C_{\mathrm{HFD}}(f) \cdot \frac{1}{\log N} + \varepsilon_{\mathrm{pol}}(N) \cdot \|f\|_{L^2}^2 \tag{93.4}$$

does not follow from the preceding identities. It would require a uniform weighted Baez–Duarte estimate for the critical-line integral (93.3). The Mellin identity and the Prime Number Theorem do not by themselves give this bound.

Proof. The exact identity is (93.3). A putative zero expansion containing $|\xi_{\mathbb{R}}(\rho)|^{-2}$ is undefined at non-trivial zeros of $\xi_{\mathbb{R}}$. The displayed integral is a weighted approximation problem for $1/\zeta$ on the critical line. Scalar control of $M_1(N) = \sum_{k\leq N}\mu(k)/k$ does not control that weighted L^2-norm. □

Corollary 93.4.3 *(the HFD Nyman–Beurling estimate is an additional input).* The limit

$$\lim_{N\to\infty} d_N^{\mathrm{HFD}}(f) = 0$$

does not follow from the preceding identities. Thus the identities do not prove A-TP on HFD.

Proof. It would follow from Theorem 93.4.2 only after that estimate is known. The exact Mellin identity gives an open weighted approximation problem. □

Remark 93.4.4 *(comparison with the bounded-interval reduction).* The bounded-interval reduction gives $G \geq 0$ on HFD and the upper bound $W_\infty \leq 2\log\pi\|f\|_2^2$. The Nyman–Beurling form adds the critical-line weighted approximation problem (93.4); it does not remove the residual $R[f]$, and it does not give full A-TP on HFD without that extra weighted estimate.

93.5 Möbius Partial-Sum Control

The Möbius partial sums $M(N)$ and $M_1(N)$ remain useful background. They do not, by themselves, prove the weighted HFD estimate of Theorem 93.4.2.

Proposition 93.5.1 *(Mertens-type bounds, unconditional).* Set $M(N) := \sum_{k\le N}\mu(k)$ and $M_1(N) := \sum_{k\le N}\mu(k)/k$. Unconditionally:

$$\begin{aligned} M(N) &= o(N), \qquad N\to\infty \quad \text{(PNT, Hadamard-de la Vallée-Poussin 1896)},\\ M_1(N) &= o(1), \qquad N\to\infty \quad \text{(Landau 1911, equivalent to PNT)}. \end{aligned}$$

Quantitative form (Titchmarsh §3.14): $M(N) = O(N\exp(-c\sqrt{\log N}))$ and $M_1(N) = O(\exp(-c\sqrt{\log N}))$ for some $c>0$.

Proof. Hadamard 1896 (*Bull. Soc. Math. France* 24) and de la Vallée-Poussin 1896 (*Ann. Soc. Sci. Bruxelles* 20) established the PNT via zero-free region of ζ just inside $\operatorname{Re} s = 1$. Landau 1911 (*Handbuch der Lehre von der Verteilung der Primzahlen*) deduced the bound on $M_1(N)$. The quantitative form follows from the de la Vallée-Poussin zero-free region $\sigma \ge 1 - c/\log(|t|+3)$. □

Proposition 93.5.2 *(Mertens bound, conditional on RH).* Under RH:

$$\begin{aligned} M(N) &= O(\sqrt{N}\log^2 N),\\ M_1(N) &= O(N^{-1/2}\log^2 N). \end{aligned}$$

Proof. Titchmarsh §14.27; the classical conditional bound via the explicit formula for $M(N)$ in terms of zeros of ζ. The bound on $M_1(N)$ follows by partial summation from the bound on $M(N)$. □

Remark 93.5.3 *(Mertens bounds do not give the weighted HFD estimate).* The scalar estimates $M_1(N) = o(1)$ and $M_1(N) = O(N^{-1/2}\log^2 N)$ do not control the norm in (93.3). That norm asks for weighted approximation to $1/\zeta(1/2+it)$ on the critical line. The Baez-Duarte–Balazard–Landreau–Saias $1/\log N$ lower obstruction is a zero-expansion statement; without a matching global critical-line upper theorem it cannot be transferred to (93.4).

93.6 Comparison of the Complementary Class with Baez-Duarte

Use the common test carrier $\mathscr{T} = \mathrm{PW}_F^{\mathrm{hol}} \cap C_c^\infty(\mathbb{R})$ and $\mathscr{T}_{\mathrm{HFD}} = \mathscr{T} \cap \mathscr{A}_{\mathrm{HFD}}$. The complement $\mathscr{T} \setminus \mathscr{T}_{\mathrm{HFD}}$ is where the quantitative auxiliary G-domination condition fails; no positivity of the signed W_∞ is inferred from HFD. For test functions outside HFD, the mass on $|t| \le t_*$ may be measured by a compact-core Nyman–Beurling distance. This compact-core distance is a shadow of the global Baez-Duarte criterion, not an equivalent replacement for it.

Theorem 93.6.1 *(complementary-class comparison with Baez-Duarte).* For $f \in \mathscr{T} \setminus \mathscr{T}_{\mathrm{HFD}}$, set

$$d_N^{\mathrm{low}}(f)^2 := \inf_{c_k} \int_{|t|\le t_*} |\widehat{f}(t)|^2 \cdot \left| \frac{1 - \zeta(s)\sum_{k=1}^N c_k(k^{-1}-k^{-s})}{s} \right|^2_{s=1/2+it} dt. \tag{93.5}$$

On $|t| \le t_*$,

$$0 \le -g(t) \le (1/4 + t_*^2)|g(0)|\,|s|^{-2}_{s=1/2+it}. \tag{93.6}$$

Thus the compact-core Nyman–Beurling norm is taken over a measure which dominates the archimedean core measure. This is a comparison of weighted error norms, not an inequality for $A[f]$ itself; the finite-prime-polar functional $R[f]$ remains in inequality (★). The compact-core norm does not imply the global Baez-Duarte vanishing $d_N \to 0$.

Proof. By Lemma 82.3.2, $W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - (B[f] - A[f])/(2\pi)$. On HFD^c, $B[f] < A[f]$ is possible, so the finite-prime-polar functional remains part of the inequality. The core integral, which contributes positively to W_∞, is

$$A[f] = \int_{|t|\le t_*} |\widehat{f}(t)|^2 \cdot (-g(t))dt.$$

By Lemma 82.2.2 and Proposition 82.2.3, $-g(t) = |g(0)| - \int_0^{|t|} g'(u)du \ge 0$ on $|t| \le t_*$. Since $|s|^{-2} = (1/4 + t^2)^{-1}$ on $s = 1/2 + it$, the bound (93.6) follows from $-g(t) \le |g(0)|$ and $1/4 + t^2 \le 1/4 + t_*^2$. Substitution into inequality (★) shows where this measure comparison enters the bounded-interval residual. The factor $|1 - \zeta(s)\sum c_k(k^{-1} - k^{-s})|^2$ is an additional approximation error, so no estimate for $A[f]$ follows without a separate approximation theorem. The implication $d_N \to 0$ is exactly the global Nyman–Beurling–Baez-Duarte criterion and cannot be inferred from the compact interval alone. □

Corollary 93.6.2 *(compact Baez-Duarte data do not remove the irreducible A-TP residual).* The residual A-TP on $\mathscr{T} \setminus \mathscr{T}_{\mathrm{HFD}}$ is not closed by the compact-core norm (93.5). Full closure would require the global Baez-Duarte vanishing $d_N \to 0$, equivalently RH, together with the retained $R[f]$-inequality of inequality (★).

Proof. Combine Theorem 93.6.1 with the global criterion Theorem 93.2.5. □

93.7 Seven Obstructions to the HFD Nyman–Beurling Bound

The estimate in Theorem 93.4.2 is the open bound $d_N^{\mathrm{HFD}}(f)^2 \le C_{\mathrm{HFD}}(f)/\log N + O((\log N)^{-2})$ on the HFD sub-class. The following seven obstructions remain after the Mellin formula is put in its pole-free form.

Remark 93.7.1 *(obstruction 1: a scalar Mertens bound is too small).* The limit $M_1(N) = \sum_{k\le N}\mu(k)/k \to 0$ is unconditional by PNT, and the de la Vallée-Poussin zero-free region gives the usual exponential decay in $\sqrt{\log N}$. This scalar statement is nevertheless too small for (93.4): the latter is an L^2 approximation estimate for $1/\zeta(1/2 + it)$ against a moving weight.

Remark 93.7.2 *(obstruction 2: the* $1/\log N$ *scale is only a lower obstruction).* The $1/\log N$ scale is forced from below by the Baez-Duarte–Balazard–Landreau–Saias zero expansion. A proof of an upper bound of the same scale for $d_N^{\mathrm{HFD}}(f)$ would have to replace the global zero-expansion by a weighted critical-line theorem. Truncating the spectral weight to $|t| > t_*$ does not by itself supply such a theorem.

Remark 93.7.3 *(Nonzero HFD tests and the arithmetic test domain).* Remark 82.4.4 constructs smooth compactly supported modulated tests satisfying (82.8). They give a nonzero domain for $G \ge 0$, not for a positive signed archimedean contribution. Their membership in any additional arithmetic test class must still be established, as must the weighted approximation estimate.

Remark 93.7.4 *(obstruction 4:* $\varepsilon_{\mathrm{pol}}(N)$ *conceals the real obstruction).* The Mellin formula has no $(s-1)^{-1}$ polar term in (93.2). The obstruction is the weighted critical-line norm in (93.3), not a finite-dimensional polar remainder.

Remark 93.7.5 *(obstruction 5: the cross-reduction identity* (93.3) *is circular).* The identity (93.3) is a Mellin–Plancherel identity and contains no zero-square residue formula. It is independent of the Weil distribution, but independence of identities is weaker than a bound. The missing step is precisely a uniform estimate for the displayed integral.

Remark 93.7.6 *(Closure and the weighted estimate).* The Nyman–Beurling closure theorem concerns an unweighted norm. The estimate (93.4) contains a specified test-dependent weight; its constants and convergence must be proved for that weight. An unweighted closure statement alone does not supply this estimate.

Remark 93.7.7 *(obstruction 7: closing A-TP on* HFD^c *via Nyman–Beurling).* The compact-core norm (93.5) measures only the archimedean negative interval. Closing A-TP on HFD^c still requires the $R[f]$-term in inequality (⋆); replacing it by the global Nyman–Beurling vanishing is exactly the RH-equivalent Baez-Duarte criterion.

93.8 The Irreducible Obstruction, Named in the Nyman–Beurling Framework

Theorem 93.8.1 *(irreducible A-TP residual, Nyman–Beurling form).* The Nyman–Beurling formulation identifies the same residual in two forms: the global Baez-Duarte vanishing $d_N \to 0$, which is RH-equivalent, and the compact-core norm (93.5), which measures only the negative archimedean interval. The latter does not close A-TP without the $R[f]$-inequality, and the HFD weighted estimate Theorem 93.4.2 remains an additional analytic input.

Proof. Assemble Theorem 93.6.1, Corollary 93.6.2, and Theorem 93.4.2. □

Remark 93.8.2 *(comparison with the bounded-interval residual inequality).* The bounded-interval reduction (Chapter 82) reduced A-TP to a exact signed domination

$$A[f] + 4\pi \log \pi \|f\|_2^2 \le B[f] + 2\pi R[f].$$

Thus the core and constant contributions are bounded by the auxiliary tail together with the finite-prime and polar functional. The Nyman–Beurling form gives a compact-core distance for the negative interval and a global distance equivalent to RH. Neither distance removes the $R[f]$-term from the bounded-interval inequality. The Nyman–Beurling construction supplies exactly the following data:

(i) the exact Mellin normal form for the weighted critical-line estimate and an $L^2(0,1)$ distance;
(ii) the precise weighted estimate whose proof would be required for HFD closure;
(iii) a reformulation of the irreducible residual as a concrete Baez-Duarte distance problem.

The weighted approximation problem and the signed Weil inequality remain distinct until a comparison controlling the full $R[f]$-coupled expression is constructed.

93.9 Mellin Boundary

(i) The Nyman–Beurling generators $\rho_\alpha(x) = \{\alpha/x\} - \alpha\{1/x\}$ have Mellin transform $(\alpha - \alpha^s)\zeta(s)/s$ (Lemma 93.2.2); A-TP is equivalent to the Nyman–Beurling closure $\chi \in H^2(0,1)$ and to the Baez-Duarte vanishing $d_N \to 0$ (Theorem 93.3.4).

(ii) The HFD-restricted Nyman–Beurling distance $d_N^{\mathrm{HFD}}(f)$ (Definition 93.4.1) is governed by the exact Mellin-Plancherel integral (93.3). The proposed $O(1/\log N)$ HFD bound is a separate weighted estimate (Theorem 93.4.2).

(iii) On HFD^c, the compact-core Baez-Duarte norm controls the negative archimedean interval but does not replace the global Baez-Duarte criterion or the retained $R[f]$-inequality (Theorem 93.6.1, Corollary 93.6.2).

(iv) The obstruction-theoretic comparison changes the form of the HFD Nyman–Beurling construction: PNT-strength Mertens estimates are background, not a proof of the weighted critical-line estimate.

(v) The exact Mellin expression identifies the weighted approximation problem. It does not establish the signed Weil inequality on HFD (Theorem 93.8.1).

Remark 93.9.1 *(the Beilinson principle on the Nyman–Beurling comparison).* The Nyman–Beurling comparison proves neither RH nor an independent HFD closure. Its mathematical content is the irreducible residual recast in $L^2(0,1)$ language and the exact weighted estimate which would imply the missing HFD bound.

Remark 93.9.2 *(cross-volume dependency).* The inputs are Chapter 78 (Rankin–Selberg kernel obstruction, A-TP conjecture 78.2.3), Chapter 82 (HFD sub-class, bounded-interval reduction), and PNT (Hadamard 1896, de la Vallée-Poussin 1896, Landau 1911). They are independent of the de Branges / Hermite–Biehler analysis of Chapter 79, the $\mathrm{R}_{\mathrm{analytic}}$ density-of-zeros analysis of Chapter 80, or the Positselski four sub-items of Chapter 75. The Nyman–Beurling construction is orthogonal to these.

Chapter 94

A-TP via de Branges Hermite–Biehler Factorisation

The function $E_\xi = \Xi + i\Xi'$ has real part Ξ. Its positive kernel, when established, is strictly Hermite–Biehler by the derivative calculation and therefore forces zero placement. Multiplication by E_ξ gives a model-space isometry under that Hermite–Biehler hypothesis. Identifying an arithmetic test space or the Weil form with this model requires additional maps.

The signed archimedean identity is $W_\infty = 2\log\pi\,\|f\|_2^2 - G[f]$ on $\mathscr{A} = C_c^\infty(\mathbb{R})$. The HFD condition makes G nonnegative, not W_∞. The full Weil target retains $R[f] \geq W_\infty(f * \widetilde{f})$ and the actual arithmetic test-domain comparison. The zero-free-region calculation below gives peripheral bands, not a central positivity region.

94.1 Context and the de Branges Comparison

Chapter 78 established:

- A-TP $\Leftrightarrow$ RH via the Weil positive cone (Theorem 78.2.4).
- Prime-side Petersson closure on $\mathrm{PW}_F^{\mathrm{hol}}$ via the Mellin lift Υ_F (Theorem 78.5.5).
- The archimedean digamma obstruction as the unabsorbed residual of the Rankin–Selberg isometry (Proposition 78.6.2).

Chapter 79 established:

- The de Branges structure theorem in the form Proposition 79.6.7: E_ξ is Hermite–Biehler if and only if the de Branges reproducing kernel K_{E_ξ} is positive-semidefinite; with $(E_\xi + E_\xi^*)/2 = \Xi$, the Hermite–Biehler separation theorem puts the zeros of Ξ on the real axis.
- The equivalence $\mathrm{HB}^+ \Leftrightarrow$ RH (Remark 79.6.11), Lagarias 1999.

Chapter 82 established:

- Positivity of G on the quantitative HFD class in $\mathscr{A}$, with $W_\infty = 2\log\pi\,\|f\|_2^2 - G$. Smooth compactly supported modulations give HFD tests with $W_\infty < 0$. A special arithmetic test class is restricted by intersection with $\mathscr{A}$, not supplied by this construction.
- The full Weil inequality is $A[f] + 4\pi\log\pi\,\|f\|_2^2 \leq B[f] + 2\pi R[f]$. The interval $[-t_*, t_*]$ is the negative region of g, not of the signed multiplier defining W_∞.
- Three non-elementary constructions that remain open: zero density, Gaussian reduction, and de Branges spectral structure (Remark 82.6.3).

The A-TP↔de Branges kernel dictionary contains the Vinogradov–Korobov coordinate change and identifies the obstruction via Lagarias 1999 and Conrey–Li 2000.

Domain

The objects are:

- The Lagarias function E_ξ, its conjugate E_ξ^*, its real part $A_\xi = \Xi$, and the de Branges kernel K_{E_ξ}.
- The model-space isometry $K(E_\xi^*/E_\xi) \simeq \mathcal{H}(E_\xi)$ and the Mellin transforms which lie in that model space.
- Coordinate comparison of the Vinogradov–Korobov zero-free region under $s = \frac{1}{2} + iz$.
- Proof that the Vinogradov–Korobov input gives only peripheral zero-free bands and no A-TP positivity closure.
- Identification of the genuine obstruction as HB^+, equivalent to RH.

The proof of HB^+ on $\xi_{\mathbb{R}}$ is RH-equivalent and is not supplied by the kernel-positivity reformulation. No argument below uses de Branges operator monotonicity beyond that reformulation.

Independent Sources

The four primary source lists below are disjoint from the restricted-class comparison and the bounded-interval reduction proof sources.

de Branges 1968, *Hilbert Spaces of Entire Functions* (Prentice-Hall). Foundational monograph. Theorems 19–27 (axiomatic structure of $\mathcal{H}(E)$, Hermite–Biehler criterion, reproducing kernel), theorems 30–33 (multiplication operator), theorems 40–41 (invariant subspaces).

Lagarias 1999, Acta Arith. 89. *On a positivity property of the Riemann ξ-function.* Explicit construction of E_ξ from Λ_ζ, exponential type computation, statement of $\mathrm{HB}^+ \Leftrightarrow$ RH with a Beurling–Malliavin density addendum.

Conrey–Li 2000, arXiv:math/9812166. *A note on some positivity conditions related to zeta and L-functions.* Counter-examples to de Branges' 1986 attempted proof: explicit L-functions for which the naive Hermite–Biehler pair fails positivity at specific points. The Conrey–Li obstruction is the precise location where any proof of HB^+ by operator monotonicity must be excluded.

Titchmarsh 1951, *The Theory of the Riemann Zeta-Function* (Oxford), Ch. V–VI. Vinogradov–Korobov zero-free region: $\zeta(\sigma + it) \neq 0$ for $\sigma \geq 1 - c_0/(\log|t|)^{2/3}(\log\log|t|)^{1/3}$ with $|t| \geq t_0$. Korobov 1958 Uspekhi; Vinogradov 1958 Izv.

Independence of inputs. The restricted-class comparison A derivation used Weil 1952, Li 1997, Rankin 1939, Selberg 1940, Jacquet 1972 (Rankin–Selberg isometry). The de Branges spectral comparison derivation used de Branges 1968 and Beurling–Malliavin 1962 for the main-direction arrow, Carleman 1926 for determinacy. The bounded-interval reduction derivation used Hurwitz 1882, Gauss 1813, Whittaker–Watson 1927, Boas 1954 (elementary digamma analysis). The additional sources are de Branges 1968 (in its Ch. III reproducing-kernel role, distinct from the structure-theorem role used by the de Branges spectral comparison), Lagarias 1999 (explicit E_ξ computation, not used in the de Branges spectral comparison's structural implication), Conrey–Li 2000 (obstruction location, not used in the de Branges spectral comparison or the bounded-interval reduction), and Titchmarsh 1951 Vinogradov–Korobov (not used in constructions 5 or 6). The derivation list is therefore disjoint from the source lists of constructions 5 A, 5 J, and 6 A.

94.2 The de Branges Function E_ξ and Its Real-Line Trace

Fix the shifted character $\Xi(z) = \xi_{\mathbb{R}}(\frac{1}{2} + iz)$ of Definition 79.2.3. We recall the Hermite–Biehler candidate.

Definition 94.2.1 (Lagarias de Branges function for $\xi_{\mathbb{R}}$). Define

$$E_\xi(z) \;:=\; \xi_{\mathbb{R}}\big(\tfrac{1}{2} - iz\big) \;+\; \xi'_{\mathbb{R}}\big(\tfrac{1}{2} - iz\big), \tag{94.1}$$

with its conjugate-partner

$$E^*_\xi(z) \;:=\; \overline{E_\xi(\overline{z})} \;=\; \xi_{\mathbb{R}}\big(\tfrac{1}{2} + iz\big) \;+\; \xi'_{\mathbb{R}}\big(\tfrac{1}{2} + iz\big).$$

The derivative is with respect to s. This is the Lagarias candidate used in the de Branges reformulation.

Lemma 94.2.2 *(Lagarias real-part identity for E_ξ).* The real part

$$A_\xi(z) := \frac{E_\xi(z) + E^*_\xi(z)}{2}$$

is exactly the shifted xi-function:

$$A_\xi(z) \;=\; \Xi(z) \;=\; \xi_{\mathbb{R}}\big(\tfrac{1}{2} + iz\big).$$

Consequently $\operatorname{div}(A_\xi) = \operatorname{div}(\Xi)$.

Proof. The functional equation gives $\xi_{\mathbb{R}}(\frac{1}{2} - iz) = \xi_{\mathbb{R}}(\frac{1}{2} + iz)$. Differentiating $\xi_{\mathbb{R}}(s) = \xi_{\mathbb{R}}(1 - s)$ gives $\xi'_{\mathbb{R}}(\frac{1}{2} - iz) = -\xi'_{\mathbb{R}}(\frac{1}{2} + iz)$. The derivative terms in $E_\xi + E^*_\xi$ cancel, and the two undifferentiated terms give $2\Xi(z)$. □

Remark 94.2.3 (the completed zeta is not a Hermite–Biehler datum). The function $\Lambda_\zeta(\frac{1}{2} + iz)$ is fixed by $*$, by the functional equation. It cannot satisfy the strict Hermite–Biehler inequality. The derivative term in (94.1) is therefore not a normalisation; it is the datum which separates $A_\xi = \Xi$ from its conjugate quadrature.

Proposition 94.2.4 *(Stirling does not supply Hermite–Biehler positivity).* No Stirling estimate for the gamma factor in $\Lambda_\zeta(\frac{1}{2} + iz)$ proves

$$|E_\xi(z)| > |E^*_\xi(z)|, \qquad \operatorname{Im} z > 0,$$

for the Lagarias function (94.1). The omitted term is the logarithmic derivative of $\xi_{\mathbb{R}}$, and the strict inequality is precisely the Hermite–Biehler condition.

Proof. If $\Lambda_\zeta(\frac{1}{2} + iz)$ were used in place of (94.1), the functional equation would give $E = E^*$, so the strict Hermite–Biehler inequality would be impossible. For the actual Lagarias function,

$$\frac{E^*_\xi(z)}{E_\xi(z)} = \frac{\xi_{\mathbb{R}}(\frac{1}{2} + iz) + \xi'_{\mathbb{R}}(\frac{1}{2} + iz)}{\xi_{\mathbb{R}}(\frac{1}{2} - iz) + \xi'_{\mathbb{R}}(\frac{1}{2} - iz)},$$

and the derivative term is not controlled by the gamma-factor asymptotic alone. Thus any proof of the strict inequality is a proof of Hermite–Biehler positivity, not a consequence of Stirling's formula. □

COROLLARY 94.2.5 *(no exterior Hermite–Biehler region from Stirling).* The estimate

$$|E_\xi(z)| > |E_\xi^*(z)| \cdot \exp\!\big(\tfrac{1}{2} r \sin\theta \log(r/2)\big)$$

is not an unconditional consequence of Stirling asymptotics. The valid unconditional zero-free input is the Vinogradov–Korobov peripheral exclusion for the real part $A_\xi = \Xi$.

Proof. Proposition 94.2.4 removes the only purported derivation of the displayed inequality. The classical zero-free theorem controls zeros of ζ, hence zeros of A_ξ, only in the peripheral bands described below. □

94.3 de Branges Reproducing Kernel and the Mellin Identification

Definition 94.3.1 *(de Branges space attached to E_ξ).* If E_ξ is Hermite–Biehler, the *de Branges space* $\mathcal{H}(E_\xi)$ is the Hilbert space of entire functions F with

$$\|F\|_{E_\xi}^2 := \int_{\mathbb{R}} \left| \frac{F(t)}{E_\xi(t)} \right|^2 dt < +\infty$$

and $F/E_\xi, F^*/E_\xi \in H^2(\mathbb{C}_+)$, with the reproducing kernel

$$K_{E_\xi}(w,z) = \frac{\overline{E_\xi(w)}\,E_\xi(z) - \overline{E_\xi^*(w)}\,E_\xi^*(z)}{2\pi i(\overline{w} - z)}.$$

PROPOSITION 94.3.2 *(de Branges real-line inner product).* For $F, G \in \mathcal{H}(E_\xi)$,

$$\langle F, G\rangle_{E_\xi} = \int_{\mathbb{R}} \frac{F(t)\overline{G(t)}}{|E_\xi(t)|^2}\, dt.$$

Here E_ξ is the Lagarias function (94.1), not $\Lambda_\zeta(\frac{1}{2} + it)$.

Proof. This is the defining inner product of a de Branges space; polarisation gives the displayed formula. □

THEOREM 94.3.3 *(Mellin model-space isometry).* Assume E_ξ is Hermite–Biehler and put

$$\Theta_\xi(z) := \frac{E_\xi^*(z)}{E_\xi(z)}.$$

Let $\Upsilon_F : \mathrm{PW}_F^{\mathrm{hol}} \to \mathcal{V}_{\mathrm{cusp,temp}}^{\mathrm{prim}}$ be the Mellin lift of Definition 78.4.2. For every $f \in \mathrm{PW}_F^{\mathrm{hol}}$ whose Mellin transform lies in the model space $K(\Theta_\xi) = H^2 \ominus \Theta_\xi H^2$, define

$$\widehat{\Upsilon}_F(f)(z) := \widehat{f}(z) \cdot E_\xi(z), \qquad z \in \mathbb{C}.$$

Then $\widehat{\Upsilon}_F(f) \in \mathcal{H}(E_\xi)$ and

$$\langle \widehat{\Upsilon}_F(f), \widehat{\Upsilon}_F(f)\rangle_{E_\xi} = \int_{\mathbb{R}} |\widehat{f}(t)|^2\, dt. \tag{94.2}$$

Proof. For a Hermite–Biehler function, multiplication by E_ξ is the standard isometric identification

$$K(\Theta_\xi) \xrightarrow{\sim} \mathcal{H}(E_\xi).$$

Indeed $F = \widehat{f}E_\xi$ satisfies $F/E_\xi = \widehat{f} \in H^2$ and $F^*/E_\xi = \Theta_\xi \widehat{f}^* \in H^2$ by the model-space condition. By Proposition 94.3.2,

$$\|\widehat{\Upsilon}_F(f)\|^2_{E_\xi} = \int_{\mathbb{R}} \frac{|\widehat{f}(t)E_\xi(t)|^2}{|E_\xi(t)|^2}\,dt = \int_{\mathbb{R}} |\widehat{f}(t)|^2\,dt,$$

which is (94.2). □

Corollary 94.3.4 *(Finite kernel Gram forms).* Assume E_ξ is Hermite–Biehler. For finitely many real points x_j and complex coefficients c_j, put $F = \sum_j c_j K_{E_\xi}(x_j, \cdot)$. Then

$$\|F\|^2_{E_\xi} = \sum_{j,k} c_j \overline{c_k} K_{E_\xi}(x_j, x_k) \geq 0. \tag{94.3}$$

A representation of the arithmetic Weil form by this Gram expression requires an actual linear map from its test carrier to these vectors and equality of the two forms. Coordinates of zeros or values of $\widehat{f}$ alone do not supply that equality.

Proof. Use the reproducing property with the Hermitian form linear in its first variable: $\langle K(x_j, \cdot), K(x_k, \cdot)\rangle = K(x_j, x_k)$. Expand the squared norm of the finite linear combination. For a zero ρ, the parameter $z_\rho = -i(\rho - 1/2)$ is real precisely when ρ is on the critical line; selecting real zero parameters is itself a zero-placement requirement. No arithmetic norm identity follows from this change of variables. □

94.4 What the Vinogradov–Korobov Region Actually Gives

The classical zero-free region is a statement near the line $\operatorname{Re} s = 1$, and by the functional equation near $\operatorname{Re} s = 0$. Under $s = \frac{1}{2} + iz$ it gives peripheral horizontal bands in the z-plane. It does not give a zero-free strip around the real z-axis. The real axis is exactly the critical line.

Definition 94.4.1 *(Vinogradov–Korobov peripheral bands).* Let $c_0 > 0$ be the Vinogradov–Korobov constant (Titchmarsh 1951 Ch. VI; Korobov 1958). Define, for sufficiently large $T > e$, the peripheral bands

$$\eta(T) := \frac{c_0}{(\log T)^{2/3}(\log\log T)^{1/3}},$$

$$\mathcal{P}_T := \left\{\alpha + i\beta : |\alpha| \leq T, \quad |\beta| \geq \frac{1}{2} - \eta(T)\right\}.$$

The central strip

$$C_T := \{z = \alpha + i\beta : |\alpha| \leq T,\ |\beta| < \eta(T)\}$$

is not a Vinogradov–Korobov zero-free region. It contains the real axis, hence contains the critical-line zeros when RH holds.

Lemma 94.4.2 *(A_ξ is zero-free in the peripheral bands).* For $T \geq T_0$, the function $A_\xi = \Xi$ has no zeros in $\mathcal{P}_T$. No zero-free conclusion follows for the central strip C_T.

Proof. A zero $z = \alpha + i\beta$ of $A_\xi = \Xi$ corresponds to a non-trivial zero

$$\rho = \frac{1}{2} + iz = \frac{1}{2} - \beta + i\alpha$$

of ζ. Vinogradov–Korobov gives

$$\operatorname{Re}\rho < 1 - \eta(|\alpha|)$$

for $|\alpha|$ large, hence $\beta > -\frac{1}{2} + \eta(|\alpha|)$. Applying the functional equation gives the reflected inequality $\beta < \frac{1}{2} - \eta(|\alpha|)$. Thus zeros with $|\alpha| \le T$ lie in the central band

$$-\frac{1}{2} + \eta(T) < \beta < \frac{1}{2} - \eta(T),$$

after decreasing c_0 and increasing T_0 in the usual uniform way. This proves zero-freeness of $\mathcal{P}_T$. It says nothing about $|\beta| < \eta(T)$. □

PROPOSITION 94.4.3 *(Vinogradov–Korobov gives no A-TP kernel closure).* The zero-freeness of $\mathcal{P}_T$ does not imply positive-semidefiniteness of K_{E_ξ} on the zero set relevant to A-TP. It only says that the sampled zero set does not meet $\mathcal{P}_T$.

Proof. Any proposed representation of the arithmetic form by a kernel Gram matrix requires the actual test and form comparison. The lemma removes only the peripheral bands $\mathcal{P}_T$. It does not locate zeros on the real axis, does not put the zero set in a de Branges positivity domain, and does not identify a positive Hilbert-space inner product on the sampled zero components. Therefore no A-TP positivity statement follows from Vinogradov–Korobov alone. □

THEOREM 94.4.4 *(Compact test functions and exact Fourier gaps).* If $f \in C_c^\infty(\mathbb{R})$ and $\widehat{f}$ vanishes on a nonempty open real interval, then $f = 0$. Consequently restricting Fourier support to the off-real peripheral bands $\mathcal{P}_T$ supplies no nonzero test on this carrier.

Proof. Compact support makes $\widehat{f}$ entire. A real interval has an accumulation point in its complex domain, so the identity theorem gives $\widehat{f} \equiv 0$. Fourier inversion then gives $f = 0$. Fourier support is a subset of the real frequency axis; the peripheral complex bands are a zero-free-region statement, not a nonzero Fourier-support class. □

Remark 94.4.5 *(The actual test-domain requirement).* The finite kernel norm in (94.3) is not an arithmetic zero-sum identity without the additional test and form map. Smooth compact tests can have quantitative frequency decay or concentration; they cannot have an exact open Fourier gap unless zero. The peripheral zero-free bands supply neither that map nor a nontrivial compact test with support in those complex bands.

94.5 The Genuine Obstruction: Hermite–Biehler Extension

THEOREM 94.5.1 *(A continuous-form criterion for kernel positivity).* Let H be a specified Hilbert space, b a continuous Hermitian form on H, and $j : \mathscr{T} \to H$ a linear map from a specified arithmetic test space with dense image. Suppose vectors $k_z \in H$, for $z \in \mathbb{C}_+$, satisfy $b(k_z, k_w) = K_{E_\xi}(w, z)$, and their span is dense in H. Then

$$b(jf, jf) \ge 0\ (f \in \mathscr{T}) \quad \Longleftrightarrow \quad K_{E_\xi} \succeq 0 \quad \Longrightarrow \quad \text{RH}.$$

These hypotheses include the continuous realization of the kernel and the actual test map; they do not follow from zero-free bands.

Proof. If b is nonnegative on $j(\mathscr{T})$, continuity and density make it nonnegative on H. Evaluating on finite sums of the k_z proves kernel positivity. Conversely, kernel positivity makes b nonnegative on their span and hence on H, by the second density hypothesis. For the exact derivative datum $E_\xi = \Xi + i\Xi'$, Proposition 79.6.7 gives strict Hermite–Biehler positivity. Its real part Ξ has no nonreal zeros, so RH follows. This argument does not construct H, b, j or identify $b(jf, jf)$ with the Weil form. □

Corollary 94.5.2 *(The full kernel comparison).* Under the Hilbert realization and density hypotheses of Theorem 94.5.1, positivity on the arithmetic test image implies RH. Peripheral zero-free bands do not supply that realization or its positivity.

Proof. Apply the continuous-form criterion and the strict derivative-kernel implication in the theorem. □

Remark 94.5.3 *(The derivative datum and the arithmetic test map).* For the actual candidate $E_\xi = \Xi + i\Xi'$, the derivative-kernel calculation rules out a degenerate positive kernel and gives strict Hermite–Biehler positivity. It requires positivity on every finite kernel matrix in the upper half-plane. An arithmetic application must construct the test map and continuous form of the theorem; real-part coordinates or a zero-free region alone provide neither.

94.6 Three Non-Elementary Constructions Further Analysed

Three candidate reductions of HB$^+$ each fall strictly short, by explicit strength comparison.

Proposition 94.6.1 *(Beurling–Malliavin density does not imply HB$^+$).* The Beurling–Malliavin sampling density argument of Proposition 79.7.3 concerns the horizontal spacing of zeros on $\mathbb{R}$ under RH, not their confinement to the real axis in the z-plane. Beurling–Malliavin density does not imply the Hermite–Biehler inequality for E_ξ.

Proof. BM density is defined on real sequences (Definition 79.7.1). If one instead forms a projected real sequence from a complex zero multiset, that projection loses the vertical information; it is not a definition of Beurling–Malliavin density for complex sets. Projection to real parts cannot detect an off-line zero: two complex multisets with the same real projections have the same projected sequence but can have different imaginary parts. Thus an estimate for a projected real sequence alone does not supply the zero-placement premise or the actual kernel comparison. □

Proposition 94.6.2 *(Selberg–Bombieri zero density does not imply HB$^+$).* The Selberg–Bombieri zero-density estimate $N(\sigma, T) \le T^{\theta(\sigma)}$ for $\sigma \in (1/2, 1)$ with $\theta(\sigma) \to 0$ as $\sigma \to 1$ controls the count of zeros with $\operatorname{Re}\rho \ge \sigma$ in imaginary height T, but $\theta(\sigma) > 0$ for all $\sigma < 1$. It does not preclude individual zeros off the critical line. Thus it does not prove HB$^+$.

Proof. The Selberg zero-density result (Selberg 1946; see Titchmarsh 1951 §9.19) $N(\sigma, T) \ll T^{\theta(\sigma)}$ with $\theta(\sigma) = (4 - 4\sigma)/(3 - 2\sigma) + \epsilon$ or sharper estimates gives a polynomial count but does not bound individual zero locations. A density theorem may leave finitely many off-line zeros, and one such zero already violates HB$^+$. The density-vs-location mismatch precludes the reduction. □

Proposition 94.6.3 *(Connes operator-trace approach reduces to HB$^+$).* The Connes adele-class-space construction (Connes 1999 arXiv:math/9811068; de Branges 1986–1992) has absorption trace equal

to the zero distribution of ζ; critical-line support of this determinant-trace datum is RH. Every operator-monotonicity argument for this support is therefore strictly equivalent to HB^+ and does not constitute an independent reduction below that threshold.

Proof. The Connes trace formula (Connes 1999 Thm. 0.1) identifies the absorption trace on the adele class space $\mathrm{GL}_1(\mathbb{A}_{\mathbb{Q}})/\mathbb{Q}^\times$ with the zero distribution of ζ. Critical-line support of that distribution is equivalent to RH. Any attempt to prove this support by operator monotonicity, semi-boundedness, or normality requires an unconditional proof which is RH-equivalent, not available at the level of the de Branges comparison. See Remark 57.3.10 for the detailed discussion. □

Remark 94.6.4 *(What the separate estimates supply).* Real-sequence completeness, regional zero counts and an operator realization concern distinct data. The bounds stated above do not construct the particular continuous kernel realization or its arithmetic form comparison. They do not impose a limit on stronger arguments that supply those missing maps and estimates.

94.7 de Branges Form of A-TP

Theorem 94.7.1 *(Conditional de Branges form comparison).* Suppose the Hilbert carrier, continuous Hermitian form, test map and two dense spans of Theorem 94.5.1 are supplied. Assume also that its test form $b(jf, jf)$ equals the full arithmetic Weil form on the declared complete test carrier. Then nonnegativity of that Weil form is equivalent to positivity of K_{E_ξ}, and implies RH.

Proof. The assumed form identity and the two density arguments of the continuous-form criterion give the equivalence. The derivative-kernel strictness gives the zero-placement conclusion. The model-space isometry and the finite Gram calculation do not construct the assumed arithmetic form identity. □

Remark 94.7.2 *(The comparison to construct).* The remaining arithmetic step is the actual carrier and form map in the theorem. The peripheral zero-free bands neither supply that map nor prove its positivity. Kernel positivity for the exact derivative datum is a precise sufficient target, not an available premise in an unconditional proof.

Remark 94.7.3 *(relation to the bounded-interval reduction).* The full signed inequality is $A[f] + 4\pi \log \pi \, \|f\|_2^2 \le B[f] + 2\pi R[f]$. The interval $[-t_*, t_*]$ describes the negative part of the auxiliary multiplier g. A de Branges formulation must transport the entire Weil form, including $R[f]$ and the signed archimedean term, through an actual test map. Positivity of a finite kernel Gram matrix by itself establishes no such transport.

Remark 94.7.4 *(de Branges boundary).* The model-space isometry and finite kernel Gram norms are explicit analytic constructions under the stated Hermite–Biehler premise. The arithmetic form identity is the separate input of Theorem 94.7.1; the continuous-form criterion explains precisely how positivity would transfer once that input and its dense realization are constructed.

94.8 Consequences

(i) The de Branges function

$$E_\xi(z) = \xi_{\mathbb{R}}(\tfrac{1}{2} - iz) + \xi'_{\mathbb{R}}(\tfrac{1}{2} - iz)$$

satisfies $(E_\xi + E_\xi^*)/2 = \Xi$, so the non-trivial zeros of ζ are the zeros of the real part A_ξ in the coordinate $s = \frac{1}{2} + iz$ (Definition 94.2.1, Lemma 94.2.2).

(ii) Stirling asymptotics for the completed zeta do not prove Hermite–Biehler positivity for E_ξ; the strict inequality is precisely the HB$^+$ input (Proposition 94.2.4, Corollary 94.2.5).

(iii) Under HB$^+$, multiplication by E_ξ identifies the model space $K(E_\xi^*/E_\xi)$ with $\mathcal{H}(E_\xi)$; the Mellin lift enters this isometry only when its transform lies in that model space (Theorem 94.3.3), giving the finite Gram norm calculation, with arithmetic form transport still required (Corollary 94.3.4).

(iv) The Vinogradov–Korobov zero-free region pulls back to peripheral horizontal bands $\mathcal{P}_T$. It gives no zero-free central strip around the real z-axis (Definition 94.4.1, Lemma 94.4.2).

(v) The peripheral zero-free bands do not imply positive-semidefiniteness of K_{E_ξ} on the zero set. Thus there is no Vinogradov–Korobov A-TP closure (Proposition 94.4.3, Theorem 94.4.4).

(vi) The continuous-form realization with its two dense spans transfers positivity to the full kernel when its arithmetic form map is given, and the exact derivative datum then gives zero placement (Theorem 94.5.1, Corollary 94.5.2).

(vii) The stated real-sequence, regional-density and operator data do not supply the missing arithmetic form comparison (Section 94.6).

(viii) The Mellin model-space isometry gives the analytic norm identity of Theorem 94.3.3. Transporting the signed archimedean contribution or the full Weil form to a kernel Gram form requires the additional arithmetic comparison of Theorem 94.7.1.

Remark 94.8.1 *(Beilinson domain boundary).* Vinogradov–Korobov 1958 gives a peripheral exclusion after the change of variables $s = \frac{1}{2} + iz$. It does not close A-TP. The obstruction is precise: HB$^+$. Every advance beyond this requires either a zero-location theorem strong enough to imply HB$^+$, or an independent proof of HB$^+$ by operator methods. Both remain open in the arithmetic branch.

Connes 1999, arXiv:math/9811068. *Trace formula in noncommutative geometry.* Cited for the operator-approach rule-out of Proposition 94.6.3.

The disjointness with constructions 5 A, 5 J, 6 A is per-source. Only de Branges 1968 appears in both the de Branges spectral comparison and the de Branges comparison; it is used in distinct roles (structure theorem vs. reproducing-kernel formalism) and these roles do not overlap in a single identification.

Chapter 95

Gaussian Tests for the Signed Gamma Form

A Gaussian decays fast enough for every term of the explicit formula, although it is not compactly supported. This extension requires exponential control in the logarithmic variable. Ordinary Schwartz continuity cannot control the uncentered critical prime measure.

95.1 An exponential test space

Definition 95.1.1 *(rapid exponential decay).* Let $\mathscr{G}$ consist of all smooth functions f such that

$$p_{a,N,j}(f) = \sup_{t\in\mathbb{R}} e^{a|t|}(1+|t|)^N |f^{(j)}(t)| < \infty \quad (a, N, j \in \mathbb{N}).$$

Give $\mathscr{G}$ the topology of these seminorms. Use $h_f(z) = \int f(t)e^{izt}\,dt$ and $f^*(t) = \overline{f(-t)}$.

Proposition 95.1.2 *(extension of the explicit formula).* The space $\mathscr{G}$ is a convolution algebra with continuous involution. Compact smooth functions are dense in $\mathscr{G}$. The explicit formula, its signed pairing, and both polar moments extend continuously to $\mathscr{G}$. In particular, for $f, g \in \mathscr{G}$,

$$W(f * g^*) = \sum_{\rho} h_f(z_\rho)\overline{h_g(\bar{z}_\rho)} = P(f * g^*) - W_\infty(f * g^*) - W_{\mathrm{fin}}(f * g^*).$$

The zero and prime sums are absolutely convergent. Positivity on all squares in $\mathscr{G}$ is equivalent to positivity on all squares in $\mathscr{A}$.

Proof. The inequality $|t| \le |v| + |t - v|$, together with the corresponding polynomial weight inequality, bounds every convolution seminorm by a weighted supremum seminorm times a weighted integral seminorm. An additional exponential weight bounds that integral. This proves continuity of convolution. Reflection proves continuity of $*$. For a compact smooth cutoff $\chi = 1$ near zero, put $f_R(t) = \chi(t/R)f(t)$. Leibniz's rule and one extra exponential weight give $p_{a,N,j}(f - f_R) \to 0$ for every seminorm.

Integration by parts gives rapid decay of h_f in each fixed horizontal strip, continuously in these seminorms. The zero count then bounds the zero sum. The polar evaluations are continuous. The gamma density has logarithmic growth, so its integral is continuous. Finally, for example,

$$\sum_{n\ge 2} \frac{\Lambda(n)}{\sqrt{n}} |f(\pm \log n)| \le p_{2,0,0}(f) \sum_{n\ge 2} \frac{\log n}{n^{5/2}}.$$

The compact explicit formula therefore passes to the limit f_R. Convolution continuity gives the paired identity and passage of positivity. The reverse positivity implication uses $\mathscr{A} \subset \mathscr{G}$. □

95.2 THE NORMALIZED SCALAR INTEGRAL

LEMMA 95.2.1 *(Gaussian Fourier transform).* For $\lambda > 0$ set $f_\lambda(t) = e^{-\lambda t^2/2}$. Then

$$h_{f_\lambda}(u) = \sqrt{\frac{2\pi}{\lambda}} e^{-u^2/(2\lambda)}, \qquad (f_\lambda * f_\lambda)(t) = \sqrt{\frac{\pi}{\lambda}} e^{-\lambda t^2/4}.$$

Consequently, with $k(u) = \log \pi - \Re \psi_\Gamma(1/4 + iu/2)$,

$$W_\infty(f_\lambda * f_\lambda) = \sqrt{\frac{\pi}{\lambda}}\, H(\lambda), \qquad H(\lambda) = \frac{1}{\sqrt{\pi\lambda}} \int e^{-u^2/\lambda} k(u)\, du.$$

Proof. Completing the square gives both Gaussian integrals. Insert $|h_{f_\lambda}|^2 = (2\pi/\lambda) e^{-u^2/\lambda}$ in the gamma pairing with its coefficient $1/(2\pi)$. □

THEOREM 95.2.2 *(convergent error-function series).* Let $c_n = n + 1/4$ and $\operatorname{erfc}(x) = \frac{2}{\sqrt{\pi}} \int_x^\infty e^{-v^2}\, dv$. For every $\lambda > 0$,

$$H(\lambda) = k(0) - \sum_{n=0}^{\infty} \left[\frac{1}{c_n} - \frac{2\sqrt{\pi}}{\sqrt{\lambda}} e^{4c_n^2/\lambda} \operatorname{erfc}(2c_n/\sqrt{\lambda}) \right].$$

Each bracket is nonnegative and at most $\lambda/(8c_n^3)$. The series converges uniformly on compact λ-intervals.

Proof. The digamma series gives $k(0) - k(u) = \sum_n (u^2/4)/(c_n(c_n^2 + u^2/4))$. Tonelli's theorem exchanges this nonnegative sum and the Gaussian integral. For $a > 0$,

$$\int_{\mathbb{R}} \frac{e^{-u^2/\lambda}}{u^2 + a^2}\, du = \sqrt{\pi} \int_0^\infty \frac{e^{-a^2 r}}{\sqrt{r + 1/\lambda}}\, dr = \frac{\pi}{a} e^{a^2/\lambda} \operatorname{erfc}(a/\sqrt{\lambda}).$$

The first equality follows by integrating $\int_0^\infty e^{-r(u^2+a^2)}\, dr$ in either order. The substitution $v = a\sqrt{r + 1/\lambda}$ gives the second. Set $a = 2c_n$ and use $\int e^{-u^2/\lambda} u^2\, du = \sqrt{\pi}\lambda^{3/2}/2$. The estimate on each bracket follows by replacing $c_n^2 + u^2/4$ by c_n^2. It proves uniform convergence. □

THEOREM 95.2.3 *(the exact Gaussian sign range).* The continuous function H is strictly decreasing on $(0, \infty)$, with limits $k(0) > 0$ at zero and $-\infty$ at infinity. There is a unique $\lambda_c > 0$ with $H(\lambda_c) = 0$, and

$$W_\infty(f_\lambda * f_\lambda) \geq 0 \quad \Longleftrightarrow \quad 0 < \lambda \leq \lambda_c.$$

Proof. After $u = \sqrt{\lambda} v$, $H(\lambda) = \pi^{-1/2} \int e^{-v^2} k(\sqrt{\lambda} v)\, dv$. Strict radial decrease of k gives strict decrease of this integral. Logarithmic growth gives a common integrable majorant on each compact λ-interval and on $0 < \lambda \leq 1$. Thus H is continuous and tends to $k(0)$ at zero. For each $v \neq 0$, the nonnegative quantity $k(0) - k(\sqrt{\lambda} v)$ increases to infinity. Monotone convergence gives the limit at infinity. The intermediate value theorem completes the proof. □

95.3 THE ARITHMETIC INEQUALITY ON GAUSSIAN SQUARES

For these Gaussian tests the polar and prime contributions are

$$P(f_\lambda * f_\lambda) = \frac{4\pi}{\lambda} e^{1/(4\lambda)}, \qquad W_{\mathrm{fin}}(f_\lambda * f_\lambda) = 2\sqrt{\frac{\pi}{\lambda}} \sum_{n \geq 2} \frac{\Lambda(n)}{\sqrt{n}} e^{-\lambda(\log n)^2/4}.$$

These expressions converge for every $\lambda > 0$ and give the complete value of $W(f_\lambda * f_\lambda)$ after subtracting the prime and gamma terms from the polar term. The gamma sign theorem alone does not determine that value.

Proposition 95.3.1 *(a single Gaussian parameter does not test a quadratic form).* For a Hermitian form, nonnegative values on a spanning collection of vectors do not imply nonnegative values on its linear span. In particular, Gaussian cross terms require their own comparison.

Proof. The Hermitian matrix $\left(\begin{smallmatrix} 1 & 2 \\ 2 & 1 \end{smallmatrix}\right)$ is positive on each coordinate vector but has value -2 on $(1, -1)$. More generally, $q(f+g, f+g) = q(f,f) + q(g,g) + 2\Re q(f,g)$. The signed arithmetic representation determines these cross terms on $\mathscr{G}$, but positivity of individual Gaussian squares does not bound them. □

95.4 The auxiliary digamma integral and Fourier normalization

The signed kernel k and the auxiliary kernel $g(u) = \Re\psi_{\mathrm{T}}(1/4 + iu/2) + \log\pi$ satisfy $k(u) + g(u) = 2\log\pi$. To compare scalar calculations, use a separate parameter $L > 0$ and define

$$I(L) = \int_{\mathbb{R}} e^{-2\pi u^2/L} g(u)\, du, \qquad m_L = \sqrt{L/2}.$$

Direct substitution in the definition of H gives

$$\frac{I(L)}{m_L} = 2\log\pi - H\!\left(\frac{L}{2\pi}\right). \tag{95.1}$$

Thus the zero of I is a level $H = 2\log\pi$, distinct from the signed threshold $H = 0$.

Proposition 95.4.1 *(the auxiliary error-function series).* With $c_n = n + 1/4$, put

$$\begin{aligned} J_n(L) &= \int_{\mathbb{R}} e^{-2\pi u^2/L} \frac{c_n}{c_n^2 + u^2/4}\, du, \\ &= 2\pi e^{8\pi c_n^2/L} \operatorname{erfc}\!\left(2c_n\sqrt{2\pi/L}\right). \end{aligned}$$

Then the paired series

$$I(L) = m_L(-\gamma_E + \log\pi) + \sum_{n\ge 0}\left(\frac{m_L}{n+1} - J_n(L)\right) \tag{95.2}$$

converges absolutely. The accelerated series is

$$\frac{I(L)}{m_L} = g(0) + \sum_{n\ge 0}\left(\frac{1}{c_n} - \frac{J_n(L)}{m_L}\right), \qquad 0 \le \frac{1}{c_n} - \frac{J_n(L)}{m_L} \le \frac{L}{16\pi c_n^3}.$$

In particular its tail from $n = N \ge 1$ is at most $L/[32\pi(N - 3/4)^2]$.

Proof. The digamma series is

$$g(u) = -\gamma_E + \log\pi + \sum_{n\ge 0}\left(\frac{1}{n+1} - \frac{c_n}{c_n^2 + u^2/4}\right).$$

Subtract its value at zero. The resulting nonnegative summands permit Tonelli's theorem. The error-function integral in Theorem 95.2.2, with $\lambda = L/(2\pi)$, gives J_n and the accelerated bound. The difference $1/(n+1) - 1/c_n$ is absolutely summable, so regrouping gives (95.2). Finally $\sum_{n=N}^{\infty}(n+1/4)^{-3} \le \int_{N-1}^{\infty}(x+1/4)^{-3}dx$ proves the tail estimate. The unaccelerated paired summands are $O_L(n^{-2})$, since $J_n(L) = m_L/c_n + O_L(c_n^{-3})$. □

Remark 95.4.2 *(the real and complex Gaussian integrals).* The integral used above, for $a, \alpha > 0$, is

$$\int_{\mathbb{R}} \frac{e^{-\alpha u^2}}{a^2+u^2}\,du = \frac{\pi}{a}e^{\alpha a^2}\operatorname{erfc}(a\sqrt{\alpha}).$$

Also

$$\int_{\mathbb{R}} \frac{e^{-\alpha u^2}}{a-iu}\,du = \pi e^{\alpha a^2}\operatorname{erfc}(a\sqrt{\alpha}).$$

Indeed $(a-iu)^{-1} = (a+iu)/(a^2+u^2)$; the imaginary term is odd and integrates to zero. The real integral was proved by a Laplace integral in Theorem 95.2.2.

PROPOSITION 95.4.3 *(the auxiliary limits and threshold).* As $L \downarrow 0$,

$$I(L) = m_L\left(g(0) + \frac{L}{8\pi}g''(0) + O(L^2)\right), \qquad g(0) = \log\pi - \gamma_E - \frac{\pi}{2} - 3\log 2 < 0.$$

As $L \to \infty$, $I(L) \sim \frac{1}{2}m_L \log L$. The normalized integral $I(L)/m_L$ is strictly increasing and has a unique zero $L_g > 0$, characterized by $H(L_g/(2\pi)) = 2\log\pi$.

Proof. Write $u = \sqrt{L/(2\pi)}v$ and use the probability density $\pi^{-1/2}e^{-v^2}$. Its second moment is $1/2$. The even Taylor expansion of g, with fourth-order remainder near zero and logarithmic growth away from zero, gives the narrow expansion. The Gaussian tail outside a fixed neighborhood is smaller than every power of L. The value at zero follows from the reflection and duplication identities for ψ_Γ. For the wide limit, $g(u) = \log|u| + O(1)$ for $|u| \ge 1$. Split the scaled integral at $|v| = \sqrt{2\pi/L}$. On the complement, $\log|v|$ is integrable against the Gaussian. On the small interval, boundedness of g gives an $O(L^{-1/2}\log L)$ error after subtracting $\frac{1}{2}\log L$. Thus $I(L)/m_L = \frac{1}{2}\log L + O(1)$. Finally (95.1) and the strict decrease of H give monotonicity and uniqueness. □

The time Gaussian $F_L(x) = e^{-\pi L x^2}$ has the Fourier transform

$$\widehat{F}_{L,2\pi}(u) = \int F_L(x)e^{-2\pi i u x}\,dx = L^{-1/2}e^{-\pi u^2/L}.$$

Since $F_L = f_{2\pi L}$, its signed pairing is

$$W_\infty(F_L * F_L) = \frac{1}{\sqrt{2L}}H(2\pi L).$$

More generally, $\mathcal{F}_+\phi(2\pi u) = \widehat{\phi}_{2\pi}(-u)$, so evenness of k and a change of variables give

$$W_\infty(\phi) = \int_{\mathbb{R}} \widehat{\phi}_{2\pi}(u)k(2\pi u)\,du.$$

This conversion includes both the kernel argument and the measure factor. The parameter in the auxiliary identity (95.1) is therefore not the physical Gaussian parameter in this last pairing.

95.5 Cross terms and the positive Gaussian cone

Proposition 95.5.1 *(the signed gamma form on positive Gaussian sums).* For $\lambda, \mu > 0$, put $\nu = 2\lambda\mu/(\lambda+\mu)$. Then

$$(f_\lambda * f_\mu)(t) = \sqrt{\frac{2\pi}{\lambda+\mu}}\, e^{-\lambda\mu t^2/[2(\lambda+\mu)]},$$

$$W_\infty(f_\lambda * f_\mu) = \sqrt{\frac{2\pi}{\lambda+\mu}}\, H(\nu).$$

Consequently, on the cone

$$C^+_{\mathrm{Gauss}} = \left\{ \sum_{j=1}^{N} a_j f_{\lambda_j} : N \geq 1,\ a_j \geq 0,\ 0 < \lambda_j \leq \lambda_c \right\},$$

one has $W_\infty(f * f^*) \geq 0$.

Proof. Complete the square in the convolution integral. The Fourier product is $(2\pi/\sqrt{\lambda\mu})e^{-u^2/\nu}$. Integrating it against $k(u)/(2\pi)$ gives the displayed pairing. For $\lambda, \mu \leq \lambda_c$, their harmonic mean satisfies $\nu \leq \lambda_c$, so every cross pairing is nonnegative. Expand the finite sum with coefficients $a_i a_j \geq 0$. □

Proposition 95.5.2 *(continuity and carrier boundaries).* The signed gamma distribution extends continuously to the Schwartz space. Its quadratic pairing is continuous there as well. The linear span of the centered Gaussians lies in the closed even subspace and is not dense in the full Schwartz space. Every nonzero element of C^+_{Gauss} is positive on all of $\mathbb{R}$, so it is not compactly supported. Its Fourier transform is not in $\mathcal{F}_+\mathscr{A}$. Both compact tests and these Gaussians belong to $\mathscr{G}$.

Proof. Logarithmic growth of k bounds its Fourier pairing by a Schwartz seminorm. The Fourier transform, convolution and involution are continuous on Schwartz space. Reflection is continuous, so its fixed subspace is closed and excludes nonzero odd Schwartz functions. Each Gaussian is strictly positive, which proves the support claim for nonzero positive combinations. Fourier injectivity would force a compact preimage to equal this noncompact function. Membership in $\mathscr{G}$ follows directly from the defining seminorms. Continuity of the complete arithmetic functional uses that exponential topology, as proved above. □

The positive Gaussian cone controls the signed gamma term only. The full Weil form still subtracts this term and the prime term from the polar term. Neither positivity of the gamma cone nor its comparison with a compact or automorphic test class proves the full arithmetic inequality.

95.6 The auxiliary Schwartz form and its Gaussian cone

The auxiliary integral also defines a quadratic form, but it is not the signed gamma form. On the complex Schwartz space use the convention $\widehat{f}(u) = \int_{\mathbb{R}} f(x) e^{-2\pi i u x}\, dx$ and set

$$\mathcal{T}_g(\phi) = \frac{1}{2\pi}\int_{\mathbb{R}} \widehat{\phi}(u)\, g(u)\, du, \qquad Q_g(f,h) = \frac{1}{2\pi}\int_{\mathbb{R}} \widehat{f}(u)\overline{\widehat{h}(u)}\, g(u)\, du.$$

Thus $\mathcal{T}_g$ is complex linear and Q_g is Hermitian, linear in its first argument, with $Q_g(f,h) = \mathcal{T}_g(f * h^*)$. The value of $\mathcal{T}_g$ is real when its Fourier argument is real, in particular for real even tests. No real-valuedness is claimed for arbitrary complex tests.

PROPOSITION 95.6.1 *(continuity and the two normalizations).* The functional $\mathcal{T}_g$ and the sesquilinear form Q_g are continuous on Schwartz space. The function I is smooth on $(0,\infty)$. With $\langle f,h\rangle_2=\int f\bar h$, one has

$$\frac{1}{2\pi}\int \widehat{f}(u)\overline{\widehat{h}(u)}k(u)\,du=\frac{\log\pi}{\pi}\langle f,h\rangle_2-Q_g(f,h),$$

$$W_\infty(f*h^*)=\int \widehat{f}(u)\overline{\widehat{h}(u)}k(2\pi u)\,du.$$

The second equality denotes the signed gamma extension; it does not extend the full prime functional to arbitrary Schwartz tests.

Proof. The function g is smooth at zero and has at most logarithmic growth. Bound its integral by a weighted supremum seminorm of $\widehat{\phi}$; for the form use the product of such seminorms of $\widehat{f}$ and $\widehat{h}$. The integrable majorant can be taken proportional to $(1+|u|)^{-2}$. Fourier transform is continuous on Schwartz space. On each compact interval of positive L, every L-derivative of $e^{-2\pi u^2/L}$ is bounded by a polynomial in u times a fixed Gaussian. Multiplication by $g(u)$ is integrable against this bound, so differentiation under the integral proves $I\in C^\infty$. The first identity uses $k+g=2\log\pi$ and Plancherel in the 2π convention. The second uses $h_f(2\pi u)=\widehat{f}(-u)$ and the change of measure $du_{\mathrm{old}}=2\pi\,du$, followed by evenness of k. □

THEOREM 95.6.2 *(auxiliary Gaussian pairings and the exact cone).* For $F_L(x)=e^{-\pi Lx^2}$, $L,M>0$, let $H_{LM}=2LM/(L+M)$. Then

$$Q_g(F_L,F_M)=\frac{I(H_{LM})}{2\pi\sqrt{LM}},\qquad Q_g(F_L,F_L)=\frac{I(L)}{2\pi L}.$$

Consequently

$$\{L>0:Q_g(F_L,F_L)\ge 0\}=[L_g,\infty),\qquad Q_g(F_L,F_L)=0\iff L=L_g,$$

where $H(L_g/(2\pi))=2\log\pi$. On the nonempty cone

$$C_g^+=\left\{\sum_{j=1}^{N}a_jF_{L_j}:a_j\ge 0,\ L_j\ge L_g,\ N\ge 1\right\}$$

one has $Q_g(f,f)\ge 0$. A nonzero element has zero value precisely when every parameter with nonzero coefficient equals L_g. The same nonnegativity holds on the closure of this cone in Schwartz topology.

Proof. The product of the two Fourier Gaussians is $(LM)^{-1/2}e^{-\pi u^2(1/L+1/M)}$, which gives the first identity. The sign and equality statements follow from the strict increase of $I(L)/m_L$ and its unique zero proved above. If $L,M\ge L_g$, then $H_{LM}^{-1}=(L^{-1}+M^{-1})/2\le L_g^{-1}$. Thus every cross pairing is nonnegative. Expanding the square of a finite sum gives

$$Q_g(f,f)=\sum_{i,j}a_ia_j\frac{I(H_{L_iL_j})}{2\pi\sqrt{L_iL_j}}\ge 0.$$

If some $a_j>0$ has $L_j>L_g$, its diagonal term is strictly positive and none of the other terms can cancel it. Otherwise all active parameters equal L_g and every term vanishes. The closure statement is continuity of Q_g. Nonemptiness follows from any F_L with $L\ge L_g$. □

Example 95.6.3 *(two auxiliary Gaussian scales).* For real a, b,

$$Q_g(aF_L + bF_M, aF_L + bF_M) = \frac{1}{2\pi}\left(\frac{a^2 I(L)}{L} + \frac{2ab I(H_{LM})}{\sqrt{LM}} + \frac{b^2 I(M)}{M}\right).$$

Choose $L_g/2 < L < L_g$ and $M > L_g L/(2L - L_g)$. Then $M > L_g$ and $H_{LM} > L_g$, while $I(L) < 0$. Taking $a = 1$ and $b > 0$ sufficiently small gives a negative value by continuity in b. This example mixes one negative and one positive Gaussian; it does not contradict the positive-cone theorem, whose parameters all lie above L_g. Nor does that theorem assert positivity for every complex linear combination of its generators.

High-frequency dominance on a specified carrier

Let $t_g > 0$ be the unique zero of g: existence follows from $g(0) < 0$, logarithmic growth and strict increase on $(0, \infty)$. Indeed the differentiated Hurwitz series has positive summands $c_n u/[2(c_n^2 + u^2/4)^2]$ for $u > 0$, uniformly convergent on compact intervals. For $f \in \mathcal{S}(\mathbb{R})$ define

$$A_g(f) = \int_{|u| \le t_g} |\widehat{f}(u)|^2 (-g(u))\, du, \qquad B_g(f) = \int_{|u| > t_g} |\widehat{f}(u)|^2 g(u)\, du.$$

The high-frequency dominance condition, in this Fourier convention, is

$$2t_g |g(0)| \sup_{|u| \le t_g} |\widehat{f}(u)|^2 \le B_g(f).$$

It implies $A_g(f) \le B_g(f)$ and hence $Q_g(f, f) = (B_g(f) - A_g(f))/(2\pi) \ge 0$. This is the auxiliary inequality associated with the condition in Chapter 82.4.1; changing the Fourier convention requires its explicit frequency rescaling, and does not turn g into k.

For a specified restricted compact test space $E \subset \mathscr{A}$, put $E_{\mathrm{HFD}} = \{f \in E : f \text{ satisfies this condition}\}$. Every nonzero element of C_g^+ is positive on all of $\mathbb{R}$, so $C_g^+ \cap E = \{0\}$; both sets contain zero. The assertion that E_{HFD} has a nonzero element requires a construction within the actual restrictions defining E. It is a separate question whether a chosen automorphic subspace admits such tests and a norm comparison. A noncompact Gaussian is not an example in that compact space.

Other positive classes and the full inequality. One may ask for other positive subspaces of Q_g, including nonconic combinations controlled by a de Branges or Connes–Deninger construction, compact smooth tests, or a spectral-density comparison with the Gaussian moments of g. No assertion that these exhaust all possible methods is made. The cone is a proper subset of its complex linear span: $-F_L$ belongs to that span for $L \ge L_g$ but cannot be a nonnegative sum of strictly positive Gaussians. For comparison, if functions φ_j are positive definite, then $\sum_j c_j \varphi_j$ is positive definite for $c_j \ge 0$: each of its finite Gram forms is the same nonnegative combination of the Gram forms of the φ_j. This elementary fact does not identify positive-definite functions with vectors on which Q_g is nonnegative. Closure of a positive cone follows from quadratic continuity; linear density of positive individual vectors alone does not control cross terms.

The signed cone and C_g^+ prove different gamma inequalities. Both lie in $\mathscr{G}$, where the full arithmetic identity is defined. For a specified $E \subset \mathscr{G}$ and $S \subset E$, positivity of the full Weil form on E is equivalent to positivity on $E \setminus S$ only after positivity on S is established. This is the elementary partition of the quantifier over E. Auxiliary positivity on S does not supply that premise, since the polar and prime terms remain. RH equivalence then requires a proved comparison of E with the full compact test criterion.

Chapter 96

Archimedean Tate Kernel Positivity: the Integral Energy Sub-Class

The digamma auxiliary form has a negative spectral core and a positive tail. An integral-energy estimate compares their masses and proves nonnegativity on an explicit class of compact smooth tests. Moment-preserving differential operators supply tests in this class and tests outside both the integral and supremum sufficient classes. The signed gamma form differs from this auxiliary form by a scalar multiple of the L^2 pairing. The complete Weil inequality also retains its prime and polar contributions.

96.1 Kernel and Integral Energy

The integral-energy estimate concerns an auxiliary digamma form. Here $\psi_\Gamma = \Gamma'/\Gamma$, and $\widehat{f} = h_f$ in this chapter. Use the angular Fourier transform $h_f(u) = \int_{\mathbb{R}} f(x)e^{iux}\,dx$ and set

$$g(u) = \Re\psi_\Gamma(1/4 + iu/2) + \log\pi, \qquad k(u) = 2\log\pi - g(u),$$

$$G_g(f,h) = \frac{1}{2\pi}\int h_f(u)\overline{h_h(u)}g(u)\,du.$$

The signed gamma form of the explicit formula is therefore

$$W_\infty(f * h^*) = 2\log\pi\langle f,h\rangle_2 - G_g(f,h).$$

This identity follows from Plancherel. It retains the angular normalization and differs from the cyclic normalization used for Q_g in Chapter 95.

Domain

Let $\mathscr{A} = C_c^\infty(\mathbb{R};\mathbb{C})$ with its inductive-limit topology. Its real even subspace is denoted by E. For $f \in E$ set

$$M_f(s) = \int f(x)e^{sx}\,dx, \qquad L(f) = \left(\int f, \int f\cosh x, \int xf(x)\sinh x\,dx\right).$$

The class $\mathscr{A}_{13} = \ker L \subset E$ has precisely the reality and double-Mellin-zero conditions at 0, 1. Compact support makes M_f entire and rapidly decreasing on every closed vertical strip. No weight-dependent strip restriction remains. These conditions impose no modularity on a coefficient multiplier.

Lemma 96.1.1 *(closed moment space and moment correction).* The space $\mathscr{A}_{13}$ is closed of real codimension three in E. There is a continuous real linear projection $\Pi : E \to \mathscr{A}_{13}$ of the form $\Pi = 1 - RL$, where $R : \mathbb{R}^3 \to E$ has compactly supported image and $LR = 1$.

Proof. Integration against each smooth weight is continuous on every fixed-support test space, hence on the inductive limit. Take normalized even mollifiers concentrated at 0, $\{\pm1\}$, and $\{\pm2\}$. Their moment columns tend to the columns obtained by evaluating 1, $\cosh x$, $x\sinh x$ at 0, 1, 2. The limiting

determinant is $2\sinh(1)(\cosh(1)-1)^2 > 0$. For a sufficiently small fixed width the moment matrix C is invertible. If the three mollifiers are b_0, b_1, b_2, define $Rv = \sum_{j=0}^{2} b_j (C^{-1}v)_j$. Then $LR = 1$, $\Pi^2 = \Pi$, and $L\Pi = 0$. The image of R has fixed compact support, so R and Π are continuous. Surjectivity of L gives the codimension. □

Write t_* for the positive zero of g, and $M = -g(0)$. For nonzero $f \in \mathscr{A}_{13}$ define the core and tail energies

$$A_g[f] = \int_{|u|<t_*} |h_f(u)|^2 (-g(u))\,du, \qquad B_g[f] = \int_{|u|>t_*} |h_f(u)|^2 g(u)\,du.$$

Thus $G_g(f,f) = (B_g[f] - A_g[f])/(2\pi)$. The supremum sufficient condition is

$$2t_* M \sup_{|u|<t_*} |h_f(u)|^2 \le B_g[f].$$

The integral-energy condition replaces this supremum by core mass. Both conditions concern G_g. The full arithmetic form remains

$$W(f * f^*) = P(f * f^*) - 2\log\pi \|f\|_2^2 + G_g(f,f) - W_{\mathrm{fin}}(f * f^*).$$

In particular, neither moment correction nor positivity of G_g proves the full Weil inequality.

For the energy comparison fix $\tau_0 > t_*$ and a continuous nondecreasing function $\ell : [\tau_0, \infty) \to (0, \infty)$ satisfying $\ell(T) \le g(T)$ and $\ell(T) = O(1 + \log(2+T))$. The unconditional choice $\ell = g|_{[\tau_0,\infty)}$ is available. Indeed, the Hurwitz series

$$g(u) = g(0) + \sum_{n\ge 0} \frac{u^2/4}{(n+1/4)((n+1/4)^2 + u^2/4)}$$

is strictly increasing for $u > 0$, and the digamma asymptotic gives logarithmic growth. Since $g(0) < 0$ and $g(u) \to \infty$, there is exactly one $t_* > 0$. Other choices of ℓ require the displayed lower-bound property. The proposed Stirling expression is one specific lower-bound question, separate from this energy theorem.

96.2 A proposed Stirling specialization of the lower weight

Stirling Series for the Digamma and Sign Control

Definition 96.2.1 (the digamma remainder). For $\Re z > 0$ and $N \geq 0$, define $R_N(z)$ by

$$\psi(z) = \log z - \frac{1}{2z} - \sum_{j=1}^{N} \frac{B_{2j}}{2j z^{2j}} + R_N(z). \tag{96.1}$$

Here log is the principal branch and B_{2j} are Bernoulli numbers, with $B_2 = 1/6$, $B_4 = -1/30$ and $B_6 = 1/42$. The proposed sectorial bound for this derivative remainder is

$$|R_N(z)| \leq \frac{|B_{2N+2}|}{(2N+2)|z|^{2N+2}} \sec^{2N+2}(\arg z/2). \tag{96.2}$$

Using this bound requires a proof for the digamma remainder with these constants. A remainder estimate for $\log\Gamma$ cannot simply be differentiated as an inequality.

The asymptotic expansion and remainder problem are treated in Whittaker–Watson 1927, §12.33, and Olver, *Asymptotics and Special Functions*, Ch. 8. The energy theorem below uses $\ell \leq g$ and does not require (96.2).

Lemma 96.2.2 *(real-part Stirling at $z = 1/4 + it/2$).* . For $t \in \mathbb{R}$ set $z(t) := 1/4 + it/2$. Then

$$\begin{aligned} \operatorname{Re} \log z(t) &= \tfrac{1}{2}\log(1/16 + t^2/4) = \tfrac{1}{2}\log\bigl((1+4t^2)/16\bigr), \\ \operatorname{Re}\frac{-1}{2z(t)} &= -\frac{1}{8|z(t)|^2} = -\frac{2}{1+4t^2}. \end{aligned}$$

The one-step truncation of (96.1) (with $N = 0$, no Bernoulli terms) gives

$$\operatorname{Re}\psi(z(t)) = \tfrac{1}{2}\log\bigl((1+4t^2)/16\bigr) - \frac{2}{1+4t^2} + \operatorname{Re} R_0(z(t)).$$

Proof. $|z(t)|^2 = (1/4)^2 + (t/2)^2 = 1/16 + t^2/4$. Hence $\log|z| = (1/2)\log(1/16 + t^2/4)$. For $1/z$: $\operatorname{Re}(1/z) = \operatorname{Re} z/|z|^2 = (1/4)/|z|^2$, so $\operatorname{Re}(-1/(2z)) = -(1/8)/|z|^2 = -2/(1+4t^2)$. The identity follows by direct substitution in (96.1). □

The Lower Bound g_L

Proposition 96.2.3 *(conditional Stirling lower weight).* Define

$$g_L(t) = \tfrac{1}{2}\log((1+4t^2)/16) + \log\pi - \frac{2}{1+4t^2},$$

and let $t_L^* > 0$ be its unique positive zero. Suppose the fourth-order bound proposed in Chapter 92.3.3, Chapter 92.3.2 holds on $|t| \geq t_L^*$ in the precise form

$$g(t) \geq g_L(t) + \frac{20u - 72}{15u^2}, \qquad u = 1 + 4t^2.$$

Then $g(t) > g_L(t)$ on that tail. Consequently $\ell = g_L|_{[\tau_0,\infty)}$ is an admissible positive lower weight for every $\tau_0 > t_L^*$.

Proof. As a function of $u \geq 1$, g_L has derivative $1/(2u) + 2/u^2 > 0$, is negative at one and tends to infinity. At $u = 18/5$, use $\pi^2 < 10$ to obtain $g_L < \log(3/2) - 5/9 < 1/2 - 5/9 < 0$. Hence the zero has $u > 18/5$, and the assumed correction $(20u - 72)/(15u^2)$ is strictly positive on the stated tail. Monotonicity and logarithmic growth give the properties of ℓ. □

Remark 96.2.4 *(the quantitative remainder question).* The first Bernoulli correction is

$$-\frac{1}{12}\Re(z(t)^{-2}) = \frac{4t^2 - 1}{192(1/16 + t^2/4)^2} = \frac{1}{3t^2} + O(t^{-4}).$$

A uniform estimate for $g - g_L$ on a finite interval requires a remainder bound in addition to this leading term. The conditional proposition states the exact lower estimate needed from the fourth-order calculation. The unconditional choice $\ell = g$ on a positive tail avoids this separate remainder question.

Corollary 96.2.5 *(the lower-weight zero).* The function g_L has exactly one positive zero t_L^*, and is nonnegative for $|t| \geq t_L^*$. Under the fourth-order hypothesis of the preceding proposition, $t_* < t_L^*$.

Proof. Existence and uniqueness follow from the derivative calculation. Under that hypothesis $g(t_L^*) > g_L(t_L^*) = 0$. Strict monotonicity of g on the positive axis gives $t_* < t_L^*$. □

Sign-domain comparison

Under the fourth-order lower-bound hypothesis, $g < 0$ on $|t| < t_*$, while $g_L < 0$ on $|t| < t_L^*$. On $t_* \leq |t| < t_L^*$, $g \geq 0 > g_L$. On $|t| \geq t_L^*$, $g > g_L \geq 0$. These specialized comparisons are conditional on that bound. For the energy argument, any positive nondecreasing lower weight $\ell \leq g$ on $[\tau_0, \infty)$ suffices.

96.3 The integral-energy class

Definition 96.3.1 *(spectral fractions).* For any nonzero $f \in L^2(\mathbb{R})$, let h_f denote its angular Fourier transform in the Plancherel sense. For $T \geq \tau_0 > t_*$, set

$$\alpha(f) = \frac{\int_{|u|<t_*} |h_f(u)|^2 du}{\|h_f\|_2^2},$$

$$\beta(f,T) = \frac{\int_{|u|>T} |h_f(u)|^2 du}{\|h_f\|_2^2},$$

$$\gamma(f,T) = 1 - \alpha(f) - \beta(f,T).$$

All three fractions are nonnegative and sum to one.

Definition 96.3.2 *(integral and supremum classes).* Use the lower weight ℓ specified above. Put

$$\mathrm{IE}(T) = \{f \in \mathscr{A}_{13} \setminus \{0\} : M\alpha(f) \leq \ell(T)\beta(f,T)\}, \qquad T \geq \tau_0. \tag{96.3}$$

Write HFD for the nonzero $f \in \mathscr{A}_{13}$ satisfying

$$2t_* M \sup_{|u|<t_*} |h_f(u)|^2 \leq B_g[f].$$

The notations $\mathrm{PW}_F^{\mathrm{hol,IE}}(T)$ and $\mathrm{PW}_F^{\mathrm{hol,HFD}}$ in the energy formulas refer to these compact moment classes, without an automorphy assertion.

Remark 96.3.3 *(dependence on the threshold).* Increasing T increases $\ell(T)$ and decreases $\beta(f,T)$. Their product need not be monotone. The threshold is therefore part of the sufficient condition.

Unconditional G_g-Positivity on $\mathrm{PW}_F^{\mathrm{hol,IE}}$

Theorem 96.3.4 *(integral-energy bound).* For a nonzero $f \in \mathscr{A}_{13}$, suppose $T_1 \geq \tau_0$ and $M\alpha(f) \leq \ell(T_1)\beta(f, T_1)$. Then

$$G_g(f, f) \geq 0, \qquad W_\infty(f * f^*) \leq 2\log\pi\|f\|_2^2.$$

The full Weil inequality holds exactly when

$$G_g(f, f) \geq 2\log\pi\|f\|_2^2 + W_{\mathrm{fin}}(f * f^*) - P(f * f^*).$$

Proof. On the core, $-g \leq M$, so $A_g[f] \leq M\alpha(f)\|h_f\|_2^2$. On the middle band $g \geq 0$, while on the far tail $g(u) \geq \ell(|u|) \geq \ell(T_1) \geq 0$. Consequently $B_g[f] \geq \ell(T_1)\beta(f, T_1)\|h_f\|_2^2$. The assumed inequality gives $B_g[f] \geq A_g[f]$. The signed gamma identity proves the second bound. Substitution into the complete explicit formula proves the last equivalence. □

Strict Enlargement over the bounded-interval reduction HFD

Proposition 96.3.5 *(strict extension of the supremum criterion).* On the nonzero tests in $\mathscr{A}_{13}$, the union of the supremum class and the integral-energy classes strictly contains the supremum class.

Proof. Fix a nonzero real even $\varphi \in C_c^\infty(\mathbb{R})$. Put $D = d/dx$, $\mathcal{L} = -D^2(D^2 - 1)^2$, and $p(u) = u^2(1 + u^2)^2$. Integration by parts gives

$$M_{\mathcal{L}v}(s) = -s^2(s^2 - 1)^2 M_v(s), \qquad h_{\mathcal{L}v}(u) = p(u)h_v(u).$$

Thus $\mathcal{L}v \in \mathscr{A}_{13}$ for every real even compact test v. For $A \geq 1$ let $\varphi_A(x) = A^{-1/2}\varphi(x/A)$. Choose $T_1 > \tau_0$, $R > T_1$, and set

$$f_A = A^2\mathcal{L}\varphi_A + c\mathcal{L}(\cos(Rx)\varphi_A), \qquad c > 0.$$

Write $H = h_\varphi$, $C_0 = \int |H(v)|^2 dv$, and $C_2 = \int v^4|H(v)|^2 dv > 0$. The three packets have centers $0, R, -R$ and width A^{-1}. At the core center, with $v = Au$,

$$h_{A^2\mathcal{L}\varphi_A}(v/A) = A^{1/2}v^2(1 + v^2/A^2)^2 H(v).$$

At each tail center the leading profile is $cA^{1/2}p(R)H(v)/2$. Schwartz decay and the substitution $v = A(u - u_0)$ give

$$\int_{|u|<t_*} |h_{f_A}|^2 \to C_2, \qquad \int_{|u|>T_1} |h_{f_A}|^2 \to D_R := \frac{c^2 p(R)^2}{2} C_0, \qquad B_g[f_A] \to g(R)D_R.$$

For justification, each off-center factor has argument differing by AR or $2AR$. Arbitrarily high Schwartz bounds make every cross integral tend to zero, also with the weight $1 + \log(2 + |u|)$. The same bounds dominate each centered integral after substitution. Choose c so that $MC_2 < \ell(T_1)D_R$. The strict integral-energy inequality then holds for all large A. Since $v^2H(v)$ is not identically zero, the core supremum grows at least linearly in A. The quantity $B_g[f_A]$ stays bounded. The supremum criterion therefore fails for all large A. Every f_A satisfies the moments exactly. □

Remark 96.3.6 *(which profile IE captures and HFD misses).* The HFD class is constrained by pointwise control of $\widehat{f}$ over the core; the IE class is constrained by integrated L^2 control and by a lower bound on the weighted tail energy. A narrow core peak with distributed tail may lie in IE and fail HFD. A tail concentrated near t_* may lie in HFD and fail IE. The two conditions are transverse sufficient criteria.

96.4 Complement of $\mathrm{PW}_F^{\mathrm{hol,IE}}$

Complement Structure

Theorem 96.4.1 *(IE residual as concentration inequality).* . $f \in \mathscr{A}_{13} \setminus \{0\} \setminus \bigcup_{T_1} \mathrm{PW}_F^{\mathrm{hol,IE}}(T_1)$ if and only if for every $T_1 \geq \tau_0$,

$$\ell(T_1)\beta(f, T_1) \;<\; M\alpha(f). \tag{96.4}$$

In particular,

$$\sup_{T_1 \geq \tau_0} \ell(T_1)\beta(f, T_1) \leq M\alpha(f).$$

Thus the residual is not the complement of high frequency; it is the locus where the logarithmic weighted tail bound never exceeds the core term.

Proof. (96.4) is (96.3) reversed. For residual f the reversed inequality holds at every T_1; conversely the reversed inequality at every T_1 excludes membership in every IE class. Taking the supremum gives the displayed necessary bound. No decay statement stronger than this weighted-tail bound follows without an independent regularity estimate on f. □

Remark 96.4.2 *(which test functions are in the residual).* Residual test functions have too little logarithmically weighted far-tail mass relative to their core mass. Low-frequency approximate identities give model examples after the weighted tail is made uniformly small. Individual Li approximants require a separate spectral comparison; no membership assertion for them is made here.

Prolate-Spheroidal Characterization

Theorem 96.4.3 *(two-scale prolate sufficient criterion).* . Fix Paley–Wiener exponential type T for h_f, i.e., $\mathrm{supp}(f) \subset [-T, T]$. Let $\{\lambda_k(T, \Omega)\}_{k=0}^{\infty}$ denote the Slepian–Pollak prolate eigenvalues of the integral operator $K_{T,\Omega}\colon L^2([-T, T]) \to L^2([-T, T])$

$$(K_{T,\Omega} f)(u) \;:=\; \int_{-T}^{T} \frac{\sin(\Omega(u - v))}{\pi(u - v)}\, f(v)\, dv,$$

sorted $\lambda_0 \geq \lambda_1 \geq \ldots > 0$. Then for $f \in \mathscr{A} \setminus \{0\}$ with support in $[-T, T]$,

$$\alpha(f) \;\leq\; \lambda_0(T, t_*). \tag{96.5}$$

For every $T_1 \geq \tau_0$,

$$\beta(f, T_1) \;\geq\; 1 - \lambda_0(T, T_1).$$

Consequently all $f \in \mathscr{A}_{13} \setminus \{0\}$ of type at most T lie in $\mathrm{PW}_F^{\mathrm{hol,IE}}(T_1)$ if

$$M\lambda_0(T, t_*) \;\leq\; \ell(T_1)\big(1 - \lambda_0(T, T_1)\big). \tag{96.6}$$

Proof. The operator $K_{T,\Omega}$ is the time-limited frequency projection onto $[-\Omega, \Omega]$. Hence

$$\frac{\int_{-\Omega}^{\Omega} |\widehat{f}(t)|^2\, dt}{\int_{\mathbb{R}} |\widehat{f}(t)|^2\, dt} = \frac{\langle K_{T,\Omega} f, f\rangle}{\langle f, f\rangle} \leq \lambda_0(T, \Omega).$$

Taking $\Omega = t_*$ gives (96.5). Taking $\Omega = T_1$ gives the mass bound inside $[-T_1, T_1]$, hence $\beta(f, T_1) \geq 1 - \lambda_0(T, T_1)$. If (96.6) holds, then

$$M\alpha(f) \leq M\lambda_0(T, t_*) \leq \ell(T_1)(1 - \lambda_0(T, T_1)) \leq \ell(T_1)\beta(f, T_1),$$

so $f \in \mathrm{PW}_F^{\mathrm{hol,IE}}(T_1)$. □

Remark 96.4.4 *(quantitative prolate bounds).* For $c = T\Omega$, positivity of the concentration operator gives $\lambda_0(T,\Omega) \le \min(1, 2c/\pi)$: its trace is the integral of its diagonal kernel, $2T\Omega/\pi$. On rescaling to $[-1,1]$, its kernel is $\sin(c(x-y))/(\pi(x-y)) = c/\pi + O(c^3)$ uniformly for small c. The operator norm of the remainder is $O(c^3)$, so $\lambda_0 = 2c/\pi + O(c^3)$ by comparison with the constant rank-one kernel. For large c, testing any fixed nonzero compact smooth function and using Fourier tail decay gives $\lambda_0 \to 1$. These single-scale facts control only the core fraction. The far-tail bound at the second scale T_1 is still required in (96.6).

Absolute Uniform Closure Sub-Class

A uniform closure from prolate theory requires a core scale and a far-tail scale.

Corollary 96.4.5 *(uniform G_g-positivity under a two-scale prolate inequality).* . Fix $T_0 > 0$ and $T_1 \ge \tau_0$. If

$$M\lambda_0(T_0, t_*) \;\le\; \ell(T_1)\big(1 - \lambda_0(T_0, T_1)\big), \tag{96.7}$$

then $G_g(f,f) \ge 0$ for every $f \in \mathscr{A}_{13} \setminus \{0\}$ of exponential type $T \le T_0$.

Proof. The top prolate eigenvalue is monotone in both the time window and the frequency window. Hence for $T \le T_0$,

$$\alpha(f) \le \lambda_0(T_0, t_*), \qquad \beta(f, T_1) \ge 1 - \lambda_0(T_0, T_1).$$

Hypothesis (96.7) gives $M\alpha(f) \le \ell(T_1)\beta(f, T_1)$. Thus $f \in \mathrm{PW}_F^{\mathrm{hol,IE}}(T_1)$, and Chapter 96.3.4 gives the claim. □

Remark 96.4.6 *(significance).* Chapter 96.4.5 is a uniform G_g-positivity result only after the two prolate eigenvalues in (96.7) are verified. The single estimate $\alpha(f) \le \lambda_0(T_0, t_*)$ controls the core but says nothing about how much mass has crossed the far-tail threshold T_1.

96.5 Quantification of the Archimedean Positivity Extension

Theorem 96.5.1 *(properness of the two sufficient classes).* The union of the supremum and integral-energy classes is a proper subset of $\mathscr{A}_{13} \setminus \{0\}$. Together with Chapter 96.3.5, this gives both strict inclusions in (96.8), with ambient class $\mathscr{A}_{13} \setminus \{0\}$.

$$\mathrm{HFD} \subsetneq \mathrm{HFD} \cup \bigcup_{T_1} \mathrm{IE}(T_1) \subsetneq \mathscr{A}_{13} \setminus \{0\}. \tag{96.8}$$

Proof. Use the compact test $f_A = A^2 \mathcal{L}\varphi_A$ from the preceding construction, omitting both tail packets. Its spectral mass converges to $C_2 > 0$ and concentrates at zero. In particular, $\alpha(f_A) \to 1$. Moreover,

$$\int_{|u|>\tau_0} (1 + \log(2 + |u|))|h_{f_A}(u)|^2 du \longrightarrow 0.$$

Indeed, after $v = Au$, the integrand is bounded by a constant times $(1 + \log(2 + |v|))(1 + |v|)^{12}|H(v)|^2$ on $|v| > A\tau_0$. This is integrable, and its tail tends to zero. Monotonicity and logarithmic growth of ℓ give

$$\sup_{T_1 \ge \tau_0} \ell(T_1)\beta(f_A, T_1) \longrightarrow 0.$$

Thus every integral-energy condition fails for large A. The same weighted-tail estimate gives $B_g[f_A] \to 0$, while the core supremum grows linearly in A. The supremum condition fails as well. The Mellin identity for $\mathcal{L}$ proves all moment conditions, without a further cutoff or a modularity assertion. □

Remark 96.5.2 *(what the gap captures).* The gap $(\mathscr{A}_{13} \setminus \{0\}) \setminus \bigcup_{T_1} \mathrm{PW}_F^{\mathrm{hol,IE}}(T_1)$ is non-empty. Its model elements are low-frequency approximate identities with negligible logarithmic far tail. No assertion about a particular Li approximant follows without computing its weighted spectral profile.

96.6 Compatibility with Chapters 61, 57, and the Bounded-Interval Reduction

IE Class and Chapter 61 Bounded-Interval Reduction

Proposition 96.6.1 *(arithmetic inequality after the energy bound).* For an integral-energy test $f \in \mathscr{A}_{13}$, one has $G_g(f,f) \geq 0$. Its full Weil inequality is equivalent to

$$G_g(f,f) \geq 2\log\pi\|f\|_2^2 + W_{\mathrm{fin}}(f * f^*) - P(f * f^*).$$

The moments defining $\mathscr{A}_{13}$ do not remove $P(f * f^*)$.

Proof. The energy estimate proves the first assertion. The explicit formula and the identity $k + g = 2\log\pi$ prove the equivalence. Chapter 78 gives a compact test in $\mathscr{A}_{13}$ with nonzero polar form. □

Three Non-Elementary Constructions Revisited

The zero-density, Gaussian and Hermite–Biehler comparisons of Chapter 82.6.3 pose separate questions. The integral-energy theorem supplies no implication between them.

Remark 96.6.2 *(Gaussian and compact test comparisons).* The function $f_\sigma(x) = e^{-x^2/(2\sigma^2)}$ has angular transform $h_{f_\sigma}(u) = \sigma\sqrt{2\pi}e^{-\sigma^2u^2/2}$. It belongs to the exponential test space $\mathscr{G}$, and has no compact support. For a fixed $T_1 > \tau_0$, its core fraction tends to zero and its far-tail fraction tends to one as $\sigma \downarrow 0$. Thus it satisfies the auxiliary integral-energy inequality for small σ. As $\sigma \to \infty$, its core fraction tends to one and its logarithmically weighted tail tends to zero. These are statements about the Gaussian spectral profile. The Gaussian does not satisfy the zero moments at 0, 1, since $M_{f_\sigma}(0) > 0$. The differential construction above instead supplies exact compact moment tests with the required energy profiles.

The explicit formula extends from compact tests to $\mathscr{G}$ in its exponential topology, as proved in Chapter 95.1.2. That extension retains $P - W_\infty - W_{\mathrm{fin}}$. A spectral-width estimate for G_g supplies no isometry into an arithmetic or automorphic Hilbert space. An identification with a positive native pairing requires a linear map I on the specified tests and the equality $\langle If, Ih\rangle = W(f * h^*)$. Zero counts and prolate concentration estimates do not construct this map or prove the pairing equality.

96.7 Consequences of the energy estimates

The lower bound ℓ gives the sufficient condition $M\alpha(f) \leq \ell(T_1)\beta(f,T_1)$ for $G_g(f,f) \geq 0$. The two-scale prolate inequality implies this condition uniformly on a fixed compact support interval whenever its displayed bound holds. The resulting signed gamma estimate is $W_\infty(f * f^*) \leq 2\log\pi\|f\|_2^2$.

The compact differential constructions prove that the union of the integral and supremum classes strictly enlarges the supremum class, and that their union is a proper subset of the nonzero tests in $\mathscr{A}_{13}$. No inclusion of the supremum class in the union of integral-energy classes is needed. The complementary class is exactly the locus where $\ell(T_1)\beta(f,T_1) < M\alpha(f)$ for every $T_1 \geq \tau_0$.

Remark 96.7.1 *(the remaining arithmetic inequality).* The energy comparison controls the auxiliary form. For each admissible test, full Weil positivity still requires

$$G_g(f,f) + P(f * f^*) \geq 2\log\pi\|f\|_2^2 + W_{\mathrm{fin}}(f * f^*).$$

A proof on the moment kernel addresses that kernel. Extending it to all compact smooth tests also requires the mixed pairings and the finite-dimensional complement of its moment projection.

Chapter 97

Archimedean Tate Kernel via Mellin–Barnes and Binet Contour Representations

The digamma weight admits both a convergent Laplace representation and a Mellin–Barnes representation with an explicit shifted-contour remainder. Their quadratic integrals describe the auxiliary form G. Its relation to the signed Weil contribution is

$$W_\infty(f * \widetilde{f}) = 2\log\pi\|f\|_2^2 - G[f].$$

We construct the Laplace identity on smooth compact tests, determine the pointwise autocorrelation obstruction, and exhibit nonzero tests of both signs for W_∞. None of these signs discards the finite-prime and polar functional in the full Weil inequality.

97.1 Integral Carriers and Conventions

The Digamma Representations

Proposition 97.1.1 *(Mellin–Barnes representation of the digamma function).* For $\operatorname{Re} z > 0$, use the principal logarithm and fix $0 < c < 1$. Then

$$\psi(z) = -\gamma_E - \frac{1}{z} + \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} \frac{\pi\zeta(1+w)}{\sin\pi w}\, z^w\, dw. \tag{97.1}$$

The integral converges absolutely, locally uniformly in the stated half-plane.

Proof. The beta integral and Mellin inversion give

$$\frac{x}{1+x} = \frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty} \frac{\pi}{\sin\pi w} x^w\, dw \qquad (x > 0).$$

Indeed, the Mellin transform of $x/(1+x)$ at $-w$ is $\int_0^\infty x^{-w}/(1+x)\,dx = \pi/\sin\pi w$. Analytic continuation gives the formula for $|\arg x| < \pi$. Apply it to $x = z/n$, multiply by $1/n$, and sum. On $\operatorname{Re} w = c$, the sum of absolute coefficients is $\zeta(1+c)|z|^c$, while the vertical integrand decays exponentially as $e^{-(\pi - |\arg z|)|\operatorname{Im} w|}$. Thus sum and integral commute. The convergent digamma series $\psi(1+z) + \gamma_E = \sum_{n\ge 1} z/[n(n+z)]$, followed by $\psi(1+z) = \psi(z) + 1/z$, proves the formula. □

Proposition 97.1.2 *(Binet second integral representation).* For $\operatorname{Re} s > 0$,

$$\psi(s) \;=\; \log s - \frac{1}{2s} - 2\int_0^\infty \frac{u}{(s^2+u^2)(e^{2\pi u}-1)}\, du. \tag{97.2}$$

The integral converges absolutely for $\operatorname{Re} s > 0$ and defines a holomorphic function in that half-plane.

Proof. Binet 1839 *Mémoire sur les intégrales définies eulériennes J. Ecole Polytech.* 16; Whittaker–Watson §12.32; Abramowitz–Stegun 6.3.21. Derivation: differentiate Binet's formula $\log\Gamma(s) = (s-1/2)\log s - s + (1/2)\log 2\pi + 2\int_0^\infty \arctan(u/s)/(e^{2\pi u}-1)\,du$ with respect to s. □

The Compact Test Carrier

Work on $\mathscr{A} = C_c^\infty(\mathbb{R})$, with $\widehat{f}(t) = \int f(u)e^{itu}\,du$, $\widetilde{f}(u) = \overline{f(-u)}$, and $C_f = f * \widetilde{f}$. Put $q_f = \|f\|_2^2 = C_f(0)$. Then $C_f(-u) = \overline{C_f(u)}$. All quadratic formulas use $\operatorname{Re} C_f$, so they apply to complex tests as well as real even tests. A further arithmetic test space is used only through its specified intersection with this carrier.

Classical Integral Identities

The Binet and Euler integral formulas for ψ are recorded in NIST DLMF, §5.9; the convergent digamma series is in §5.7. The Mellin–Barnes formula above follows directly from that series and the beta integral. The Fourier normalization here is the one in Lemma 82.3.2.

97.2 The Binet Decomposition of the Archimedean Kernel

Insertion of the Binet Representation

Inserting (97.2) into (82.1) and taking real parts at $s = 1/4 + it/2$ yields a three-term decomposition of g.

Lemma 97.2.1 *(Binet form of g).* For every $t \in \mathbb{R}$,

$$g(t) \;=\; g_{\log}(t) + g_{\mathrm{shift}}(t) - 2\,g_{\mathrm{Binet}}(t), \tag{97.3}$$

where

$$\begin{aligned} g_{\log}(t) &:= \tfrac{1}{2}\log\!\left(\tfrac{1}{16} + \tfrac{t^2}{4}\right) + \log\pi, \\ g_{\mathrm{shift}}(t) &:= -\frac{1/4}{2(1/16 + t^2/4)} \;=\; -\frac{1/2}{1/4 + t^2}, \\ g_{\mathrm{Binet}}(t) &:= \int_0^\infty \operatorname{Re}\!\left[\frac{u}{(1/4 + it/2)^2 + u^2}\right] \cdot \frac{1}{e^{2\pi u} - 1}\,du. \end{aligned} \tag{97.4}$$

The integral in (97.4) converges absolutely and uniformly on compact sets.

Proof. Set $s = 1/4 + it/2$. Binet (97.2): $\psi(s) = \log s - 1/(2s) - 2\int_0^\infty u/[(s^2 + u^2)(e^{2\pi u} - 1)]\,du$. Take real parts. For the first term, $\operatorname{Re}\log(1/4 + it/2) = (1/2)\log|1/4 + it/2|^2 = (1/2)\log(1/16 + t^2/4)$. For the second, $\operatorname{Re}[1/(2s)] = \operatorname{Re}[(1/4 - it/2)/(2|s|^2)] = (1/4)/[2(1/16 + t^2/4)] = (1/2)/(1/4 + t^2)$; so $-\operatorname{Re}[1/(2s)] = -1/2 \cdot 1/(1/4 + t^2) = g_{\mathrm{shift}}(t)$. For the third, $u/(s^2 + u^2)$ with $s^2 = (1/4 + it/2)^2 = 1/16 - t^2/4 + it/4$: $s^2 + u^2 = (1/16 - t^2/4 + u^2) + it/4$. The real part of $u/(s^2 + u^2)$ is $u(1/16 - t^2/4 + u^2)/|s^2 + u^2|^2$. Adding $\log\pi$ gives (97.3).

For $s = 1/4 + it/2$, neither factor $s + iu$ nor $s - iu$ vanishes for real u. On compact t-sets the denominator is uniformly nonzero for bounded u; near zero the factor $u/(e^{2\pi u} - 1)$ is bounded. At infinity the integrand is $O(u^{-1}e^{-2\pi u})$, uniformly on compact t-sets. These estimates prove absolute and locally uniform convergence. □

Remark 97.2.2 *(structural content of the decomposition).* The decomposition (97.3) isolates three contributions: $g_{\log}(t) \geq 0$ for $|t| \geq 2\sqrt{\pi^{-2} - 1/16}$ (the logarithmic threshold; eventually dominant; numerically ≈ 0.394, real since $\pi^{-2} = 1/\pi^2 > 1/16$); $g_{\mathrm{shift}}(t) < 0$ for all t (the Cauchy shift, bounded); and $g_{\mathrm{Binet}}(t)$, whose sign depends on the sign of $u^2 - t^2/4 + 1/16$ inside the u-integral, is not pointwise sign-definite. For $u > \sqrt{t^2/4 - 1/16}$ (when $|t| > 1/2$; for all $u > 0$ when $|t| \leq 1/2$) the integrand of g_{Binet} is non-negative.

Sign of $g_{\mathrm{Binet}}(t)$: Two-Region Structure

Lemma 97.2.3 *(two-region structure of g_{Binet}).* For $|t| \le 1/2$, $g_{\mathrm{Binet}}(t) \ge 0$ unconditionally (the u-integrand is pointwise non-negative). For $|t| > 1/2$,

$$g_{\mathrm{Binet}}(t) \;=\; g^{+}_{\mathrm{Binet}}(t) - g^{-}_{\mathrm{Binet}}(t), \tag{97.5}$$

where

$$g^{+}_{\mathrm{Binet}}(t) \;=\; \int_{u_0(t)}^{\infty} u \cdot \frac{u^2 - t^2/4 + 1/16}{|s^2 + u^2|^2} \cdot \frac{1}{e^{2\pi u} - 1}\, du \;\ge\; 0,$$
$$g^{-}_{\mathrm{Binet}}(t) \;=\; \int_{0}^{u_0(t)} u \cdot \frac{t^2/4 - 1/16 - u^2}{|s^2 + u^2|^2} \cdot \frac{1}{e^{2\pi u} - 1}\, du \;\ge\; 0,$$

with $u_0(t) := \sqrt{t^2/4 - 1/16}$ for $|t| > 1/2$ and $s = 1/4 + it/2$.

Proof. From the proof of Lemma 97.2.1, the integrand of $g_{\mathrm{Binet}}(t)$ is $u(u^2 - t^2/4 + 1/16)/|s^2 + u^2|^2 \cdot 1/(e^{2\pi u} - 1)$. The factor $u^2 - t^2/4 + 1/16$ vanishes at $u = u_0(t)$ for $|t| > 1/2$ and is non-negative for $u \ge u_0(t)$, strictly negative for $0 < u < u_0(t)$. Splitting the integral at $u = u_0(t)$ gives (97.5). For $|t| \le 1/2$, $u^2 - t^2/4 + 1/16 \ge 1/16 - t^2/4 \ge 0$ for all $u \ge 0$, so the integrand is non-negative and $g_{\mathrm{Binet}}(t) \ge 0$ unconditionally. □

Remark 97.2.4 *(The Binet decomposition and the zero of g).* The logarithmic term alone vanishes at $2\sqrt{\pi^{-2} - 1/16}$; the additional negative rational term means this is not the zero of their sum. The two-region integral must also be retained. The unique positive zero of the complete weight is certified by the positive-series calculation of Proposition 82.2.5. The Binet splitting is an exact representation of the same weight, not an independent assertion that either signed piece dominates.

97.3 The Hankel Integral Construction

Hankel Representation of ψ at Argument $1/4 + it/2$

The Hankel (also Dirichlet–Abel) integral representation of ψ is

$$\psi(s) + \gamma_E \;=\; \int_0^1 \frac{1 - u^{s-1}}{1 - u}\, du, \qquad \operatorname{Re} s > 0. \tag{97.6}$$

Insertion into $g(t)$ is complicated by the fact that $s = 1/4 + it/2$ lies on the line $\operatorname{Re} s = 1/4$, so u^{s-1} oscillates as $u \to 0$. We extract the real part first.

Lemma 97.3.1 *(Hankel form of g).* For $t \in \mathbb{R}$,

$$g(t) + \gamma_E - \log \pi \;=\; \int_0^1 \frac{1 - u^{-3/4}\cos(t \log u/2)}{1 - u}\, du. \tag{97.7}$$

The integral in (97.7) converges at $u = 1$ because the numerator $1 - u^{-3/4}\cos(t \log u/2)$ vanishes to first order as $u \to 1^-$. Near $u = 0^+$, the factor $u^{-3/4}$ is absolutely integrable, including at $t = 0$. Equivalently one substitutes $v = -\log u$ ($u = e^{-v}$, $du = e^{-v}dv$, $v \in (0, \infty)$), obtaining $\int_0^\infty [e^{-v} - e^{-v/4}\cos(tv/2)]/(1 - e^{-v})\, dv$, which is absolutely convergent at $v = \infty$ (the $e^{-v/4}$ factor) and at $v = 0^+$ (the numerator vanishes to first order).

Proof. Apply (97.6) at $s = 1/4 + it/2$: $u^{s-1} = u^{-3/4+it/2} = u^{-3/4}(\cos(t\log u/2) + i\sin(t\log u/2))$. The real part of u^{s-1} for real $u \in (0,1)$ and $s = 1/4 + it/2$ is $u^{-3/4}\cos(t\log u/2)$. Since $\psi(1/4 + it/2) + \gamma_E = \int_0^1 [1 - u^{s-1}]/(1-u)\,du$ and the integral represents a holomorphic function, taking the real part gives $\operatorname{Re}\psi(1/4+it/2) + \gamma_E = \int_0^1 [1 - u^{-3/4}\cos(t\log u/2)]/(1-u)\,du$. Since $g(t) = \operatorname{Re}\psi(1/4+it/2) + \log\pi$, the left-hand side of (97.7) is $g(t) + \gamma_E - \log\pi$. The substitution $v = -\log u$ converts the integral to the absolutely convergent Laplace-type form of the lemma statement. □

The Convergent Laplace Quadratic Form

Proposition 97.3.2 *(Laplace forms of G and W_∞).* For $f \in \mathscr{A}$, the integral

$$I[f] = \int_0^\infty \frac{e^{-v}q_f - e^{-v/4}\operatorname{Re} C_f(v/2)}{1 - e^{-v}}\,dv$$

is absolutely convergent and satisfies

$$G[f] = (\log\pi - \gamma_E)q_f + I[f], \qquad W_\infty(C_f) = (\log\pi + \gamma_E)q_f - I[f]. \tag{97.8}$$

Proof. In the Euler integral put $u = e^{-v}$, obtaining

$$g(t) = \log\pi - \gamma_E + \int_0^\infty \frac{e^{-v} - e^{-v/4}\cos(tv/2)}{1 - e^{-v}}\,dv.$$

Near zero, decompose its numerator as $e^{-v} - e^{-v/4} + e^{-v/4}(1 - \cos(tv/2))$. Its absolute quotient is bounded by $C(1 + t^2 v)$ for $0 < v < 1$. For $v \geq 1$, it is bounded by $Ce^{-v/4}$, independently of t. Since $\widehat{f}$ is Schwartz, these bounds justify absolute Fubini after multiplication by $|\widehat{f}(t)|^2$. Fourier inversion and Plancherel give

$$\frac{1}{2\pi}\int |\widehat{f}(t)|^2\cos(tv/2)\,dt = \operatorname{Re} C_f(v/2), \qquad \frac{1}{2\pi}\int |\widehat{f}(t)|^2\,dt = q_f.$$

This proves the first identity. The signed gamma identity $W_\infty = 2\log\pi\, q_f - G$ proves the second. □

Remark 97.3.3 *(The integrated signed condition).* The signs of the two quadratic forms require different inequalities:

$$G[f] \geq 0 \iff I[f] \geq -(\log\pi - \gamma_E)q_f, \qquad W_\infty(C_f) \geq 0 \iff I[f] \leq (\log\pi + \gamma_E)q_f.$$

Neither inequality alone is the full Weil condition $R[f] - W_\infty(C_f) \geq 0$.

Pointwise Autocorrelation Domination

Definition 97.3.4 *(Pointwise Hankel condition).* Let $\mathscr{A}_{\mathrm{HD}}$ consist of tests satisfying

$$e^{-3v/4}q_f \geq \operatorname{Re} C_f(v/2) \qquad (v > 0).$$

On any specified restricted test space, HD denotes its intersection with this class.

Theorem 97.3.5 *(The smooth pointwise obstruction).* On the compact smooth carrier,

$$\mathscr{A}_{\mathrm{HD}} = \{0\}.$$

Proof. The real part of the autocorrelation is even and smooth. Integration by parts gives $\operatorname{Re} C_f''(0) = -\|f'\|_2^2$, hence

$$\operatorname{Re} C_f(v/2) = q_f - \frac{v^2}{8}\|f'\|_2^2 + O_f(v^4).$$

In contrast $e^{-3v/4}q_f = q_f - (3/4)q_f v + O_f(v^2)$. For $f \neq 0$, their difference is negative for all sufficiently small positive v. Thus the pointwise condition fails. □

Proposition 97.3.6 *(Nonzero compact tests of both signed types).* There are real even nonzero tests in $\mathscr{A}$ with $W_\infty(C_f) > 0$, and real even HFD tests with $W_\infty(C_f) < 0$. Neither family satisfies HD.

Proof. Choose real even nonzero $\chi \in C_c^\infty$. For $f_L(u) = L^{-1/2}\chi(u/L)$, Fourier scaling gives $\widehat{f_L}(t) = \sqrt{L}\widehat{\chi}(Lt)$. Consequently

$$W_\infty(C_{f_L}) \longrightarrow (\log\pi - \psi(1/4))\|\chi\|_2^2 > 0.$$

Dominated convergence follows from the logarithmic growth of the multiplier and Schwartz decay. The constant is positive since $\psi(1/4) = -\gamma_E - \pi/2 - 3\log 2$. For the opposite sign, take $f_M(u) = \chi(u)\cos(Mu)$, with $\int \chi \neq 0$. The two Fourier translates have rapidly vanishing core supremum and retain positive mass near $\pm M$. Since $g(t) \sim \log|t|$, these tests eventually satisfy HFD and $G[f_M] \to \infty$, while their norms stay bounded. Therefore $W_\infty(C_{f_M}) = 2\log\pi q_{f_M} - G[f_M] < 0$. The preceding theorem excludes HD in both nonzero families. □

Remark 97.3.7 *(The original test space).* Both constructions use actual smooth compact tests. Membership in a further automorphic or moment-constrained subspace requires its own verification. The pointwise HD condition gives no nonzero extension of the HFD domain on any such subspace.

97.4 Mellin–Barnes Evaluation and Finite Residue Sums

The Complex Integral Before Taking Real Parts

Lemma 97.4.1 *(Mellin–Barnes form of g).* For $z = 1/4 + it/2$ and $0 < c < 1$,

$$g(t) = \log\pi - \gamma_E - \operatorname{Re}\frac{1}{z} + \operatorname{Re}\left\{\frac{1}{2\pi i}\int_{c-i\infty}^{c+i\infty}\frac{\pi\zeta(1+w)z^w}{\sin\pi w}\,dw\right\}.$$

Proof. Take the real part of Proposition 97.1.1. The real part is applied to the complete contour integral, not to one factor of a complex integrand. □

Residues with Their Remainder

Proposition 97.4.2 *(Finite shifted-contour identity).* Let $J_c(z)$ denote the contour integral in (97.1). For any noninteger $b < 0$,

$$J_c(z) = J_b(z) + \log z + \gamma_E + \sum_{1\le n<-b}(-1)^n\zeta(1-n)z^{-n}.$$

In particular the individual residues at zero and at $-n$, $n \geq 1$, are

$$R_0(z) = \log z + \gamma_E, \qquad R_n(z) = (-1)^n\zeta(1-n)z^{-n}.$$

A zero value of $\zeta(1-n)$ means the putative pole is removable.

Proof. At zero, use $\zeta(1+w) = w^{-1} + \gamma_E + O(w)$, $\pi/\sin \pi w = w^{-1} + O(w)$, and $z^w = 1 + w \log z + O(w^2)$. At $-n$, the sine factor has residue $(-1)^n$ and the other factors are holomorphic. Shift the vertical contour across this finite set of poles. On a fixed vertical strip the zeta function has polynomial growth, while the sine denominator and z^w give exponential decay; the horizontal integrals tend to zero. This proves the finite identity with the remaining integral J_b. □

Theorem 97.4.3 *(Residue identities retain the signed functional).* The finite contour formula evaluates g, with remainder J_b. It does not express G or W_∞ as a sum of nonnegative quadratic forms on all of $\mathscr{A}$.

Proof. Broad dilations have $G[f_L] \to g(0)\|\chi\|_2^2 < 0$, whereas high-frequency modulations have negative W_∞, as proved above. A sum of nonnegative quadratic forms cannot equal either functional on its entire carrier. This does not exclude useful estimates on specified subspaces or rearrangements retaining signed terms and their remainders. □

Remark 97.4.4 *(Analytic roles of the representations).* Binet separates logarithmic, rational and integral terms; the Laplace formula retains the short-distance autocorrelation; the Barnes identity supplies finite residue sums with a contour remainder. None changes the sign convention of the Weil functional.

97.5 The Full Weil Comparison

Proposition 97.5.1 *(Exact residual inequality).* For every test in the declared domain of the finite-prime and polar functional R,

$$W[f] = R[f] - (\log \pi + \gamma_E) q_f + I[f].$$

Thus its nonnegativity is exactly

$$R[f] + I[f] \geq (\log \pi + \gamma_E) q_f. \tag{97.9}$$

Proof. Substitute (97.8) into $W = R - W_\infty$. □

Remark 97.5.2 *(Frequency and autocorrelation conditions).* HFD proves $G \geq 0$, while HD has only the zero test on this smooth carrier. The signed families above prove neither the full Weil inequality nor a comparison with an arithmetic pairing.

Question 97.5.3 *(The arithmetic comparison).* Construct the maps from the arithmetic test carrier to the spectral or automorphic realization that preserve the full quadratic form $R - W_\infty$, including domains, normalization and all finite-prime terms. A matching gamma multiplier alone does not construct this map.

97.6 Integral Identities and Remaining Comparison

The Binet splitting, convergent Laplace identity and finite Barnes residue formula hold on their stated carriers. Smooth compact tests realize both signs of the signed archimedean term, and the pointwise HD condition is trivial. The full target is (97.9) on the complete Weil test class, together with its required arithmetic realization.

Remark 97.6.1 *(Preserving the full target).* The explicit local integral calculations do not establish the finite-prime/polar domination or its arithmetic comparison. These remain the substantive construction problem.

Chapter 98

A-TP via the Exact Hadamard Factorisation: Reflected Resolvents and Tautology Comparison

98.1 Hadamard Factorisation

Setup

The archimedean Tate positivity conjecture A-TP (Conjecture 78.2.3) is the statement that the Weil distribution $W(f * \widetilde{f}) \geq 0$ for all f in the Paley–Wiener space $\mathrm{PW}(\mathbb{R})$ (entire functions of exponential type whose restriction to $\mathbb{R}$ is square-integrable; $\widetilde{f}(x) := \overline{f(-x)}$). Chapters 79 and 82 tested A-TP via de Branges / Hermite–Biehler spectral theory and via the digamma-kernel elementary decomposition, respectively; each construction bottomed out at a hypothesis equivalent to RH.

Hadamard factorisation gives $\xi_{\mathbb{R}}(s) = e^{a+bs}\prod_{\rho}(1 - s/\rho)e^{s/\rho}$ of $\xi_{\mathbb{R}}$ as an entire function of order 1 and genus 1 (Proposition 79.2.1). Logarithmic differentiation yields $\xi'_{\mathbb{R}}/\xi_{\mathbb{R}}$ as a sum over zeros plus a linear correction. The reflected-resolvent kernel $\mathcal{K}_{\rho}(t)$ obtained by multiplying opposite critical-line resolvents is not the Guinand–Weil zero summand; it is nevertheless sign-indefinite even when ρ lies on the critical line. Thus the Hadamard construction gives no termwise positivity theorem. The positivity statement is the full Weil distribution, hence RH-level.

Classical Sources

The Hadamard-factorisation obstruction uses four classical sources disjoint from the restricted-class comparison and the bounded-interval reduction.

Hadamard 1893. Hadamard, J. *Étude sur les propriétés des fonctions entières et en particulier d'une fonction considérée par Riemann. J. Math. Pures Appl.* (4) 9 (1893), 171–215. Original Hadamard factorisation theorem for entire functions of finite order.

Pi* 8 (2020), e6. The de Bruijn–Newman constant Λ; RH iff $\Lambda \leq 0$; unconditional lower bound $\Lambda \geq 0$.

Hadamard 1893, Guinand 1948, de Bruijn 1950, Newman 1976, and Rodgers–Tao 2020 are classical entire-function complex analysis and heat-flow literature. None enter the de Branges spectral comparison de Branges / Hermite–Biehler derivation (Chapter 79); none enter the bounded-interval reduction

elementary digamma kernel analysis (Chapter 82); none enter the Mellin–Rankin–Selberg isometry of Chapter 78. These sources are disjoint from Chapters 43, 47, 67.

98.2 The Exact Hadamard Formula for $\xi_{\mathbb{R}}'/\xi_{\mathbb{R}}$

Hadamard Product Logarithmic Derivative

Lemma 98.2.1 *(Hadamard formula for $\xi_{\mathbb{R}}'/\xi_{\mathbb{R}}$).* Fix the Hadamard factorisation (79.1) $\xi_{\mathbb{R}}(s) = e^{a+bs}\prod_\rho(1-s/\rho)e^{s/\rho}$ with a, b real constants of Proposition 79.2.1 and product over non-trivial zeros. The logarithmic derivative satisfies

$$\frac{\xi_{\mathbb{R}}'(s)}{\xi_{\mathbb{R}}(s)} \;=\; b + \sum_\rho\Big(\frac{1}{s-\rho}+\frac{1}{\rho}\Big), \tag{98.1}$$

where the series converges absolutely and uniformly on compact subsets avoiding the zero locus, after pairing $\rho \leftrightarrow 1-\rho$.

Proof. Logarithmic differentiation of (79.1): $\log\xi_{\mathbb{R}}(s) = a + bs + \sum_\rho[\log(1-s/\rho)+s/\rho]$. Differentiating: $\xi_{\mathbb{R}}'(s)/\xi_{\mathbb{R}}(s) = b + \sum_\rho[(-1/\rho)/(1-s/\rho)+1/\rho] = b + \sum_\rho[1/(s-\rho)+1/\rho]$ after the simplification $(-1/\rho)/(1-s/\rho) = 1/(s-\rho)$. Absolute convergence: under the pairing $\rho\mapsto 1-\rho$, the paired term $[1/(s-\rho)+1/(s-(1-\rho))]+[1/\rho+1/(1-\rho)]$ has both halves absolutely summable since $\sum_\rho(|\rho(1-\rho)|)^{-1}<\infty$ by the Riemann–von Mangoldt bound $N(T)\asymp T\log T$. □

Comparison with the Completed Zeta Formula

Proposition 98.2.2 *(partial-fraction and gamma-factor identity).* (Titchmarsh *The Theory of the Riemann Zeta Function* (Oxford 1986), §3.3; Iwaniec–Kowalski §5.9). For $s\notin\{0,1\}\cup\{\rho\}$,

$$\frac{\xi_{\mathbb{R}}'(s)}{\xi_{\mathbb{R}}(s)} \;=\; \frac{1}{s}+\frac{1}{s-1}+\frac{1}{2}\psi\Big(\frac{s}{2}\Big)-\frac{\log\pi}{2}+\frac{\zeta'(s)}{\zeta(s)}. \tag{98.2}$$

Proof. $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$; logarithmic derivative of each factor: $(s(s-1))'/(s(s-1)) = 1/s+1/(s-1)$, $(\pi^{-s/2})'/\pi^{-s/2} = -\frac{1}{2}\log\pi$, $(\Gamma(s/2))'/\Gamma(s/2) = \frac{1}{2}\psi(s/2)$, and ζ'/ζ. □

Corollary 98.2.3 *(Hadamard and explicit formula match).* Equating (98.1) and (98.2):

$$b+\sum_\rho\Big(\frac{1}{s-\rho}+\frac{1}{\rho}\Big) \;=\; \frac{1}{s}+\frac{1}{s-1}+\frac{1}{2}\psi\Big(\frac{s}{2}\Big)-\frac{\log\pi}{2}+\frac{\zeta'(s)}{\zeta(s)}. \tag{98.3}$$

This is the standard Stark identity; setting $s = 1/2+it$ and taking the real part gives a pointwise formula for the Weil kernel.

Proof. Both sides express the same meromorphic function; comparison is algebraic, valid away from the zero/pole locus. □

Remark 98.2.4 *(the two decompositions of $\xi_{\mathbb{R}}'/\xi_{\mathbb{R}}$).* The right-hand side of (98.3) is the Weil-kernel split of Chapter 78: polar terms $1/s+1/(s-1)$, archimedean digamma $\frac{1}{2}\psi(s/2)-\frac{1}{2}\log\pi$ (the kernel $g(t)$ of Chapter 82 after shifting argument), finite-prime ζ'/ζ. The left-hand side is the sum over non-trivial zeros. The following section separates the logarithmic-derivative zero sum from a reflected-resolvent quadratic form; the latter is not the Guinand–Weil zero side.

98.3 The Reflected Pair-Pole Diagnostic

Pairing Conjugate Zeros

Definition 98.3.1 *(pair-pole kernel).* Write each non-trivial zero $\rho = \beta + i\gamma$ with $0 \le \beta \le 1$ (non-trivial strip), and pair with its complex conjugate $\bar\rho = \beta - i\gamma$ and functional-equation partner $1-\rho = 1-\beta-i\gamma$ (and $1-\bar\rho = 1-\beta+i\gamma$). For $s = 1/2 + it$ on the critical line, define the *pair-pole kernel*

$$\mathcal{K}_\rho(t) \;:=\; \mathrm{Re}\!\left[\frac{1}{(1/2+it-\rho)(1/2-it-\rho)}\right]. \tag{98.4}$$

When ρ is paired with the reflected pole in the t-variable, the denominator becomes $((1/2-\beta)+i(t-\gamma))((1/2-\beta)-i(t+\gamma))$, explicit sign structure computed below.

Lemma 98.3.2 *(explicit form of the pair-pole kernel).* For $\rho = \beta + i\gamma$ with $\beta \in [0,1]$, $\gamma \in \mathbb{R}$, and $\alpha := 1/2 - \beta$,

$$\mathcal{K}_\rho(t) \;=\; \frac{\alpha^2 + t^2 - \gamma^2}{[\alpha^2 + (t-\gamma)^2][\alpha^2 + (t+\gamma)^2]}. \tag{98.5}$$

When $\beta = 1/2$ (RH), this simplifies to $\mathcal{K}_\rho(t)\big|_{\beta=1/2} = 1/(t^2-\gamma^2)$, which is a sign-indefinite distribution: positive for $|t| > |\gamma|$, negative for $|t| < |\gamma|$, with distributional poles at $t = \pm\gamma$. The pair-pole sum $\int |\widehat{f}|^2 \mathcal{K}_\rho \, dt$ is a principal-value term; it is not sign-definite term by term (Lemma 98.3.4).

Proof. Write $\alpha := 1/2 - \beta$ and compute: $(1/2+it-\rho)(1/2-it-\rho) = (\alpha + i(t-\gamma))(\alpha - i(t+\gamma))$. Expanding: $\alpha^2 - 2i\alpha\gamma + (t^2-\gamma^2)$. The real part of the reciprocal is $[\alpha^2 + (t^2-\gamma^2)]/[(\alpha^2+(t^2-\gamma^2))^2 + 4\alpha^2\gamma^2]$, and the denominator equals $[\alpha^2+(t-\gamma)^2][\alpha^2+(t+\gamma)^2]$ by expanding both sides. The specialisation $\alpha = 0$ yields $\mathcal{K}_\rho(t)\big|_{\alpha=0} = (t^2-\gamma^2)/(t^2-\gamma^2)^2 = 1/(t^2-\gamma^2)$; the symmetric contour gives the principal-value distribution of Lemma 98.3.4. □

Remark 98.3.3 *(the sign of $\mathcal{K}_\rho(t)$).* For any $\beta \in [0,1]$, the numerator $\alpha^2 + t^2 - \gamma^2$ of (98.5) is negative for $|t| < \sqrt{\gamma^2 - \alpha^2}$ (when $|\gamma| > |\alpha|$), while the denominator is always positive. Hence $\mathcal{K}_\rho(t) < 0$ on this interval, including in the on-critical case $\alpha = 0$ where $\mathcal{K}_\rho(t) < 0$ for $|t| < |\gamma|$. Thus no term-by-term positivity follows from the pair-pole kernel.

Residue Extraction and Dirac Limits

Lemma 98.3.4 *(principal value at an on-critical pole).* Let $\rho = 1/2 + i\gamma$ be on the critical line ($\beta = 1/2$, $\gamma \neq 0$, $\gamma \in \mathbb{R}$). For $f \in \mathrm{PW}(\mathbb{R})$ real and even with $\widehat{f}$ smooth at $t = \pm\gamma$,

$$\lim_{\varepsilon \downarrow 0} \mathrm{Re} \int_{\mathbb{R}} |\widehat{f}(t)|^2 \cdot \frac{dt}{(1/2+\varepsilon+it-\rho)(1/2+\varepsilon-it-\rho)} \;=\; \mathrm{PV}\int_{\mathbb{R}} \frac{|\widehat{f}(t)|^2}{t^2-\gamma^2}\, dt,$$

with the reflected pole convention of (98.4). This principal value is not sign-definite.

Proof. With the reflected pole convention the regularised real kernel is

$$\mathrm{Re}\frac{1}{(\varepsilon + i(t-\gamma))(\varepsilon - i(t+\gamma))} = \frac{\varepsilon^2 + t^2 - \gamma^2}{(\varepsilon^2 + (t-\gamma)^2)(\varepsilon^2 + (t+\gamma)^2)}.$$

As $\varepsilon \downarrow 0$ this converges in distributions to $\mathrm{PV}(t^2-\gamma^2)^{-1}$. Pairing with the smooth function $|\widehat{f}|^2$ gives the displayed identity. □

Theorem 98.3.5 *(the reflected pair-pole kernel is not the Guinand–Weil summand).* For $f \in \mathrm{PW}(\mathbb{R})$ real and even, the reflected-resolvent expression

$$\mathcal{R}_{\mathrm{ref}}(f) := \lim_{T\to\infty} \sum_{|\mathrm{Im}\rho|\le T} R_\rho[f], \qquad R_\rho[f] := \mathrm{PV}\int_{\mathbb{R}} |\widehat{f}(t)|^2\, \mathcal{K}_\rho(t)\, dt, \tag{98.6}$$

where $\mathcal{K}_\rho$ is the reflected pair-pole kernel (98.5), the sum is over non-trivial zeros of $\xi_{\mathbb{R}}$, each paired once with its conjugate. When the symmetric limit exists, it is not the zero side of the Guinand–Weil formula. It is a diagnostic quadratic form obtained by multiplying reflected resolvents.

Proof. It is enough to compare a single on-critical conjugate pair. For $\rho = 1/2 + i\gamma$,

$$\frac{1}{1/2 + it - \rho} + \frac{1}{1/2 + it - \bar{\rho}} = -i\left(\frac{1}{t-\gamma} + \frac{1}{t+\gamma}\right) = -\frac{2it}{t^2-\gamma^2}.$$

Thus the zero contribution to the imaginary part of the logarithmic derivative is the odd principal-value distribution $-2t\,\mathrm{PV}(t^2-\gamma^2)^{-1}$. The reflected kernel $\mathcal{K}_\rho(t) = \mathrm{PV}(t^2-\gamma^2)^{-1}$ is even. It therefore cannot be the residue summand obtained from $\xi'_{\mathbb{R}}/\xi_{\mathbb{R}}$. The displayed $\mathcal{R}_{\mathrm{ref}}$ is consequently not a Guinand–Weil decomposition. □

Under RH: No Termwise Positivity

Proposition 98.3.6 *(the on-critical pair-pole term is sign-indefinite).* Let $\rho = 1/2 + i\gamma$ be on the critical line with $\gamma \neq 0$. Then

$$\mathcal{K}_\rho(t) = \mathrm{PV}\frac{1}{t^2-\gamma^2}.$$

It is sign-indefinite. In particular there are real even $f \in \mathrm{PW}(\mathbb{R})$ for which the single principal-value term $R_\rho[f]$ is negative. RH gives positivity of the full Weil distribution, not positivity of each reflected pair-pole term.

Proof. This is Lemma 98.3.4. On $|t| < |\gamma|$ the kernel is negative, away from the poles. Choose $\widehat{f}$ real, even, smooth, and supported in a sufficiently small neighbourhood of 0. Then the principal-value integral is an ordinary integral over a region where the kernel is negative. □

98.4 Tautology Comparison: Where Positivity Becomes Circular

Even under RH, a single pair-pole kernel is sign-indefinite. The following proposition records the failure of the pointwise construction.

Proposition 98.4.1 *(pointwise pair-pole positivity fails).* The statement "$\mathcal{K}_\rho(t) \ge 0$ pointwise for every non-trivial zero ρ" is false for the zeta zero set. Hence any attempt to prove A-TP by *term-by-term* pointwise non-negativity of $\mathcal{K}_\rho(t)$ is not merely circular; it has no valid on-critical case.

Proof. For an on-critical zero, $\alpha = 0$, and $\mathcal{K}_\rho(0) = -\gamma^{-2} < 0$. Thus RH itself does not make the pair-pole kernel pointwise non-negative. □

Remark 98.4.2 *(pointwise positivity versus integrated positivity).* Proposition 98.4.1 establishes that pointwise $\mathcal{K}_\rho(t) \ge 0$ cannot be the mechanism for A-TP. Sum-level non-negativity belongs to the actual Weil distribution; the reflected-resolvent form $\mathcal{R}_{\mathrm{ref}}$ is not that distribution. The Hadamard logarithmic derivative has the same RH ceiling as the de Branges construction (Chapter 79) and the digamma-kernel construction (Chapter 82).

Corollary 98.4.3 *(the valid reformulations coincide).* The two valid positivity statements

(i) *(Weil)* $W(f * \widetilde{f}) \ge 0$ for all $f \in \mathrm{PW}(\mathbb{R})$;

(ii) *(Hermite–Biehler)* the de Branges datum $E_\xi(z) = A_\xi(z) - iB_\xi(z)$ (defined in Chapter 79) is Hermite–Biehler and satisfies $\mathrm{div}(A_\xi) = \mathrm{div}(\Xi)$;

are equivalent and each equivalent to RH. The pointwise pair-pole positivity statement is false and is not a third reformulation.

Proof. (1) $\Leftrightarrow$ RH: Corollary 78.2.1. (2) $\Leftrightarrow$ RH: Lagarias' Hermite–Biehler theorem and Theorem 79.6.9. Proposition 98.4.1 excludes the pointwise pair-pole statement. □

98.5 de Bruijn–Newman $\Lambda \le 0$ is RH

The pair-pole pointwise positivity statement is false. The de Bruijn–Newman bound $\Lambda \le 0$ is a valid construction to A-TP only because it is RH itself.

The de Bruijn–Newman Family

Definition 98.5.1 *(de Bruijn–Newman heat flow).* Let $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ and $\Xi(t) = \xi(1/2 + it)$. Use the normalization

$$\Phi(u) := \sum_{n=1}^{\infty} \left(2\pi^2 n^4 e^{9u} - 3\pi n^2 e^{5u}\right) \exp(-\pi n^2 e^{4u}).$$

For $\lambda \in \mathbb{R}$, define

$$H_\lambda(z) := \int_0^\infty \Phi(u) e^{\lambda u^2} \cos(zu)\, du, \qquad \Xi_\lambda(t) := 8H_\lambda(2t).$$

Super-exponential decay of Φ gives locally uniform absolute convergence for complex z, including all complex derivatives. Thus these functions are entire. The theta-integral identity gives $H_0(z) = \xi(1/2 + iz/2)/8$, so $\Xi_0 = \Xi$. The de Bruijn–Newman constant Λ is the infimum of λ for which all zeros of H_λ, equivalently Ξ_λ, are real. The positive rescaling of the variable and nonzero scalar factor leave this condition unchanged.

Theorem 98.5.2 *(de Bruijn–Newman bounds).* (Newman 1976; Rodgers–Tao 2020).

(i) $\Lambda \le 1/2$ (de Bruijn 1950: for $\lambda \ge 1/2$, Ξ_λ has only real zeros; Newman 1976 introduced Λ as an infimum).

(ii) $\Lambda \ge 0$ (Rodgers–Tao 2020, unconditional).

(iii) RH $\Leftrightarrow \Lambda \le 0$: the real-zero parameters form $[\Lambda, \infty)$, and $H_0(z) = \xi(1/2 + iz/2)/8$.

(iv) Newman conjectured the lower bound $\Lambda \ge 0$, proved by Rodgers–Tao. Combining this with (iii) gives RH $\Longleftrightarrow \Lambda = 0$; the equality is not an unconditional bound.

Proof. Newman 1976 *Proc. AMS* 61; de Bruijn 1950 *Duke Math. J.* 17; Rodgers–Tao 2020 *Forum Math. Pi* 8; and the classical equivalence RH $\Leftrightarrow$ Ξ has only real zeros (Riemann 1859). □

$\Lambda \le 0$ Implies A-TP via RH

Lemma 98.5.3 *(critical-line reformulation of $\Lambda \le 0$).* The statement $\Lambda \le 0$ is equivalent to: every non-trivial zero of $\xi_{\mathbb{R}}$ lies on the critical line $\operatorname{Re} s = 1/2$.

Proof. $\Lambda \le 0 \Leftrightarrow \Xi_0 = \Xi$ has only real zeros $\Leftrightarrow \xi_{\mathbb{R}}(1/2 + it) = 0$ for t real only $\Leftrightarrow$ every non-trivial zero ρ of $\xi_{\mathbb{R}}$ satisfies $\operatorname{Re} \rho = 1/2$. This is RH. □

Corollary 98.5.4 *($\Lambda \le 0$ implies A-TP).* . Under $\Lambda \le 0$ (equivalent to RH), A-TP holds.

Proof. Lemma 98.5.3 reduces $\Lambda \le 0$ to RH. Then Corollary 78.2.1 gives A-TP. □

Remark 98.5.5 *($\Lambda \le 0$ is equivalent to RH).* $\Lambda \le 0$ is equivalent to RH, not weaker. The Rodgers–Tao theorem $\Lambda \ge 0$ places the constant at the Newman barrier. change on Λ is change towards RH, not a weaker substitute. The Hadamard-factorisation construction is tautological: it reduces A-TP to RH without passing through any strictly weaker intermediate.

The candidate "$\Lambda \le \lambda_0$ for some $\lambda_0 > 0$ still implies A-TP" is not supplied by the de Bruijn–Newman theory. The heat flow parameterises the zero-reality problem; the value $\lambda = 0$ is exactly RH.

Proposition 98.5.6 *(zero-free regions do not give a pair-pole positivity criterion).* A classical zero-free region, including the Korobov–Vinogradov region, does not imply A-TP or a partial-support A-TP statement through the pair-pole kernels. It excludes zeros near the edge of the critical strip; it does not make the central principal-value kernels positive.

Proof. Proposition 98.3.6 shows that even an on-critical zero gives a sign-indefinite principal-value kernel. Moving zeros away from the edge of the strip cannot turn these central kernels into positive kernels. A zero-free region is a zero-location theorem; A-TP is a positivity theorem for the full Weil sum. □

Remark 98.5.7 *(zero-free region boundary).* The Korobov–Vinogradov region is an edge exclusion near $\operatorname{Re} s = 1$, with the reflected exclusion near $\operatorname{Re} s = 0$. It is not a central critical-line positivity statement. No partial-support A-TP closure is recorded here from that input.

98.6 Zero Density and Pair-Pole Convergence

Convergence of the Pair-Pole Sum

Proposition 98.6.1 *(reflected pair-pole form converges distributionally after pairing).* For $f \in \mathrm{PW}(\mathbb{R})$, the reflected pair-pole form (98.6) is a paired principal-value distribution. It is not, in general, an absolutely convergent sum of ordinary integrals. Absolute convergence holds only after imposing vanishing near the finitely many zero ordinates met by $\operatorname{supp} \widehat{f}$, or after keeping the explicit regularisation.

Proof. Away from $t = \pm\gamma$, the displayed kernel has the stated $|\gamma|^{-2}$ decay after pairing, and the zero-counting estimate controls the tail. At $t = \pm\gamma$, however, the on-critical kernel is $\mathrm{PV}(t^2 - \gamma^2)^{-1}$, whose absolute value is not locally integrable. Thus the reflected-resolvent expression is a principal-value distribution unless the test function kills those poles or a regularisation is retained. □

Remark 98.6.2 *(sum-level positivity versus pointwise positivity).* For $\rho = \beta + i\gamma$ with $\alpha = 1/2 - \beta$, the functional-equation partner $1 - \rho = (1 - \beta) - i\gamma$ has $\alpha' = 1/2 - (1 - \beta) = -\alpha$. Since (98.5) depends on α^2, $\mathcal{K}_{1-\rho}(t) = \mathcal{K}_\rho(t)$; the two kernels are equal. The sum-level non-negativity of the Weil distribution is

equivalent to RH by Corollary 78.2.1. It is not the pointwise positivity of $\mathcal{K}_\rho$, and it is not the positivity of the reflected-resolvent form $\mathcal{R}_{\mathrm{ref}}$.

Exact Domain of the Hadamard-Factorisation Construction

Theorem 98.6.3 *(Hadamard-factorisation construction: exact domain).* The exact Hadamard-factorisation obstruction on A-TP has the following outcomes.

(i) *Reflected pair-pole diagnostic* (Theorem 98.3.5): unconditional; explicit pointwise form (98.5), but not the Guinand–Weil zero side.

(ii) *No termwise positivity under RH* (Proposition 98.3.6): under RH, $\mathcal{K}_\rho(t) = \mathrm{PV}(t^2 - \gamma^2)^{-1}$, and single pair-pole terms can be negative.

(iii) *Valid reformulations coincide* (Corollary 98.4.3): Weil positivity and Hermite–Biehler positivity are equivalent to RH. Pointwise pair-pole positivity is false (Proposition 98.4.1).

(iv) *de Bruijn–Newman sufficient condition* (Corollary 98.5.4): $\Lambda \le 0$ implies A-TP; but $\Lambda \le 0 \Leftrightarrow$ RH, so this is not weaker than RH.

(v) *Zero-free region boundary* (Proposition 98.5.6): the Korobov–Vinogradov-style zero-free region does not give a pair-pole positivity criterion or a partial-support A-TP closure.

The genuine content of the Hadamard-factorisation construction is the logarithmic-derivative identity and the reflected-resolvent diagnostic. It does not give a termwise Weil decomposition and does not close A-TP below the RH threshold.

Proof. Combine the cited results. □

Remark 98.6.4 *(the tautology map).* The three constructions to A-TP considered across the restricted-class comparison, the bounded-interval reduction, and the analytic refinement are:

the de Branges spectral comparison (de Branges). $\mathrm{HB}^+ + \mathrm{EC}_\pi + \mathrm{Det} + \mathrm{SH}$; tautology level: each hypothesis is RH-equivalent or strictly finer.

the bounded-interval reduction (digamma). Bounded-interval positivity on $[-t_*, t_*]$ after elementary reductions, with the finite-prime and polar functional $R[f]$ retained; tautology level: the full inequality is RH-equivalent.

the Hadamard reduction (Hadamard). Logarithmic derivative and reflected pair-pole diagnostic; failure mode: pointwise positivity is false even on the critical line (Proposition 98.4.1).

All three constructions bottom out at RH. The content each provides is a *different local rewriting* of the same positivity question. The Hadamard construction offers the pointwise reflected-resolvent formula (98.5), which clarifies the sign obstruction but does not give the Weil zero side.

98.7 Conclusion

The Hadamard factorisation $\xi_{\mathbb{R}}(s) = e^{a+bs}\prod_\rho (1 - s/\rho)e^{s/\rho}$ gives the logarithmic derivative

$$\frac{\xi_{\mathbb{R}}'(s)}{\xi_{\mathbb{R}}(s)} = b + \sum_\rho \left(\frac{1}{s-\rho} + \frac{1}{\rho}\right).$$

The reflected kernel (98.5) is not the Guinand–Weil zero summand. Pointwise non-negativity of $\mathcal{K}_\rho$ fails even under RH (Proposition 98.4.1), so the Hadamard construction cannot prove A-TP by termwise

positivity. The de Bruijn–Newman constant $\Lambda \leq 0$ is likewise equivalent to RH (Lemma 98.5.3). The Korobov–Vinogradov zero-free region gives no pair-pole positivity criterion. The valid reformulations of A-TP remain Weil positivity and the Hermite–Biehler condition (Corollary 98.4.3).

Remark 98.7.1 *(the non-tautological content of the Hadamard construction).* The Hadamard construction yields the exact logarithmic derivative of $\xi_{\mathbb{R}}$ and an explicit reflected-resolvent kernel (98.5). Pointwise pair-pole positivity is false (Proposition 98.4.1), so the construction does not close A-TP via this mechanism. Classical zero-free regions remain zero-location input, not positivity input.

Chapter 99

A-TP as Gram Matrix Positivity: Hermite Basis Reduction

The full Weil inequality can be tested on a countable family of compactly supported Hermite functions. Their finite Gram matrices retain the signed gamma, prime, and polar terms. Fixed cutoffs and continuous moment projections give dense families in the compact test algebra and its specified moment kernels. The uncut Hermite functions instead belong to the exponential test space and supply a separate Gaussian matrix.

99.1 Hermite Cutoff

A test family determines the Weil inequality only when its span is dense for a topology in which the form is continuous. Multiplication of Hermite expansions by a fixed compact cutoff gives convergence of every derivative with a common support. This proves the required density in the compact test topology. A finite list of Li coefficient inequalities concerns different tests. A comparison with a finite Hermite matrix requires an actual change-of-family map and control of any remaining error.

Quadratic Reduction

Negative semidefiniteness of all compact Gram blocks is equivalent to the full Weil inequality. Projection onto a moment kernel gives the restricted inequality on that kernel.

99.2 The Weil form and its moment subspaces

Definition 99.2.1 *(Weil quadratic form).* For $f, h \in \mathscr{A} = C_c^\infty(\mathbb{R};\mathbb{C})$ put $q(f,h) = -W(f * h^*)$, linear in the first argument, and $Q[f] = q(f,f)$. Write $M_f(s) = \int f(x)e^{sx}\,dx$ and $\psi_\Gamma = \Gamma'/\Gamma$. With $h_f(u) = \int f(x)e^{iux}\,dx$ and $k(u) = \log\pi - \Re\psi_\Gamma(1/4 + iu/2)$, one has

$$Q[f] = W_\infty(f * f^*) + W_{\mathrm{fin}}(f * f^*) - P(f * f^*).$$

Proposition 99.2.2 *(integral representation).* The form q is continuous and Hermitian in the compact test topology. For all $f, h \in \mathscr{A}$,

$$q(f,h) = \frac{1}{2\pi}\int h_f(u)\overline{h_h(u)}k(u)\,du + W_{\mathrm{fin}}(f * h^*) - a(f)\overline{b(h)} - b(f)\overline{a(h)}, \tag{99.1}$$

where $a(f) = M_f(-1/2)$ and $b(f) = M_f(1/2)$.

Proof. Apply the compact explicit formula to $f * h^*$. The Fourier convolution identity gives the integral, and evaluation at $\pm i/2$ gives the polar terms. Continuity follows from continuity of convolution and the three explicit-formula distributions. Their involution identities give Hermitian symmetry. □

Definition 99.2.3 *(the map to the continuous antidual).* Let $\mathscr{A}^\times$ denote the continuous conjugate-linear functionals on $\mathscr{A}$. Define the linear map $Q : \mathscr{A} \to \mathscr{A}^\times$ by

$$(Qf)(h) = q(f,h).$$

This is a Hermitian form map. A self-adjoint operator on a Hilbert space requires a Hilbert realization and an operator domain.

Remark 99.2.4 *(domains and the auxiliary form).* Compact smooth tests have rapidly decreasing angular Fourier transforms on the real axis. This proves convergence against $k(u) = O(\log(2 + |u|))$. For $g(u) = 2\log\pi - k(u)$, define $G_g(f,h) = (2\pi)^{-1}\int h_f\overline{h_h}g$. Then $W_\infty(f * h^*) = 2\log\pi\langle f, h\rangle_2 - G_g(f,h)$. The real even moment class $\mathscr{A}_{13}$ imposes moments at 0, 1, whereas $\mathscr{A}_{\mathrm{pol}} = \ker(a,b)$ imposes moments at $\pm 1/2$. These are different subspaces. The latter is a closed complex subspace of codimension two. To construct its projection, take a nonnegative compact even bump b_0 and two distinct translates $b_j(x) = b_0(x - t_j)$. Their moment columns are $(e^{-t_j/2}a(b_0), e^{t_j/2}b(b_0))^t$, hence are independent. Writing this matrix as C, set $R_{\mathrm{pol}}v = \sum_{j=1}^2 b_j(C^{-1}v)_j$ and $\Pi_{\mathrm{pol}}f = f - R_{\mathrm{pol}}(a(f), b(f))^t$. It is continuous and projects onto $\mathscr{A}_{\mathrm{pol}}$. The real projection Π onto $\mathscr{A}_{13}$ is given in Chapter 96.1.1.

99.3 The Weber–Hermite Basis and Gram Matrix

The Hermite functions are Fourier eigenfunctions and form an orthonormal basis of $L^2(\mathbb{R})$. Their rapidly convergent expansions of compact smooth tests become compact approximations after multiplication by a fixed cutoff.

Weber–Hermite Basis

Definition 99.3.1 *(Weber–Hermite functions).* . For $n \geq 0$, set

$$\phi_n(x) \;:=\; (2^n n!\sqrt{\pi})^{-1/2}H_n(x)e^{-x^2/2}, \qquad x \in \mathbb{R},$$

where H_n is the physicist's Hermite polynomial $H_n(y) = (-1)^n e^{y^2}\frac{d^n}{dy^n}e^{-y^2}$. The normalization is chosen so that $\{\phi_n\}_{n\geq 0}$ is orthonormal in $L^2(\mathbb{R})$ for the angular Fourier normalization used in Chapter 78.1.1.

Proposition 99.3.2 *(Hermite self-reciprocity).* . Under the Fourier normalization $\widehat{f}(t) = \int f(x)e^{itx}\,dx$,

$$\widehat{\phi_n}(t) = (2\pi)^{1/2} i^n \phi_n(t).$$

Equivalently, the unitary angular Fourier transform $(2\pi)^{-1/2}\widehat{\ }$ has eigenvalue i^n on ϕ_n.

Proof. Hermite 1864; see Whittaker–Watson 1927 §16.61. The Hermite functions diagonalize the harmonic oscillator $-\partial_x^2 + x^2$ which commutes with the Fourier transform (conjugated by the appropriate scaling). □

Remark 99.3.3 *(Schwartz convergence and compact support).* Their finite span is dense in Schwartz space and in $L^2(\mathbb{R})$. For $f \in \mathscr{A}$ with $\operatorname{supp}(f) \subset [-T, T]$, the Hermite expansion $f = \sum_n c_n \phi_n$ converges in Schwartz topology with $|c_n| \le C_{T,N} n^{-N}$ for every N: this is the classical Hermite-series rapid decay for Schwartz functions (Reed–Simon II Thm. V.13). However, the Hermite functions are *not* compactly supported, so the expansion does not preserve Paley–Wiener support; the truncation $f_N := \sum_{n=0}^{N} c_n \phi_n$ belongs to the Schwartz class but generally not to $\mathscr{A}$.

The subtlety of Chapter 99.3.3 is essential: a Schwartz expansion alone does not preserve the compact-test topology. The fixed-cutoff construction below supplies that convergence, without asserting a compact Hilbert-space operator.

The Gram Matrix Q_{mn}

Definition 99.3.4 *(compact Hermite Gram family).* Fix a real even $\chi \in C_c^\infty(\mathbb{R})$ equal to one on $[-1, 1]$. Set $\chi_R(x) = \chi(x/R)$ for integers $R \ge 1$ and $e_{R,n} = \chi_R \phi_n$ for $n \ge 0$. Enumerate the pairs (R, n) by $j \ge 0$, and write $e_j = e_{R,n}$. Define the Hermitian matrix

$$Q_{ij} = q(e_i, e_j), \qquad q\left(\sum_i c_i e_i, \sum_j c_j e_j\right) = \sum_{i,j} c_i \overline{c_j} Q_{ij}.$$

Its finite principal matrices need no removed-cutoff limit. The projected families $\Pi e_{R,2n}$ and $\Pi_{\mathrm{pol}} e_{R,n}$ give, respectively, real moment matrices and complex polar-kernel matrices.

Theorem 99.3.5 *(completeness of the compact families).* The complex span of the $e_{R,n}$ is dense in $\mathscr{A}$. The real span of $\Pi e_{R,2n}$ is dense in $\mathscr{A}_{13}$. The complex span of $\Pi_{\mathrm{pol}} e_{R,n}$ is dense in $\mathscr{A}_{\mathrm{pol}}$. All three statements use the respective compact test topologies.

Proof. Let f be compact smooth and choose R with $\chi_R = 1$ on its support. Its Hermite coefficients satisfy

$$|\langle f, \phi_n \rangle_2| \le (2n+1)^{-m} \|(-D^2 + x^2)^m f\|_2 \quad (m \ge 0).$$

This follows by integration by parts and the oscillator eigenvalue identity. The ladder identities for multiplication by x and application of D bound the L^2 norms of $x^a D^b \phi_n$ by a polynomial in n for each fixed a, b. The one-dimensional estimate $\|v\|_\infty^2 \le 2\|v\|_2 \|v'\|_2$ gives the corresponding supremum bounds. Arbitrarily rapid coefficient decay therefore makes the Hermite series and all its Schwartz seminorms converge. Its L^2 limit is f, by completeness of the Hermite functions. If s_N is its partial sum, then $\chi_R s_N \to f$ with a common compact support and uniform convergence of every derivative. This is convergence in the compact test topology. For real even f only even indices occur and the coefficients are real. Applying the continuous projection Π, or Π_{pol}, proves the corresponding kernel-density statements. □

THEOREM 99.3.6 *(compact Gram formula).* For $d_i = e_i$, or for either projected family, write $h_i = \mathcal{F}_+ d_i$ and $F_{ij} = d_i * d_j^*$. Then

$$q(d_i, d_j) = \frac{1}{2\pi} \int h_i(u)\overline{h_j(u)}k(u)du + (Q_{\text{fin}})_{ij} - (Q_{\text{polar}})_{ij},$$

where

$$(Q_{\text{fin}})_{ij} = \sum_{m\geq 2} \frac{\Lambda(m)}{\sqrt{m}}(F_{ij}(\log m) + F_{ij}(-\log m)),$$
$$(Q_{\text{polar}})_{ij} = a(d_i)\overline{b(d_j)} + b(d_i)\overline{a(d_j)}.$$

The prime sum is finite. The polar term vanishes for the Π_{pol} family, but need not vanish for the Π family.

Proof. Apply (99.1) to the two compact tests. Compact support bounds the prime-power logarithms in the sum. □

Remark 99.3.7 *(reality and the Gaussian extension).* Every even Hermite index occurs for real even tests, including $n \equiv 2 \pmod 4$. Its Fourier eigenvalue is real and needs no pairing with another index. Compact cutoffs need not be Fourier eigenfunctions. For uncut Hermites, convergence $\chi_R\phi_n \to \phi_n$ holds in $\mathscr{G}$ of Chapter 95.1.2. The extended form consequently gives well-defined entries $q(\phi_m, \phi_n)$ as a separate Gaussian matrix. Its signed archimedean entry is $i^{m-n}\int \phi_m(u)\phi_n(u)k(u)du$.

The uncut auxiliary diagonal

PROPOSITION 99.3.8 *(auxiliary and signed Hermite moments).* For each $n \geq 0$ the auxiliary uncut moment is

$$A_n := G_g(\phi_n, \phi_n) = \int_{\mathbb{R}} |\phi_n(u)|^2 g(u)du.$$

The corresponding signed gamma diagonal is $2\log\pi - A_n$. These are moments of the uncut Hermites in $\mathscr{G}$.

Proof. Use $h_{\phi_n} = \sqrt{2\pi}i^n\phi_n$ and $\|\phi_n\|_2 = 1$. The Gaussian times polynomial decay of ϕ_n proves absolute convergence against the logarithmic weight. The identity $k + g = 2\log\pi$ gives the signed diagonal. □

LEMMA 99.3.9 *(the zeroth auxiliary moment).*

$$A_0 = \frac{1}{\sqrt{\pi}} \int_{\mathbb{R}} e^{-u^2} g(u)du < 0.$$

If $I(L) = \int e^{-2\pi u^2/L} g(u)du$, then $A_0 = I(2\pi)/\sqrt{\pi}$. In particular, the signed zeroth gamma moment $2\log\pi - A_0$ is positive.

Proof. The normalized Gaussian measure $e^{-u^2}du/\sqrt{\pi}$ has second moment $1/2$. The digamma series gives, for $c_n = n + 1/4$,

$$g(u) = g(0) + \sum_{n\geq 0} \frac{u^2/4}{c_n(c_n^2 + u^2/4)}.$$

All increments are nonnegative, so Tonelli applies. The function $y/(c^2+y)$ is concave on $y \ge 0$. For $n = 0$, Jensen's inequality bounds the Gaussian mean by

$$\frac{1/8}{(1/4)((1/4)^2+1/8)} = \frac{8}{3}.$$

For $n \ge 1$ the mean is at most $1/(8c_n^3)$, and

$$\frac{1}{8}\sum_{n\ge 1}(n+1/4)^{-3} \le \frac{1}{8}\left((5/4)^{-3} + \int_{5/4}^{\infty} x^{-3}dx\right) = \frac{13}{125}.$$

Finally $g(0) = -\gamma - \pi/2 - 3\log 2 + \log\pi < -3$. For example, $\gamma > 0.57$, $\pi > 3.14$, $\log 2 > 0.69$, and $\log\pi < 1.15$ give this strict bound. Hence $A_0 < -3 + 8/3 + 13/125 < 0$. Substituting $L = 2\pi$ proves the stated normalization. □

Remark 99.3.10 *(arithmetic interpretation of a diagonal).* The auxiliary sign does not determine the Weil sign. For an uncut Hermite test the full diagonal is

$$q(\phi_n, \phi_n) = 2\log\pi - A_n + W_{\mathrm{fin}}(\phi_n * \phi_n^*) - P(\phi_n * \phi_n^*).$$

The prime and polar terms converge in the exponential test topology. For compact projected tests the formula in Chapter 99.3.6 gives their separate diagonals.

99.4 Hadamard Factorization and the Zero-Sum Decomposition

Applying the explicit formula to each pair of compact tests expresses its Gram entry as minus the corresponding zero sum. The definition of the form has already subtracted the polar term.

Theorem 99.4.1 *(zero decomposition of the Gram matrix).* Put $z_\rho = -i(\rho - 1/2)$, where ρ runs over the zeros of ξ with multiplicity. For the compact family d_i of Chapter 99.3.6,

$$q(d_i, d_j) = -\sum_{\rho} h_i(z_\rho)\overline{h_j(\bar z_\rho)}.$$

The sum converges absolutely. The same identity holds for uncut Hermite tests using the extension to $\mathscr{G}$.

Proof. The explicit formula gives $W = P - W_\infty - W_{\mathrm{fin}}$. The form $q = -W = W_\infty + W_{\mathrm{fin}} - P$ therefore equals minus the zero sum. Its polar contribution has already been subtracted. The compact formula and the continuous extension to $\mathscr{G}$ prove the two assertions. □

Corollary 99.4.2 *(complete compact Gram criterion).* The Riemann Hypothesis is equivalent to negative semidefiniteness of every finite principal matrix for the full complex compact family $e_{R,n}$. Equivalently, every finitely supported complex vector c satisfies

$$\sum_{i,j} c_i\overline{c_j}Q_{ij} = -\sum_{\rho}\left(\sum_i c_i h_i(z_\rho)\right)\overline{\left(\sum_i c_i h_i(\bar z_\rho)\right)} \le 0.$$

For either projected family the same criterion characterizes nonpositivity on its specified moment kernel only.

Proof. Matrix nonpositivity is nonpositivity of q on the corresponding finite span. Density from Chapter 99.3.5 and continuity of q extend it to the stated test space. The converse follows by restriction. On all of $\mathscr{A}$, Weil's criterion identifies this condition with RH. Under RH the zero expression is minus a sum of absolute squares. □

Remark 99.4.3 *(restriction and the full form).* A continuous projection $\Pi = 1 - RL$ gives $f = \Pi f + RLf$. Consequently

$$q(f,f) = q(\Pi f, \Pi f) + 2\Re q(\Pi f, RLf) + q(RLf, RLf).$$

A sign theorem on the moment kernel supplies only the first term. The mixed terms and the finite-dimensional complement remain in the full form. The complete compact Gram family retains all of them.

99.5 Finite-N Truncation and Bombieri–Lagarias Numerical Content

At each finite truncation, Q_N is a computable Hermitian matrix for its specified compact tests. A finite comparison with Li tests requires the corresponding change-of-family map. The infinite criterion uses every principal block.

Definition 99.5.1 *(truncated Gram matrix).* . For $N \geq 0$, set $Q_N := (Q_{mn})_{m,n \leq N}$, the $(N+1) \times (N+1)$ upper-left block of the full Gram matrix. It is Hermitian. On a real even projected family it is real symmetric.

THEOREM 99.5.2 *(finite-N Hermite blocks do not follow from Li positivity).* . Negative-semidefiniteness of the Hermite block Q_N is not a formal consequence of the inequalities $\lambda_n \geq 0$ for $1 \leq n \leq N$. Such a transfer would require an explicit finite change-of-test-family matrix between the Hermite cutoff functions and the Li test functions, together with control of the cutoff error. No such matrix is constructed here.

Proof. Li positivity is a family of scalar inequalities for a distinguished Li test family. Negative-semidefiniteness of Q_N is a matrix inequality for the first $N+1$ Hermite cutoff tests. Positivity of one finite list of scalar evaluations does not imply negativity of a different finite Gram block without a proved change of basis and error bound. The Hermite functions are not themselves Paley–Wiener tests, so the cutoff error is part of the statement, not a harmless normalization. □

PROPOSITION 99.5.3 *(finite Li inequalities with error bounds).* Suppose real approximations a_n and proven bounds ε_n satisfy $|\lambda_n - a_n| \leq \varepsilon_n < a_n$ for $1 \leq n \leq N$. Then $\lambda_n > 0$ for those indices. This certifies only that finite list of Li inequalities, not a distinct compact Gram block.

Proof. For each index, $\lambda_n \geq a_n - \varepsilon_n > 0$. A Gram-block assertion involves the quadratic form on all linear combinations of its specified tests, as established above. □

Coffey 2005, Appendix D, pp. 29–32 of arXiv:math-ph/0505052, tabulates approximate Li values for $1 \leq n \leq 100$. The displayed values are positive. A claim through $N = 10^5$ requires its own values and rigorous error bounds; a stated decimal precision alone is not an error bound. The analytic series and Li-test comparisons of Coffey and Bombieri–Lagarias remain distinct from the compact Hermite matrices constructed here.

Proposition 99.5.4 *(a three-mode Gaussian matrix).* For $m, n \in \{0, 4, 8\}$ define the uncut Gaussian matrix $\widetilde{Q}_{mn} = q(\phi_m, \phi_n)$ using the extension to $\mathscr{G}$. Its entries are

$$\widetilde{Q}_{mn} = i^{m-n} \int_{\mathbb{R}} \phi_m(u)\phi_n(u)k(u)du + W_{\mathrm{fin}}(\phi_m * \phi_n^*) - P(\phi_m * \phi_n^*).$$

All three terms converge absolutely. This real symmetric 3×3 matrix is distinct from Q_2, the first three entries of the chosen compact enumeration. All even Hermite indices are real even tests; the choice 0, 4, 8 is a selected three-mode example.

Proof. Each Hermite function lies in $\mathscr{G}$, so the extended explicit formula defines the entries and proves convergence of the prime and polar terms. Fourier self-reciprocity gives the displayed gamma integral, which converges by Gaussian decay. Hermitian symmetry and reality of the chosen tests give a real symmetric matrix. The compact matrix Q_2 instead uses the first three specified functions $\chi_R\phi_n$ in its enumeration. □

Determining the sign of $\widetilde{Q}$ requires estimates for its own gamma integrals, prime tails, and polar evaluations. No sign assertion for this Gaussian matrix or for Q_2 follows from the definition or from a finite list of Li coefficients alone.

The Uniform Bound Obstruction

Theorem 99.5.5 *(all compact Gram blocks).* For the enumeration of the full compact family, let Q_N be its first $N + 1$ principal matrix. Then

$$\sup_N \lambda_{\max}(Q_N) \le 0 \quad \Longleftrightarrow \quad q(f, f) \le 0 \ (f \in \mathscr{A}).$$

The latter condition is equivalent to RH. For either moment-projected family, the same statement characterizes nonpositivity on that moment space.

Proof. A finitely supported vector lies in some initial block. Thus the displayed eigenvalue condition is exactly nonpositivity on the finite span. Apply compact-topology density and continuity. No uniform strict spectral gap is used. □

Remark 99.5.6 *(coefficient norms).* These compact families need not be linearly independent. A strict bound $Q_N \preceq -cI$ for $c > 0$ refers to the chosen coefficient norm and can fail because of linear dependence alone. It is not equivalent to the Weil inequality.

99.6 Three Natural Regularizations and Their Failure

Tikhonov shifts, diagonal damping, and finite-rank perturbations change the finite matrices in different ways. The complete compact criterion still requires all principal blocks. Compact completeness has been proved above.

Tikhonov Regularization

Definition 99.6.1 *(Tikhonov regularized Gram).* . For $\varepsilon > 0$, set $Q_N^\varepsilon := Q_N - \varepsilon \cdot I_{N+1}$ (a negative shift by ε).

Proposition 99.6.2 *(Tikhonov shift and the ceiling).* . For fixed N and $\varepsilon > 0$, $Q_N^\varepsilon \prec 0$ if and only if $\lambda_{\max}(Q_N) < \varepsilon$. This is a finite-dimensional shift, not a proof of $Q_N \preceq 0$, and no unshifted Gram conclusion follows from a finite list of Li coefficients alone.

Proof. $Q_N^\varepsilon c = (Q_N - \varepsilon I)c$, and $\langle Q_N^\varepsilon c, c\rangle = \langle Q_N c, c\rangle - \varepsilon\|c\|^2$; it is strictly negative for every non-zero c exactly when every eigenvalue of Q_N is $< \varepsilon$. □

Remark 99.6.3 *(Tikhonov does not reach A-TP).* Tikhonov regularization with ε-dependent shift does not extend to $N \to \infty$: the uniform bound $\lambda_{\max}(Q_N) \le \varepsilon$ uniformly in N does not imply the desired unshifted inequality unless $\varepsilon \downarrow 0$ is controlled. The regularization changes the question.

Gaussian Windowing

Definition 99.6.4 *(diagonally damped Gram form).* For $\sigma > 0$, define $Q^\sigma_{mn} = e^{-(m+n)\sigma/2} Q_{mn}$. On finitely supported complex sequences put

$$q_{Q^\sigma}(c) = \sum_{m,n} c_m \overline{c_n} Q_{mn} e^{-(m+n)\sigma/2}.$$

This is the coefficient form $q_Q(T_\sigma c)$ with $(T_\sigma c)_n = e^{-n\sigma/2} c_n$.

LEMMA 99.6.5 *(diagonal damping on finite vectors).* For any $\sigma > 0$, put $(T_\sigma c)_n = e^{-n\sigma/2} c_n$. On finitely supported complex sequences, $q_{Q^\sigma}(c) = q_Q(T_\sigma c)$. Thus Q^σ is negative semidefinite on every finite vector if and only if Q is.

Proof. The map T_σ and its coordinatewise inverse both preserve finite support. The equality follows by expanding the finite sums. No assertion that the infinite matrix defines an operator on all of ℓ^2 is required. □

Finite-Rank Perturbation Ceiling

THEOREM 99.6.6 *(finite-rank perturbations of the coefficient form).* Let $V = c_{00}(\mathbb{N}_0; \mathbb{C})$ and define

$$q_Q(c, d) = \sum_{i,j} c_i \overline{d_j} Q_{ij}.$$

Here $Q_{ij} = q(e_i, e_j)$ is the compact Gram family and both sums are finite. Let $V^\times$ be the algebraic conjugate-linear dual. Suppose $p : V \times V \to \mathbb{C}$ is Hermitian, linear in its first argument, and its linear map

$$P : V \to V^\times, \qquad (Pc)(d) = p(c, d),$$

has finite rank r. Put $K = \ker P$. Then K has codimension r and is infinite-dimensional. For $c \in K$,

$$(q_Q + p)(c, c) = q_Q(c, c).$$

Consequently, nonpositivity of $q_Q + p$ on V implies nonpositivity of q_Q on K. The same identity holds on any specified common vector domain of two Hermitian forms, with K the kernel of the second form map.

Proof. The map P identifies V/K with its r-dimensional image. Thus K has finite codimension in the infinite-dimensional space V. For $c \in K$, the functional Pc vanishes on every vector, including c. Hence $p(c, c) = 0$, which proves the identity and sign implication. Hermitian symmetry also gives $p(d, c) = 0$ for every $d \in V$. No boundedness, closability, or operator realization on ℓ^2 is needed for these finite coefficient sums. □

Remark 99.6.7 *(existence and the remaining sign condition).* Finite-rank forms exist: if $L : V \to \mathbb{C}^r$ is linear and A is an $r \times r$ Hermitian matrix, then $p(c,d) = \sum_{a,b} (Lc)_a \overline{(Ld)}_b A_{ab}$ has rank at most r. A specified such form changes no diagonal value on its kernel. The existence of a finite-rank p with $q_Q + p \le 0$ remains a separate assertion. The displayed identity supplies a necessary condition on its infinite-dimensional kernel, not that existence.

Remark 99.6.8 *(what the three modifications determine).* The Tikhonov shift gives an exact finite eigenvalue criterion. Invertible diagonal damping preserves the sign condition on finite vectors. A finite-rank perturbation leaves the form unchanged on its kernel. These statements give no sign theorem on the complete compact test family without the remaining quadratic inequalities. They do not exclude additional arguments using a specified perturbation.

99.7 The full form and restricted realizations

Theorem 99.7.1 *(compact matrix criterion).* The complete compact Gram family characterizes the full Weil inequality. Its two projected families characterize the respective $(0,1)$ Mellin moment and polar-moment restrictions. Every compact entry is given by the signed gamma integral, a finite prime sum, and the polar Hermitian form. Its zero decomposition is minus the full zero sum.

Proof. The entry formula and zero decomposition were proved above. The density theorem and continuity of the form give the three matrix criteria on their stated carriers. □

Remark 99.7.2 *(finite comparisons).* A finite matrix calculation establishes its own finite inequality. An inference from Li coefficients requires a proved finite comparison. A Tikhonov shift changes the finite eigenvalues. Invertible diagonal damping preserves the finite sign question. A finite-rank perturbation leaves the quadratic form unchanged on its kernel. The auxiliary integral-energy criterion controls G_g, with $W_\infty = 2 \log \pi \langle\ ,\ \rangle_2 - G_g$. It does not determine the remaining prime and polar contributions.

99.8 Gram forms and pairing maps

Remark 99.8.1 *(positive Hilbert realization).* If a linear map $I : E \to H$ into a positive Hilbert space satisfies $\langle If, Ih \rangle_H = W(f * h^*)$, then the Weil form is nonnegative on E. For $E = \mathscr{A}$, such a realization is equivalent to the full inequality by quotienting its nullspace and completing. A realization of an arithmetic or automorphic sector additionally requires its native carrier, the map I, and this exact pairing identity. Moment projection and Hermite expansion supply test functions, but neither construction supplies that native pairing identity.

Chapter 100

A–TP through the Guinand–Burnol Co–Poisson Alternative

The Weil distribution has additive and multiplicative descriptions, related by the logarithmic coordinate. Its signed archimedean term is a distribution, and its full positivity criterion retains both polar evaluations and the prime term. The moment condition and its finite-dimensional complement can be analyzed before a co-Poisson or automorphic realization is constructed.

100.1 The full pairing and logarithmic transport

For $f \in \mathscr{A} = C_c^\infty(\mathbb{R})$, put $f^*(t) = \overline{f(-t)}$ and $h_f(z) = \int f(t)e^{izt}\,dt$. The arithmetic positivity condition is

$$W_\infty(f * f^*) \le P(f * f^*) - W_{\mathrm{fin}}(f * f^*),$$

with the signed conventions of Chapter 78.1.2. Its difference is $q_W(f,f) = W(f * f^*)$. On the full compact-test space this is equivalent to RH. A restricted Petersson realization requires a specified map and equality with this entire form. Rankin–Selberg coefficient multiplication does not give that identity. Indeed Chapter 78.5.5 gives a negative finite-prime square on compact tests.

The multiplicative moment question

The substitution $x = e^t$ transports compact additive tests to compact multiplicative tests with Haar measure dx/x. It gives a convergent mean for a transported autocorrelation. The additive expression evaluated directly against dy/y instead diverges at zero for a nonzero test. The mean-zero kernel below has an explicit projection. Extending positivity from that kernel requires its finite complement and the cross pairings with it. A proposed co-Poisson identification must supply an actual transform and the complete signed pairing on these carriers.

Classical references

The explicit-formula, theta and Hilbert-transform comparisons use the following references. Rankin 1939, Selberg 1940, Hecke 1936 and Deligne 1974 concern the separate automorphic coefficient comparison. Hurwitz 1882, Gauss 1813, Whittaker–Watson 1927 and Boas 1954 provide the special-function and entire-function background.

Guinand 1948. Guinand, A. P. *A summation formula in the theory of prime numbers*. *Proc. London Math. Soc.* (2) 50 (1948), 107–119. Fourier-dual alternative form of the Riemann–von Mangoldt explicit formula; zero-side / time-side duality.

Guinand 1945. Guinand, A. P. *Some formulae for the Riemann zeta-function*. *Quart. J. Math. Oxford* 16 (1945), 1–10. Self-dual summation identity; time-domain pairing formalism.

Burnol 2001. Burnol, J.-F. *Sur certains espaces de Hilbert de fonctions entières, liés à la transformation de Fourier et aux fonctions L de Dirichlet et de Riemann*. *C. R. Acad. Sci. Paris* 333 (2001), 201–206. Fourier transformation and entire-function Hilbert spaces.

Burnol 2002. Burnol, J.-F. *Sur les "espaces de Sonine" associés par de Branges à la transformation de Fourier*. *C. R. Math.* 335 (2002), 689–692, doi:10.1016/S1631-073X(02)02546-3; arXiv:math/0208121, §§2–5, Theorems 4 and 8. Sonine orthogonal projection and the associated de Branges space of completed Mellin transforms.

For this Sonine result use the cyclic Fourier convention $\mathcal{F}_{2\pi}f(x) = \int_{\mathbb{R}} e^{2\pi i x y} f(y)\,dy$. On even $L^2(\mathbb{R})$, normalized by $\|f\|^2 = \int_0^\infty |f(t)|^2\,dt$, put

$$K_\lambda = \{f : f = \mathcal{F}_{2\pi}f = 0 \text{ on } (-\lambda, \lambda)\}, \qquad \lambda > 0.$$

This is a closed subspace: it is the intersection of the kernels of two bounded restriction maps. Thus it has an orthogonal projection; Burnol's Theorem 4 computes it using the compressed cosine transform. For $f \in K_\lambda$, the integral $\widehat{f}(s) = \int_0^\infty f(t) t^{-s}\,dt$ converges for $\Re s > 1/2$ by Cauchy–Schwarz. Its completed continuation $\pi^{-s/2}\Gamma(s/2)\widehat{f}(s)$ is entire. Burnol's Theorem 8 identifies their Hilbert space isometrically with $\mathcal{B}(E_\lambda)$, using the critical line $\Re s = 1/2$ and measure $|ds|/(2\pi)$ in the Hardy-space definition. This supplies a specific Fourier–Mellin Hilbert space. A comparison with the complete Weil pairing in this chapter still requires a map from the chosen compact-test domain to K_λ and a proof of the identity of forms, including prime and polar terms.

Secondary: Riesz 1928 on the $M(x)$ function for the asymptotic co-Poisson comparison; Cotlar 1955 on the Hilbert transform almost everywhere convergence; Cartier–Voros 1990 for the distributional extension of Guinand's formula to Schwartz test functions; Meyer R. 2005 on distributional Selberg moments.

100.2 The Guinand Alternative Explicit Formula

The compact explicit formula admits a spectral-density notation in which the gamma term occurs with a plus sign. Its relation to the signed Weil density is a sign reversal, not a change in the arithmetic functional.

The completed function and Fourier tests

Let $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$. Its logarithmic derivative has a pole at each zero ρ with residue its multiplicity. It has no pole at 0 or 1, since $\xi(0) = \xi(1) = 1/2$. By contrast, $\Lambda_\zeta(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$ has simple poles there, and its logarithmic derivative has residue -1. The identity

$$\frac{\xi'}{\xi}(s) = \frac{1}{s} + \frac{1}{s-1} - \frac{\log \pi}{2} + \frac{1}{2}\psi(s/2) + \frac{\zeta'}{\zeta}(s)$$

holds meromorphically, with cancellations at 0, 1.

Definition 100.2.1 *(Fourier-pair conventions).* For an even $v \in \mathscr{A}$, use the pair

$$h(t) = \int_{\mathbb{R}} v(u) e^{itu}\,du, \qquad v(u) = \frac{1}{2\pi}\int_{\mathbb{R}} h(t) e^{-itu}\,dt.$$

The function h is entire. Evenness alone does not imply reality; when v is real and even, h is real and even on the real axis. The letter v distinguishes this inverse transform from the auxiliary digamma density g.

Theorem 100.2.2 *(the compact explicit formula in spectral-density form).* For the pair (h, v) above and $z_\rho = -i(\rho - 1/2)$,

$$\sum_\rho h(z_\rho) = h(i/2) + h(-i/2) - 2\sum_{n\geq 2} \frac{\Lambda(n)}{\sqrt{n}} v(\log n) + \int_{\mathbb{R}} h(t)\Phi_\infty^G(t)dt,$$

where

$$\Phi_\infty^G(t) = \frac{\Re\psi(1/4 + it/2) - \log\pi}{2\pi}.$$

Zeros are counted with multiplicity. The zero sum is absolutely convergent, and the prime sum is finite.

Proof. Apply Chapter 78.1.2 to v. Evenness combines the two prime evaluations. Its signed gamma density is $-\Phi_\infty^G$, which gives the plus sign above. This establishes the formula on the exact compact Fourier carrier. A contour proof would use the test $h(-i(s - 1/2))$, count the actual poles of the chosen logarithmic derivative, and use the Dirichlet series for $-\zeta'/\zeta$ only in $\Re s > 1$ before continuation. No direct critical-line Dirichlet-series expansion is required here. Guinand 1948 and Patterson 1988, Ch. 3, treat related explicit-formula conventions. □

Signed and auxiliary gamma conventions

Proposition 100.2.3 *(the exact convention dictionary).* With $\Phi_\infty^W(t) = k(t)/(2\pi)$ and $\Phi_\infty^{\mathrm{aux}}(t) = g(t)/(2\pi)$, where $k = \log\pi - \Re\psi(1/4 + it/2)$ and $g = 2\log\pi - k$,

$$\Phi_\infty^G = -\Phi_\infty^W = \Phi_\infty^{\mathrm{aux}} - \frac{\log\pi}{\pi}.$$

The constant difference pairs with h as $-2\log\pi\, v(0)$.

Proof. The density identities follow by substitution. Fourier inversion at zero gives $\int h(t)dt = 2\pi v(0)$. □

Remark 100.2.4 *(the constant term on convolution squares).* For $v = f * f^*$, the constant difference is $-2\log\pi\|f\|_2^2$. It is not a multiple of $\int f$, and it does not vanish merely because f has mean zero. Changing from the auxiliary density to the signed gamma density therefore requires the complete norm correction. The full explicit formula is unchanged only when this correction and its sign remain.

100.3 The Burnol Co–Poisson Transform

Ordinary Poisson summation exchanges a Schwartz function with its Fourier transform. A reciprocal change of variables is a different operation. The following calculation fixes that distinction before posing a co-Poisson realization of the Weil form.

Jacobi Theta and Co–Poisson

Definition 100.3.1 *(Jacobi theta function).* . Let

$$\theta(x) := \sum_{n\in\mathbb{Z}} e^{-\pi n^2 x} = 1 + 2\sum_{n\geq 1} e^{-\pi n^2 x}, \qquad x > 0,$$

with functional equation $x^{1/2}\theta(x) = \theta(1/x)$ (Jacobi 1828; modular S-transform).

Definition 100.3.2 *(the mean-subtracted dilation sum).* Let $\varphi \in \mathcal{S}(\mathbb{R})$ be real and even, with $\varphi(0) = 0$ and $\int_0^\infty \varphi = 0$. Use the cyclic Fourier transform $\widehat{\varphi}_2(\xi) = \int \varphi(t) e^{-2\pi i t\xi}\, dt$. Set

$$(C\varphi)(y) = \sum_{n\geq 1} \varphi(ny) - \frac{1}{y}\int_0^\infty \varphi(t)\,dt, \qquad y > 0.$$

The second term vanishes under the stated mean condition, and the series converges absolutely for every $y > 0$.

THEOREM 100.3.3 *(Poisson symmetry of the dilation sum).* The cyclic transform preserves the stated even Schwartz class with zero value and zero mean. On this class,

$$(C\varphi)(y) = y^{-1}(C\widehat{\varphi}_2)(1/y).$$

Both sides decrease faster than every power at zero and infinity. Writing $M_+\varphi(s) = \int_0^\infty \varphi(t) t^{s-1}\,dt$, one has

$$M_+(C\varphi)(s) = \zeta(s) M_+\varphi(s) \quad (0 < \Re s < 1),$$

where the product is continued from $\Re s > 1$.

Proof. The values $\widehat{\varphi}_2(0) = \int \varphi = 0$ and $\int \widehat{\varphi}_2 = \varphi(0) = 0$ follow from Fourier inversion. Poisson summation gives $\sum_{n\in\mathbb{Z}} \varphi(ny) = y^{-1} \sum_{n\in\mathbb{Z}} \widehat{\varphi}_2(n/y)$. Remove the zero terms and use evenness to obtain the identity. Schwartz decay bounds each dilation sum by $C_N y^{-N}$ for $y \geq 1$. The identity gives arbitrary-power decay at zero. For $\Re s > 1$, absolute convergence permits termwise Mellin integration and the change of variables $t = ny$, giving $\zeta(s) M_+\varphi(s)$. Because $\varphi(t) = O(t^2)$ at zero, $M_+\varphi$ is holomorphic on $\Re s > -2$. Its value at one vanishes, cancelling the pole of ζ there. Analytic continuation gives the asserted strip. The Mellin transform of $C\varphi$ itself is entire by its two-sided rapid decay. □

Remark 100.3.4 *(reciprocal pullback and the native comparison).* For $J\varphi(t) = t^{-1}\varphi(1/t)$ on the positive line, $M_+(J\varphi)(1-s) = M_+\varphi(s)$ wherever the integrals converge. It is not a substitute for $\widehat{\varphi}_2$ in the Poisson identity. Choose a nonzero smooth test supported away from zero with $\int_0^\infty \varphi(t)\,dt = \int_0^\infty \varphi(t)\,dt/t = 0$, and extend it evenly. Such a test exists by solving two homogeneous linear equations on three disjoint compact bumps. Then both φ and the even extension of $J\varphi$ belong to the stated zero-mean class. If their reciprocal dilation-sum identity held, Mellin continuation would give $(\zeta(s) - \zeta(1-s)) M_+\varphi(s) = 0$. The meromorphic factor is not identically zero, so Mellin uniqueness would force $\varphi = 0$, a contradiction. Burnol's Sonine and co-Poisson spaces concern additional specified Fourier-compatible constructions. Identifying a realization in one of those spaces with the full signed Weil pairing remains a separate map and pairing problem; the elementary Poisson identity alone provides no zero-spectrum decomposition or positivity theorem.

The archimedean distribution in multiplicative coordinates

Let $Lf(x) = f(\log x)$ for $x > 0$. The transported archimedean functional is $T(\Phi) = W_\infty(L^{-1}\Phi)$ on $C_c^\infty(\mathbb{R}_{>0})$ with its usual compact-test topology. It has an explicit convergent subtraction formula.

PROPOSITION 100.3.5 *(the exact transported gamma distribution).* For $\Phi = Lf$, one has

$$T(\Phi) = W_\infty(f) = \frac{1}{2\pi}\int_{\mathbb{R}} h_f(u)(\log\pi - \Re\psi(1/4 + iu/2))\,du,$$

$$T(\Phi) = (\log\pi + \gamma)\Phi(1) + \int_1^\infty \frac{x^{-1/2}[\Phi(x) + \Phi(x^{-1})] - 2x^{-2}\Phi(1)}{1 - x^{-2}}\,\frac{dx}{x}.$$

Here γ is Euler's constant. Both expressions converge. Away from $x = 1$, its density relative to dx/x is

$$K(x) = \frac{e^{-|\log x|/2}}{1 - e^{-2|\log x|}} > 0.$$

At $x = 1$ this density requires the subtraction in the preceding formula and is not locally integrable by itself.

Proof. Use the digamma identity already applied in Chapter 78.1.3: $\psi(z) + \gamma = \int_0^\infty (e^{-v} - e^{-zv})/(1 - e^{-v})\, dv$. First truncate the v integral away from zero and infinity. Fourier inversion gives $f(0)$ from the constant term and $[f(v/2) + f(-v/2)]/2$ from $\cos(uv/2)$. Put $v = 2t$. The result is

$$W_\infty(f) = (\log \pi + \gamma) f(0) + \int_0^\infty \frac{e^{-t/2}[f(t) + f(-t)] - 2e^{-2t} f(0)}{1 - e^{-2t}} dt.$$

The numerator is $O(t)$ at zero and the denominator is asymptotic to $2t$. At infinity the compact terms vanish and the remaining term decays exponentially. Thus the integral converges. The truncated digamma integrands, after integration, are bounded by a constant times $1 + \log(2 + |u|)$, uniformly in the truncations: near $v = 0$, use $1 - \cos(uv/2) \le \min(2, u^2v^2/8)$. Rapid decay of h_f permits dominated convergence. The substitution $x = e^t$ gives the displayed formula. For tests vanishing near one, the subtraction vanishes and the change $x \mapsto x^{-1}$ gives the stated density on both sides. Its asymptotic $K(x) \sim 1/(2|\log x|)$ proves the last assertion. □

Remark 100.3.6 *(support and sign).* The off-diagonal density is positive on both $(0, 1)$ and $(1, \infty)$. The subtraction at one is part of the distribution. There is no sign change at $1/\pi$ in this exact density. Positivity of the off-diagonal density does not imply positivity of its quadratic pullback, because the subtraction must remain.

100.4 Co–Poisson Diagnostic and Exact Restatement

The archimedean term on multiplicative tests is the distribution T above. Its application to a transported autocorrelation retains the subtraction at one. Hilbert-transform parity gives a separate elementary identity, but identifying a Hilbert-transform pairing with T requires an operator comparison.

Hilbert Transform on Even Functions

Definition 100.4.1 *(Hilbert transform).* . For $\phi \in L^2(\mathbb{R})$, the Hilbert transform $H\phi$ is the Cauchy principal value

$$(H\phi)(t) = \frac{1}{\pi}\, \text{p.v.} \int_{-\infty}^{\infty} \frac{\phi(s)}{t - s}\, ds. \tag{100.1}$$

The operator $H\colon L^2 \to L^2$ is isometric with $H^2 = -\mathrm{id}$, and the pointwise convergence of the principal value holds almost everywhere (Cotlar 1955).

Lemma 100.4.2 *(Hilbert symmetry on even functions).* . For $\phi \in L^2(\mathbb{R})$ even, $H\phi$ is odd. For ϕ odd, $H\phi$ is even. The pairing $\langle \phi, H\chi \rangle$ vanishes whenever ϕ and χ share the same parity.

Proof. From (100.1), substitute $s \mapsto -s$, $t \mapsto -t$: if $\phi(-s) = \phi(s)$ then $(H\phi)(-t) = \frac{1}{\pi}\, \text{p.v.} \int \frac{\phi(s)}{-t-s}\, ds = -\frac{1}{\pi}\, \text{p.v.} \int \frac{\phi(s)}{t+s}\, ds = -\frac{1}{\pi}\, \text{p.v.} \int \frac{\phi(-u)}{t-u}\, du = -(H\phi)(t)$, with $u = -s$ and evenness. So $H\phi$ is odd. The parity-orthogonality follows from $\int (\text{odd}) \cdot (\text{even}) = 0$. □

PROPOSITION 100.4.3 *(the full inequality after logarithmic transport).* For $f \in \mathscr{A}$, put $\varphi = f * f^*$ and $\Phi(x) = \varphi(\log x)$. Then archimedean Tate positivity for this test is exactly

$$T(\Phi) \le P(\varphi) - W_{\mathrm{fin}}(\varphi).$$

It is equivalent to $q_W(f,f) \ge 0$.

Proof. By definition $T(\Phi) = W_\infty(\varphi)$. The signed explicit formula gives $W(\varphi) = P(\varphi) - W_{\mathrm{fin}}(\varphi) - T(\Phi)$. Rearranging proves the assertion. No additional zero term is added to the right-hand side of the inequality. □

The moment condition in logarithmic coordinates

An additive autocorrelation cannot have a vanishing unregularized dy/y mean near its additive origin. This determines the necessary change of variables before a multiplicative moment is imposed. For $f \in \mathscr{A}$, put $\varphi = f * f^*$. Then $\varphi(0) = \|f\|_2^2$. If $f \ne 0$, continuity gives $\Re\varphi(y) \ge \|f\|_2^2/2$ for sufficiently small positive y. Consequently $\int_0^\infty \varphi(y)\,dy/y$ diverges at zero.

Define the logarithmic transport

$$(Lf)(x) = f(\log x), \qquad x > 0.$$

It is an isomorphism from $C_c^\infty(\mathbb{R})$ to $C_c^\infty(\mathbb{R}_{>0})$. On the latter space use multiplicative Haar measure dx/x, convolution $(F *_\times G)(x) = \int_0^\infty F(y)G(x/y)\,dy/y$, and $F^{*\times}(x) = \overline{F(1/x)}$. Changing variables $y = e^t$ gives

$$L(f * g) = Lf *_\times Lg, \qquad L(f^*) = (Lf)^{*\times}.$$

Thus the multiplicative autocorrelation is $\Phi(x) = \varphi(\log x)$ and

$$\int_0^\infty \Phi(x)\frac{dx}{x} = \int_{\mathbb{R}} \varphi(t)\,dt = \left|\int_{\mathbb{R}} f(t)\,dt\right|^2.$$

It is compactly supported away from zero, so the integral converges.

Definition 100.4.4 *(the mean-zero moment space).* Set $K_0 = \{f \in \mathscr{A} : \int f = 0\}$. For real even tests, use its real even part $K_0^{\mathbb{R},\mathrm{ev}}$. The multiplicative mean of $L(f * f^*)$ vanishes exactly on K_0. Give these spaces the compact-test topology. Write

$$C_0 = \{f \in K_0 : q_W(f,f) \ge 0\}, \qquad q_W(f,g) = W(f * g^*).$$

Membership in C_0 is a quadratic inequality in addition to the linear moment condition. No identification with a Sonine space or a co-Poisson image is included in this definition.

PROPOSITION 100.4.5 *(nonzero moment tests and their projection).* Fix a compact smooth η of integral one. The map $\Pi_0 f = f - (\int f)\eta$ is a continuous projection onto K_0, which is closed of complex codimension one. Choosing η real and even restricts this projection to real even tests. This restricted kernel contains nonzero functions.

Proof. The integral is continuous on compact tests and has value one on η. Therefore $\Pi_0^2 = \Pi_0$ and its image is exactly K_0. For a nonzero real even compact smooth b, the derivative b'' is real and even and has integral zero. It is nonzero, since a compactly supported affine function must vanish. □

Theorem 100.4.6 *(closed positivity on the moment space).* The set C_0 is closed in K_0. It is dense there if and only if $q_W(f,f) \geq 0$ for every $f \in K_0$. If $S \subset \mathscr{A}$ is dense, then $\Pi_0 S$ is dense in K_0. To deduce positivity from a dense linear span, the form must be nonnegative on every finite linear combination from that span.

Proof. Convolution and W are continuous on compact tests, so $f \mapsto q_W(f,f)$ is a continuous real-valued function. Its inverse image of $[0,\infty)$ is closed. A closed dense subset of K_0 equals K_0, proving the equivalence. Continuity and surjectivity of Π_0 prove the density assertion. For two generators, positivity of their individual diagonals gives no bound on the cross term $2\Re q_W(f,g)$ of their sum. This proves the last distinction. □

The finite complement and the full form

Every compact test has the exact decomposition $f = u + c\eta$ with $u = \Pi_0 f \in K_0$ and $c = \int f$. Thus

$$q_W(f,f) = q_W(u,u) + 2\Re\big(\bar{c}\, q_W(u,\eta)\big) + |c|^2 q_W(\eta,\eta).$$

The missing part of a full positivity proof is determined by this one-dimensional complement and its cross pairings.

Theorem 100.4.7 *(extension from the mean-zero kernel).* Assume $q_W(u,u) \geq 0$ for all $u \in K_0$. Then full Weil positivity is equivalent to

$$q_W(\eta,\eta) \geq 0, \qquad |q_W(u,\eta)|^2 \leq q_W(u,u) q_W(\eta,\eta) \quad (u \in K_0).$$

In particular, if $q_W(\eta,\eta) = 0$, the required condition is $q_W(u,\eta) = 0$ for every $u \in K_0$.

Proof. Full positivity implies these inequalities by Cauchy–Schwarz. Conversely the cross bound and the preceding decomposition give

$$q_W(u + c\eta, u + c\eta) \geq \left(\sqrt{q_W(u,u)} - |c|\sqrt{q_W(\eta,\eta)}\right)^2 \geq 0.$$

All compact tests have this decomposition. □

Corollary 100.4.8 *(a sufficient norm bound).* Under positivity on K_0, suppose the functional $u \mapsto q_W(u,\eta)$ is bounded for the seminorm $q_W(u,u)^{1/2}$ with squared bound at most $q_W(\eta,\eta)$, and that $q_W(\eta,\eta) \geq 0$. Then full Weil positivity holds and hence RH holds.

Proof. The bound is exactly the cross inequality in the preceding theorem. Apply the compact Weil criterion. □

Proposition 100.4.9 *(what Hilbert-transform isometry supplies).* The Hilbert transform on $L^2(\mathbb{R})$ is skew-adjoint. Thus $\Re\langle v, Hv\rangle = 0$. Its norm isometry supplies no identity with the cross pairing $q_W(u,\eta)$ above.

Proof. The Fourier multiplier of the Hilbert transform is purely imaginary, of modulus one almost everywhere, and changes sign under complex conjugation. Hence $H^* = -H$ and $H^*H = 1$. Taking the real part of its quadratic pairing gives zero. The cross pairing instead uses the full Weil distribution. Equating the two would require an additional operator identity. □

100.5 THE MULTIPLICATIVE COMPARISON PROBLEM

THEOREM 100.5.1 *(moment transport and the positivity boundary).* The logarithmic map L transports additive convolution and involution to multiplicative convolution and involution. The multiplicative mean-zero autocorrelations correspond exactly to K_0. This kernel has the explicit continuous projection Π_0. Its nonnegative Weil locus is closed. Positivity on K_0 extends to all compact tests precisely under the complement inequalities in Chapter 100.4.7.

Proof. The change-of-variables calculations, projection construction, closedness argument, and quadratic decomposition above prove each assertion. □

Remark 100.5.2 *(the proposed co-Poisson realization).* A co-Poisson realization must specify a space, a transform, its measure and domain, and an identity with the full signed Weil form. The exact transport L gives the requisite multiplicative test algebra. It does not turn Fourier transformation into reciprocal pullback, nor produce an ordinary time-domain kernel from a spectral logarithmic derivative. Such a kernel requires a proved distributional transform and a prescription at its singularities. In particular the asserted split at $1/\pi$ cannot be used without an exact kernel and sign proof. A bound on one auxiliary spectral form also supplies no cross inequality for q_W. The nonzero tests b'' establish that the linear moment kernel is nonempty. Their full Weil positivity requires a separate proof. Likewise density of a proposed co-Poisson image must be proved in a topology controlling the complete Weil form. The explicit projection and complement criterion state exactly what such a density and positivity argument would have to establish.

100.6 POSITIVE SECTORS OF THE WEIL FORM

The full compact-test functional W of Theorem 78.1.2 has positive sectors without assuming its positivity on the entire test algebra. Its prime-power terms couple test functions on separated intervals. A sufficiently small width makes the archimedean contribution dominate these couplings. This gives a positive space of functions with infinitely many independent directions, while retaining the full arithmetic functional.

Conventions and the full form

For $f \in C_c^\infty(\mathbb{R})$ use

$$\widehat{f}(t) = \int_{\mathbb{R}} f(u) e^{itu}\, du, \qquad f^*(u) = \overline{f(-u)}, \qquad (f * g)(u) = \int_{\mathbb{R}} f(v) g(u-v)\, dv.$$

Let $\Lambda(n)$ be the von Mangoldt function: it is $\log p$ for $n = p^a$ and zero otherwise. Put

$$k_\infty(t) = \operatorname{Re} \psi(1/4 + it/2) - \log \pi,$$

where $\psi = \Gamma'/\Gamma$. Define the full arithmetic functional by

$$\begin{aligned} L_\zeta(h) = \widehat{h}(i/2) + \widehat{h}(-i/2) + \frac{1}{2\pi} \int_{\mathbb{R}} \widehat{h}(t) k_\infty(t)\, dt \\ - \sum_{n \geq 2} \frac{\Lambda(n)}{\sqrt{n}} \big(h(\log n) + h(-\log n) \big). \end{aligned} \tag{100.2}$$

With the preceding sign convention, $L_\zeta(h) = W(h)$. For compact smooth h the prime sum is finite and the Fourier integral converges. Define

$$B_\zeta(f,g) = L_\zeta(f^* * g), \qquad Q_\zeta(f) = B_\zeta(f,f).$$

The form is conjugate-linear in its first argument, linear in its second and Hermitian. The estimates below use this displayed functional directly.

A coercive estimate on one narrow interval

The convergent digamma series gives

$$k_\infty(t) = k_\infty(0) + \sum_{n\ge 0}\left(\frac{1}{n+1/4} - \frac{n+1/4}{(n+1/4)^2 + t^2/4}\right). \tag{100.3}$$

Every summand is nonnegative and increasing with $|t|$. Also

$$k_\infty(0) = -\gamma - \frac{\pi}{2} - 3\log 2 - \log\pi > -6.$$

For example $\gamma < 1, \pi < 22/7, \log 2 < 7/10$ and $\log\pi < 6/5$ suffice. The last two exponential inequalities follow from their finite positive Taylor lower bounds. Finally $k_\infty(T) \to +\infty$: for $n + 1/4 \le T/2$, the corresponding summand in (100.3) is at least $1/(2(n+1/4))$, whose partial sums diverge.

Let f have support in an interval of length L. Cauchy–Schwarz gives $|\widehat{f}(t)|^2 \le L\|f\|_2^2$, and Plancherel gives

$$\frac{1}{2\pi}\int_{-T}^{T} |\widehat{f}(t)|^2 dt \le \frac{LT}{\pi}\|f\|_2^2, \qquad \frac{1}{2\pi}\int_{\mathbb{R}} |\widehat{f}(t)|^2 dt = \|f\|_2^2.$$

Let $T > 0$ and $M \ge -6$ satisfy $k_\infty(T) \ge M$. The archimedean contribution is then at least

$$\left(M - (M+6)\frac{LT}{\pi}\right)\|f\|_2^2.$$

When $L < \log 2$, the support of $f^* * f$ contains no nonzero prime-power logarithm, so its prime contribution is zero. The polar term is bounded below by $-2Le^{L/2}\|f\|_2^2$: translate the interval to be centred at zero and apply Cauchy–Schwarz to $\int f(u)e^{u/2}du$ and $\int f(u)e^{-u/2}du$. The translation factors cancel between these two integrals. Consequently

$$Q_\zeta(f) \ge c(L,T,M)\|f\|_2^2, \qquad c(L,T,M) = M - (M+6)\frac{LT}{\pi} - 2Le^{L/2}. \tag{100.4}$$

The estimate holds uniformly over all smooth functions in the interval.

The cross-window kernel retains the arithmetic primes

Away from zero, the distribution given by the sum of the polar and archimedean contributions in (100.2) is the smooth even kernel

$$K(u) = 2\cosh(u/2) - \frac{e^{-|u|/2}}{1 - e^{-2|u|}} \qquad (u \ne 0). \tag{100.5}$$

To verify it, use the integral expression

$$\psi(a+it/2) = -\gamma + \int_0^\infty \frac{e^{-v} - e^{-(a+it/2)v}}{1-e^{-v}}\,dv.$$

Test on a smooth function supported away from zero. Terms constant in t vanish on that test. Fourier inversion of the cosine term, followed by $v = 2|u|$, gives the negative second summand in (100.5). The two polar evaluations give $2\cosh(u/2)$. This argument is on separated supports; it does not ignore a delta term at zero in the diagonal form.

Fix distinct positions $a_1, \dots, a_N$. Let $I_L = (-L/2, L/2)$ and

$$F(u) = \sum_{j=1}^{N} f_j(u - a_j), \qquad f_j \in C_c^\infty(I_L).$$

Choose L so small that these supports are disjoint and each difference interval contains a prime-power logarithm only if its centre equals that logarithm. This is possible because there are only finitely many prime powers in a bounded interval. Put

$$w_{ij} = \begin{cases} \Lambda(n)/\sqrt{n}, & |a_i - a_j| = \log n \text{ for an integer } n \geq 2, \\ 0, & \text{otherwise.} \end{cases}$$

For a resonant pair its prime term is exactly $-w_{ij}\int f_j(v)\overline{f_i(v)}dv$. The smooth part is the integral kernel (100.5) evaluated at $a_j - a_i + v - u$. If M_{ij} bounds $|K|$ there, its absolute value is at most $LM_{ij}\|f_i\|_2\|f_j\|_2$. Thus

$$Q_\zeta(F) \geq \left(c(L,T,M) - \max_i \sum_{j\neq i} (w_{ij} + LM_{ij}) \right) \sum_i \|f_i\|_2^2. \tag{100.6}$$

Apply $2ab \leq a^2 + b^2$ to each unordered pair to obtain this bound.

Theorem 100.6.1 *(Positive arithmetic windows of arbitrary finite multiplicity).* For any fixed finite set of distinct real positions $a_1, \dots, a_N$, there exists $L > 0$ such that the full Weil form is positive definite on the infinite-dimensional space

$$\bigoplus_{j=1}^{N} C_c^\infty(a_j + I_L).$$

It has a uniform strictly positive lower bound by the L^2 norm. All prime-power terms in (100.2) are retained.

Proof. The finite row sums of the w_{ij} are fixed. Choose M larger than their maximum plus two, and then T with $k_\infty(T) \geq M$. For sufficiently small L, the separation requirements hold, LT and $Le^{L/2}$ tend to zero, and the M_{ij} remain bounded because their arguments stay away from zero. The coefficient in (100.6) is then positive, in fact larger than one after making L smaller. □

An explicit four-window theorem with a prime-power coupling

Choose

$$(a_0, a_1, a_2, a_3) = (0, \log 2, \log 3, \log 4), \qquad L = 10^{-3}.$$

The resonant pairs are $(0,1)$, $(0,2)$, $(0,3)$, $(1,3)$; their weights are respectively

$$\frac{\log 2}{\sqrt{2}}, \quad \frac{\log 3}{\sqrt{3}}, \quad \frac{\log 2}{2}, \quad \frac{\log 2}{\sqrt{2}}.$$

In particular the $\log 4$ term is a genuine prime-power term, not $\log 4/2$. Every other logarithmic difference is separated from prime-power logarithms by more than L.

Theorem 100.6.2 *(A quantitative positive sector).* For arbitrary $f_j \in C_c^\infty((-1/2000, 1/2000))$, the function

$$F(u) = f_0(u) + f_1(u - \log 2) + f_2(u - \log 3) + f_3(u - \log 4)$$

satisfies

$$\boxed{Q_\zeta(F) \geq \frac{1}{5} \sum_{j=0}^{3} \|f_j\|_2^2.} \tag{100.7}$$

Proof. A finite rational calculation gives

$$\sum_{n=0}^{99} \left(\frac{1}{n + 1/4} - \frac{n + 1/4}{(n + 1/4)^2 + 2500} \right) > 8.$$

For an explicit integer calculation, put

$$d_n = (4n+1)((4n+1)^2 + 40000), \qquad b_j = \sum_{n=10j}^{10j+9} \left\lfloor \frac{1600000000}{d_n} \right\rfloor.$$

The values for $j = 0, \ldots, 9$ are

$$(b_0, \ldots, b_9) = (64860, 6514, 3300, 1958, 1248, 832, 574, 411, 300, 226).$$

Their sum is 80223. The rational partial sum is therefore at least $80223/10000 > 8$. Since all later summands are nonnegative and $k_\infty(0) > -6$, we have $k_\infty(100) > 2$. Equation (100.4), $\pi > 3$, and $e^{1/2000} < 3/2$ give a diagonal lower bound

$$2 - \frac{8}{30} - \frac{3}{1000} = \frac{5191}{3000}.$$

All cross-kernel arguments have absolute value between $\log(4/3) - 10^{-3}$ and $\log 4 + 10^{-3}$. On this interval each of the two positive terms in (100.5) is less than three. For the denominator term, $\log(4/3) > 1/4$ and $\log(3/2) < 1/2 - 1/8 + 1/24 < 0.498$ imply $1 - e^{-2|u|} > 1/3$. For the polar term use $2\cosh((\log 4 + 10^{-3})/2) < 2(1.001) + 1/2 < 3$. Thus $|K(u)| < 3$, and the smooth row cost is less than $9/1000$.

The largest prime row sum is bounded by

$$\frac{1}{2} + \frac{11}{17} + \frac{7}{20} = \frac{509}{340},$$

using $\log 2 < 7/10$, $\sqrt{2} > 7/5$, $\log 3 < 11/10$, $\sqrt{3} > 17/10$. Substitution into (100.6) gives

$$\frac{5191}{3000} - \frac{9}{1000} - \frac{509}{340} = \frac{5719}{25500} > \frac{1}{5}.$$

This proves (100.7) for the entire stated infinite-dimensional space. □

This sector is not a convolution algebra. Its support windows are not preserved under repeated convolution, and the permissible window width in Theorem 100.6.1 depends on the whole finite set of positions. Neither theorem supplies a dense convolution-stable exhaustion with one uniform estimate. That missing extension is exactly where the global Weil-positivity problem remains. Global positivity on the full convolution algebra is not a consequence of these estimates.

Finite-rank operators from the arithmetic pairing

Let $\mathscr{H}$ be the Hilbert completion of this four-window space for B_ζ, with the inner product conjugate-linear in its first argument. For $f, g \in \mathscr{H}$, define the bounded rank-one operator $\Theta_{f,g}h = B_\zeta(g,h)f$. Direct substitution gives

$$\Theta_{f,g}\Theta_{u,v} = B_\zeta(g,u)\Theta_{f,v}, \qquad \Theta_{f,g}^* = \Theta_{g,f}, \qquad \operatorname{Tr}(\Theta_{f,g}\Theta_{u,v}) = B_\zeta(g,u)B_\zeta(v,f).$$

The trace identity follows from $\operatorname{Tr}(\Theta_{f,v}) = B_\zeta(v,f)$ in an orthonormal basis. For vectors in the original test space, every displayed contraction has its prime, archimedean and polar terms given by the full functional above. These operators represent the selected quadratic pairing. A representation of convolution would additionally require compatible operators for every convolution multiplier on a common invariant domain.

For a finite-dimensional flavour subspace $V \subset \mathscr{H}$, take the charged fermion space

$$\mathcal{F}_V = \Lambda_{\mathbb{C}}\left(\bigoplus_{r \in \mathbb{Z}_{>0}-1/2} (V \oplus \overline{V})t^r\right).$$

Use its algebraic finite-particle domain and the induced positive Hermitian form. Exterior multiplication and its adjoint satisfy the canonical anticommutation relations with contraction B_ζ. Writing the resulting charged fields as $\psi_f(z)$, linear in f, and $\psi_g^*(w)$, conjugate-linear in g, the vacuum contraction in the expansion $|w| < |z|$ is

$$B_\zeta(g,f)\sum_{k\geq 0} z^{-k-1}w^k = \frac{B_\zeta(g,f)}{z-w}.$$

For a finite-rank A, choose V containing the ranges of A and A^*, and define $J_{\Theta_{f,g}}(z) =: \psi_f(z)\psi_g^*(z) :$, extending linearly in A. Normal ordering places creation operators to the left, with fermion signs. The singular operator product is

$$J_A(z)J_B(w) \sim \frac{\operatorname{Tr}(AB)}{(z-w)^2} + \frac{J_{[A,B]}(w)}{z-w}.$$

Indeed the two single contractions compose the matrices in their two orders, with opposite fermion signs. The double contraction sums their closed index pair and gives $\operatorname{Tr}(AB)$. Equivalently, the current modes satisfy

$$[J_A(m), J_B(n)] = J_{[A,B]}(m+n) + m\delta_{m+n,0}\operatorname{Tr}(AB)I.$$

For $m > 0$, exactly m half-integer modes cross the vacuum in the scalar term. Antisymmetry determines the remaining signs. For fixed mode and finite-energy vector, only finitely many creation terms survive. Enlarging V preserves these identities, so they apply to every finite set of finite-rank operators on $\mathscr{H}$. The arithmetic pairing thus occurs as the contraction of singular currents on this specified positive sector. Its support is still not stable under convolution.

Chapter 101

Adelic Scaling, Scattering, and the Weil Trace

The Weil pairing is positive precisely when the nontrivial zeta zeros lie on the critical line. A scattering operator instead compares two self-adjoint dynamics on their absolutely continuous subspaces. The question is whether arithmetic dynamics can produce the full signed Weil trace. The distinction between these two constructions already appears in a positive rank-one perturbation.

101.1 A Rank-One Trace Difference

Use the complex test algebra $\mathscr{A} = C_c^\infty(\mathbb{R})$, with additive convolution and $f^*(u) = \overline{f(-u)}$. Put

$$h_f(z) = \int_{\mathbb{R}} f(u) e^{izu}\, du, \qquad \mathscr{P} = \{h_f : f \in \mathscr{A}\}, \qquad h^\sharp(z) = \overline{h(\bar{z})}.$$

Then $h_{f*f^*} = h_f h_f^\sharp$, whose restriction to the real line is $|h_f|^2$. The signed Weil distribution is $W = P - W_\infty - W_{\mathrm{fin}}$, with all three terms as in Chapter 78.1.2. Its positivity condition is $W(f * f^*) \geq 0$ for every $f \in \mathscr{A}$. No evenness restriction is imposed.

Proposition 101.1.1 *(Complete scattering with a signed trace).* On $L^2(\mathbb{R}, d\lambda) \oplus \mathbb{C}$, let

$$A_0 = M_\lambda \oplus 0, \qquad A_1 = M_\lambda \oplus a, \qquad a > 0,$$

with common domain $\mathrm{Dom}\, M_\lambda \oplus \mathbb{C}$, where $\mathrm{Dom}\, M_\lambda = \{g : \lambda g \in L^2\}$. The difference is positive and has rank one. The wave operators are complete and the scattering operator is the identity. For every $h \in \mathscr{S}(\mathbb{R})$, however,

$$\mathrm{Tr}(h(A_1) - h(A_0)) = h(a) - h(0) = \int_0^a h'(\lambda)\, d\lambda.$$

The corresponding spectral shift is $\xi = \mathbf{1}_{(0,a)}$, and $-d\xi = \delta_a - \delta_0$ is not positive, even on the tests $|h_f|^2$, $f \in \mathscr{A}$.

Proof. The absolutely continuous subspace of each operator is the first summand. On that summand $e^{itA_1} e^{-itA_0} = 1$, so both wave operators have exactly that range. Functional calculus gives the displayed trace difference on the one-dimensional second summand. The integral identity fixes its spectral-shift sign. Choose $\phi \in \mathscr{A}$ with $\int \phi = 1$, and set $f(u) = \phi(u) + \phi(u - \pi/a)$. Then $h_f(z) = (1 + e^{i\pi z/a}) h_\phi(z)$, so $|h_f(a)|^2 - |h_f(0)|^2 = -4$. Also $e^{-2\pi i \xi} = 1$ almost everywhere, despite the negative atom of $-d\xi$. □

The example separates a unitary scattering phase from a positive trace distribution. To test an arithmetic comparison, the Hilbert spaces, domains, and perturbation must first be specified.

101.2 The Idele Scaling Operator

Definition 101.2.1 *(Idele carrier and measure).* Let $\mathbb{A}$ be the adele ring of $\mathbb{Q}$, let $C_{\mathbb{Q}} = \mathbb{Q}^{\times}\backslash\mathbb{A}^{\times}$, and put $C_{\mathbb{Q}}^{1} = \ker(|\cdot| : C_{\mathbb{Q}} \to \mathbb{R}_{>0})$. The section represented by the idele $(x, 1, 1, \dots)$, $x > 0$, gives $C_{\mathbb{Q}} \cong \mathbb{R}_{>0} \times C_{\mathbb{Q}}^{1}$. Give the compact group $C_{\mathbb{Q}}^{1}$ Haar probability measure $d\mu_{1}$, and use dx/x on the first factor. Define

$$\mathcal{K} = L^{2}(C_{\mathbb{Q}}, d^{\times}x) = L^{2}(\mathbb{R}, du; E), \qquad E = L^{2}(C_{\mathbb{Q}}^{1}, d\mu_{1}), \quad u = \log x.$$

Here $d^{\times}x$ is the product measure, of infinite total mass. Let P_{0} be the rank-one orthogonal projection of E onto its constant functions.

LEMMA 101.2.2 *(Unitary Mellin transform and domain).* The transform

$$(\mathcal{M}g)(\tau) = (2\pi)^{-1/2} \int_{0}^{\infty} g(x) x^{-i\tau} \, \frac{dx}{x}$$

extends to a unitary from $\mathcal{K}$ to $L^{2}(\mathbb{R}, d\tau; E)$. On the logarithmic side put $D_{0} = -i\partial_{u}$, with domain $H^{1}(\mathbb{R}; E)$. It is self-adjoint, has purely absolutely continuous spectrum $\mathbb{R}$, and transforms to $M_{\tau} \otimes 1_{E}$, with domain $\{F : \int \tau^{2} \|F(\tau)\|_{E}^{2} d\tau < \infty\}$. A core is $\mathscr{S}(\mathbb{R}) \otimes_{\mathrm{alg}} E$.

Proof. The substitution $x = e^{u}$ preserves the stated measures. The ordinary Fourier Plancherel theorem, applied in each coordinate of an orthonormal basis of E, proves unitarity. Integration by parts on the Schwartz core gives $\mathcal{M}(-i\partial_{u} g) = \tau \mathcal{M} g$. Real multiplication on its maximal domain is self-adjoint: its adjoint has the same domain, as testing against compactly supported functions shows. Truncate in τ and in finitely many E-coordinates, then approximate the resulting functions by smooth compactly supported functions. This gives graph-norm density of the stated core. Each spectral measure has density $\|F(\tau)\|_{E}^{2}$ with respect to Lebesgue measure. Every real interval has nonzero spectral projection, proving the spectrum claim. □

The spherical space $L^{2}(\mathbb{R}) \otimes \operatorname{im} P_{0}$ is a reducing subspace. Its Schwartz functions are not a dense operator core for all of $\mathcal{K}$. The transform above uses the unitary character $x^{-i\tau}$. A formula with exponent $1/2 + i\tau$ requires an additional weight in the source measure or a specified multiplication by $x^{1/2}$.

101.3 The Critical Modular Generator on a Common Carrier

The critical Bost–Connes generator acts on a different Hilbert space. By Chapter 77.2.4, its orthonormal basis and domain are

$$N_{\mathrm{BC}} v_{q,r} = \nu_{q} v_{q,r}, \qquad \nu_{q} = \tfrac{1}{2}\log q, \qquad (q, r) \in \mathbb{Q}_{>0} \times \mathbb{Q}/\mathbb{Z},$$
$$\operatorname{Dom} N_{\mathrm{BC}} = \Big\{ \sum c_{q,r} v_{q,r} : \sum \nu_{q}^{2} |c_{q,r}|^{2} < \infty \Big\}.$$

Every eigenvalue has infinite multiplicity. The simple occupation energies $\log m$ instead occur in the reducing space $K_{2} = \overline{\operatorname{span}}\{v_{m^{2},0} : m \geq 1\}$, as in Chapter 77.3.2.

Definition 101.3.1 *(Tensor comparison operators).* Define

$$\widetilde{\mathcal{K}} = L^{2}(\mathbb{R}, d\tau) \widehat{\otimes} \mathcal{H}_{1} = L^{2}\big(\mathbb{R}; \ell^{2}(\mathbb{Q}_{>0} \times \mathbb{Q}/\mathbb{Z})\big).$$

The joint multiplication operators are

$$(\widetilde{D}_{0} F)_{q,r}(\tau) = \tau F_{q,r}(\tau), \qquad (\widetilde{D}_{\mathrm{BC}} F)_{q,r}(\tau) = (\tau + \nu_{q}) F_{q,r}(\tau).$$

Each has its maximal multiplication domain. In particular,

$$\operatorname{Dom} \widetilde{D}_{\mathrm{BC}} = \left\{ F : \int_{\mathbb{R}} \sum_{q,r} |\tau + \nu_q|^2 |F_{q,r}(\tau)|^2 \, d\tau < \infty \right\}.$$

This operator is the closure of $M_\tau \otimes 1 + 1 \otimes N_{\mathrm{BC}}$ on finite channel Schwartz functions. The common tensor construction does not identify $\widetilde{\mathcal{K}}$ with an arithmetic quotient of $\mathcal{K}$.

Proposition 101.3.2 *(Tensor wave obstruction).* Both tensor operators are self-adjoint and purely absolutely continuous. The strong limits of $e^{it\widetilde{D}_{\mathrm{BC}}} e^{-it\widetilde{D}_{\mathrm{o}}}$, as $t \to +\infty$ or $t \to -\infty$, exist on precisely the closed subspace supported on $q = 1$. They equal the identity there.

Proof. The maximal multiplication argument in the preceding lemma applies on each channel. Finite channel truncations followed by smooth compact approximations converge in the graph norm of either operator, proving the assertion about closures. The spectral measure of F for $\widetilde{D}_{\mathrm{BC}}$ is the sum of the translated measures $|F_{q,r}(\lambda - \nu_q)|^2 d\lambda$, hence is absolutely continuous. The free case is identical without translation. On each channel the wave family is multiplication by $e^{it\nu_q}$. If this family converges on a vector, its projection onto any nonzero channel also converges. For $\nu_q \neq 0$, choose s with $e^{is\nu_q} \neq 1$. The norm of the difference at times $t + s$ and t is the nonzero constant $|e^{is\nu_q} - 1| \|F_{q,r}\|$, which contradicts convergence. Thus all such channels vanish. Since $\nu_q = 0$ exactly when $q = 1$, the remaining assertion follows. □

Remark 101.3.3 *(Transport and the zero divisor).* An isometry intertwining N_{BC} with a bounded operator cannot exist: the unit vectors $v_{q,r}$ have unbounded eigenvalues. An isometry intertwining it with D_{o} cannot exist either, since D_{o} has no eigenvectors. Abstract isomorphism of separable Hilbert spaces asserts neither intertwining property. The hypothetical zero-divisor operator of Chapter 77.4.1 requires its separately stated operator, domain, and determinant comparison. The tensor construction supplies none of those zero-divisor data.

101.4 Trace-Class Scattering

Definition 101.4.1 *(Wave operators).* For self-adjoint operators A_0, A_1 on one complex Hilbert space, write $P_{\mathrm{ac}}(A_j)$ for the absolutely continuous spectral projection. When the strong limits exist, define

$$W_{\pm}(A_1, A_0) = \operatorname*{s-lim}_{t \to \pm\infty} e^{itA_1} e^{-itA_0} P_{\mathrm{ac}}(A_0).$$

Completeness means that both ranges equal $P_{\mathrm{ac}}(A_1)\mathcal{H}$. In that case

$$S = W_+^* W_-$$

is unitary on $P_{\mathrm{ac}}(A_0)\mathcal{H}$.

Theorem 101.4.2 *(Trace-class scattering and spectral shift).* Let A_0 be self-adjoint and let $V = V^*$ be trace class. Set $A_1 = A_0 + V$ on $\operatorname{Dom} A_0$. The wave operators exist and are complete. There is a real $\xi \in L^1(\mathbb{R})$, with $\|\xi\|_1 \leq \|V\|_1$, such that for $h \in \mathscr{S}(\mathbb{R})$,

$$\operatorname{Tr}(h(A_1) - h(A_0)) = \int_{\mathbb{R}} h'(\lambda)\xi(\lambda) \, d\lambda.$$

In a direct-integral spectral representation of A_0 on its absolutely continuous subspace, S has unitary fibres $S(\lambda)$, with $S(\lambda) - 1$ trace class almost everywhere, and

$$\det S(\lambda) = e^{-2\pi i \xi(\lambda)} \quad \text{almost everywhere.}$$

The normalization of ξ is specified by

$$\Delta_V(z) = \det(1 + V(A_0 - z)^{-1}), \qquad \xi(\lambda) = \pi^{-1} \operatorname{Im} \log \Delta_V(\lambda + i0),$$

where the analytic logarithm in the upper half-plane tends to zero as $\operatorname{Im} z \to +\infty$.

These are the Kato–Rosenblum, Krein trace, and Birman–Krein scattering theorems with the sign convention of Chapter 101.1.1. The operator and logarithm hypotheses are recorded in Behrndt–Malamud–Neidhardt, pp. 2–3, equations (1.1)–(1.5); their Theorem 2.7, p. 15, also treats finite-deficiency self-adjoint extension pairs. The determinant relation by itself determines ξ only modulo integer-valued functions. It does not replace the normalized perturbation determinant.

PROPOSITION 101.4.3 *(A specified rank-one pair on the idele carrier).* On the Mellin realization of $\mathcal{K}$, choose $g \in C_c^\infty(\mathbb{R})$ with $\|g\|_2 = 1$, and $a \in \mathbb{R}$. Let $Q_g F = g \int \overline{g(\lambda)} F(\lambda)\, d\lambda$, and set

$$V_a = a Q_g \otimes P_0, \qquad D_a = D_0 + V_a, \qquad \operatorname{Dom} D_a = \operatorname{Dom} D_0.$$

This pair has complete wave operators. Its perturbation determinant is

$$\Delta_a(z) = 1 + a \int_{\mathbb{R}} \frac{|g(\lambda)|^2}{\lambda - z}\, d\lambda.$$

Almost everywhere, the scattering matrix is the identity on $(1 - P_0)E$ and is multiplication on $P_0 E$ by

$$s_a(\lambda) = \frac{\overline{\Delta_a(\lambda + i0)}}{\Delta_a(\lambda + i0)}.$$

The spectral shift is the boundary argument of Δ_a with exactly the preceding logarithm normalization.

Proof. The operator $Q_g \otimes P_0$ is an orthogonal projection of rank one. Hence V_a is bounded self-adjoint and trace class, with trace norm $|a|$. The general theorem applies. The rank-one determinant formula $\det(1 + u\ell) = 1 + \ell(u)$ gives the displayed determinant. On the complementary compact channels both dynamics are identical. The remaining channel has spectral multiplicity one for D_0, so its scattering fibre is its determinant. The Birman–Krein formula and $\xi_a = \pi^{-1} \arg \Delta_a(\lambda + i0)$ give the stated quotient. The boundary values and the quotient are understood almost everywhere, as in the general theorem. □

Remark 101.4.4 *(Finite truncations and trace ideals).* Any specified finite-rank self-adjoint perturbation of D_0 satisfies the same theorem. A limit requires its own trace-ideal estimate. For example, on orthonormal vectors u_j, the diagonal operator $\sum_j b_j |u_j\rangle\langle u_j|$ is trace class exactly when $\sum_j |b_j| < \infty$. Square summability gives only the Hilbert–Schmidt ideal. Neither a formal cutoff nor nuclearity between different Schwartz spaces proves this Hilbert trace-class condition. The functions g and coefficients a above have not been identified with the Bost–Connes generator.

101.5 Positivity of a Spectral-Shift Distribution

Theorem 101.5.1 *(The ordinary trace-class positivity obstruction).* Let $\xi \in L^1(\mathbb{R})$ be real, and define $T(h) = \int h'\xi$ on $\mathscr{S}(\mathbb{R})$. The following conditions are equivalent:

$$T(|h_f|^2) \geq 0 \quad (f \in \mathscr{A}), \qquad -d\xi \geq 0, \qquad \xi = 0 \text{ almost everywhere.}$$

In particular, a nonzero positive trace distribution cannot arise as the ordinary trace difference of a trace-class perturbation.

Proof. The map T is Schwartz-continuous, since $|T(h)| \leq \|\xi\|_1 \|h'\|_\infty$. Compactly supported smooth functions are dense in Schwartz space: for a Schwartz function f, multiplication by $\chi(u/R)$, where $\chi = 1$ near zero, converges to f in every Schwartz seminorm. Fourier transformation is a Schwartz isomorphism. Thus the first inequality implies $T(|g|^2) \geq 0$ for every $g \in \mathscr{S}$.

Let $\varphi \in C_c^\infty$ be nonnegative. Choose a nonnegative compact smooth function η equal to one on a neighborhood of $\operatorname{supp} \varphi$. The function $g_\varepsilon = (\varphi + \varepsilon\eta^2)^{1/2}$ is smooth: on a neighborhood of the support of φ its argument is positive, and outside that neighborhood it equals $\sqrt{\varepsilon}\eta$. It has compact support. Consequently $T(\varphi) + \varepsilon T(\eta^2) \geq 0$. Letting $\varepsilon \downarrow 0$ proves that $-d\xi$ is a positive distribution.

For a nonnegative smooth approximate identity ρ_ε, $\xi * \rho_\varepsilon$ is a real, nonincreasing, integrable smooth function. Such a function is zero: a positive value forces an infinite integral on its left, and a negative value forces one on its right. Hence $\xi * \rho_\varepsilon = 0$ for every ε, and convergence in L^1 gives $\xi = 0$. The reverse implications follow directly. □

Remark 101.5.2 *(The phase and its derivative).* For locally integrable ξ, its distributional derivative is defined on smooth compact tests by $\langle -d\xi, h\rangle = \int \xi h'$. It need not initially be a signed measure. Positivity makes it a positive measure and forces ξ to have a nonincreasing representative. The additional global L^1 condition in the theorem forces that measure to vanish. A regularized trace outside this class requires a separate theorem, including its test space and normalization.

101.6 Mellin Divisibility and Multiplication Phases

An ordinary Mellin integral near zero records the Taylor coefficients of an entire function as poles. This constrains a proposed divisibility by the entire completed xi-function before any zero-location argument is available.

Definition 101.6.1 *(The entire-Mellin test class).* Let PW_2 denote the entire functions of exponential type whose real restrictions belong to $L^2(\mathbb{R})$. Define $\mathrm{PW}^{\mathrm{TM}}$ to consist of its real even functions f for which the ordinary Mellin integral continues as

$$Mf(s) = \xi_{\mathbb{R}}(s)b(s), \qquad b(s) = \overline{b(1-\bar{s})},$$

where b is entire of exponential type and decreases faster than every inverse power on each closed vertical strip. Here $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ with its entire continuation. This Mellin integral uses $f(t)$ on $t > 0$; it is distinct from the Fourier transform of the logarithmic compact test algebra $\mathscr{A}$.

Theorem 101.6.2 *(Entire continuation forces the zero function).* If f is entire, $f|_{\mathbb{R}} \in L^2$, and its ordinary Mellin transform is entire, then $f = 0$. In particular, $\mathrm{PW}^{\mathrm{TM}} = \{0\}$.

Proof. The Mellin integral converges absolutely on $0 < \Re s < 1/2$. Near zero this follows from boundedness of f. At infinity, Cauchy–Schwarz applies because $\int_1^\infty t^{2\Re s-2}dt < \infty$. Both estimates are locally uniform on smaller strips, including logarithmic factors from differentiation, so the integral is holomorphic there. Write $a_n = f^{(n)}(0)/n!$. For each $N \geq 0$,

$$Mf(s) = \int_1^\infty f(t)t^{s-1}dt + \int_0^1 \left(f(t) - \sum_{n=0}^{N} a_n t^n\right)t^{s-1}dt + \sum_{n=0}^{N} \frac{a_n}{s+n}.$$

The first integral is holomorphic for $\Re s < 1/2$. The Taylor remainder makes the second holomorphic for $\Re s > -N - 1$. The residue at $s = -n$ is therefore a_n. Entire continuation forces every coefficient to vanish. The identity theorem gives $f = 0$. The divisibility condition makes Mf entire, proving the final assertion. □

Remark 101.6.3 *(Zeros and the test topology).* The completed xi-function vanishes at all nontrivial zeros, with multiplicity. It does not vanish at the trivial zeros of ζ, where gamma poles cancel those zeros. The zero-class theorem uses neither this divisor nor RH. It implies nondensity of $\mathrm{PW}^{\mathrm{TM}}$ in every nonzero normed PW_2 space. A measure-zero condition on values of a transform, by itself, would not imply nondensity in an L^2 topology.

Functional equations and wave limits

PROPOSITION 101.6.4 *(The completed functional-equation ratio).* The meromorphic ratio

$$\frac{\xi_{\mathbb{R}}(1/2 + iz)}{\xi_{\mathbb{R}}(1/2 - iz)}$$

has the removable continuation 1 on $\mathbb{C}$. For an entire function of real type, $b(\bar{s}) = \overline{b(s)}$, the ratio $b(1/2 + it)/b(1/2 - it)$ has modulus one wherever defined. The distinct symmetry $b(s) = \overline{b(1 - \bar{s})}$ alone does not imply this modulus identity.

Proof. The functional equation $\xi_{\mathbb{R}}(s) = \xi_{\mathbb{R}}(1 - s)$ identifies numerator and denominator as entire functions, including their zero orders. The real-type assertion follows by complex conjugation. For the last assertion take $b(s) = 1 + i(s - 1/2)$. It has the stated reflection symmetry, whereas the ratio on the critical line is $(1 - t)/(1 + t)$. This example tests the algebraic implication of that symmetry; it is not an element of the entire-Mellin test class. □

PROPOSITION 101.6.5 *(Multiplication perturbations).* Let $v : \mathbb{R} \to \mathbb{R}$ be measurable and finite almost everywhere. On $L^2(\mathbb{R})$, give M_λ and $M_{\lambda+v(\lambda)}$ their maximal domains. Their ordinary wave operators exist on the full free space if and only if $v = 0$ almost everywhere.

Proof. The wave family is $M_{e^{itv}}$. If it converges strongly, then for every real s and every $g \in L^2$,

$$\|(e^{isv} - 1)g\| = \|e^{i(t+s)v}g - e^{itv}g\| \longrightarrow 0.$$

Thus $e^{isv} = 1$ almost everywhere for every rational s. The intersection of these countably many full-measure sets forces $v = 0$. The converse follows because the two operators coincide. □

A functional-equation ratio therefore needs a separately constructed scattering realization. Replacing D_0 by multiplication by $\tau + \frac{1}{2}\arg \xi_{\mathbb{R}}(1/2 + i\tau)$ does not supply one unless that perturbation vanishes almost everywhere.

101.7 Arithmetic Trace Carriers

Definition 101.7.1 *(The adele quotient and a Hilbert seminorm).* The adele class space is the quotient $X_{\mathbb{Q}} = \mathbb{A}/\mathbb{Q}^{\times}$. Let $\mathscr{S}(\mathbb{A})$ be the Bruhat–Schwartz space for the additive adeles, with self-dual additive Haar measure. Put

$$\mathscr{S}(\mathbb{A})_0 = \{\phi : \phi(0) = 0,\ \int_{\mathbb{A}} \phi(x)dx = 0\}, \qquad (E\phi)(x) = |x|^{1/2} \sum_{q\in\mathbb{Q}^{\times}} \phi(qx).$$

For $\delta > 1$, give this space the seminorm

$$\|\phi\|_{\delta}^2 = \int_{C_{\mathbb{Q}}} |E\phi(x)|^2 (1 + \log^2 |x|)^{\delta/2}\, d^{\times}x.$$

Quotient by its nullspace and complete. This is the Hilbert construction in Connes, *Trace formula in noncommutative geometry and the zeros of the Riemann zeta function*, §III, (6)–(19), pp. 10–12. Write $L^2_{\delta}(C_{\mathbb{Q}})$ for the weighted target space with measure $(1 + \log^2 |x|)^{\delta/2} d^{\times}x$. The completed map E is isometric and has closed image. Its cokernel $H_{\delta} = L^2_{\delta}(C_{\mathbb{Q}})/\operatorname{im} E$ carries the quotient of $V(a)\eta(x) = \eta(a^{-1}x)$. The identity $EU(a) = |a|^{1/2}V(a)E$, for $U(a)\phi(x) = \phi(a^{-1}x)$, makes the image invariant. The weighted norm-direction representation is polynomially bounded, not asserted to be unitary. The quotient generator in Connes's convention is the derivative of $V(e^t)$; its critical-zero spectral values are imaginary. This is distinct from the self-adjoint free generator on unweighted $L^2(C_{\mathbb{Q}})$.

Proposition 101.7.2 *(Scope of the critical-zero realization).* In the quotient representation on H_{δ}, Connes's §III, Theorem 1, p. 13, realizes the zeros on the critical line in each norm-one character sector. For $\delta > 1$, the multiplicity of a critical zero of multiplicity m is the largest integer n satisfying $n < (1 + \delta)/2$ and $n \le m$. Its Corollary 2 gives the trace of integrated Schwartz operators with these multiplicities. This theorem is a critical-zero realization, not a self-adjoint realization of every nontrivial zero.

Meyer's *On a representation of the idele class group related to primes and zeros of L-functions*, Theorems 5.8 and 5.11, pp. 43 and 47, uses a different carrier: a smooth summable virtual representation $\pi_+ \ominus \pi_-$. Its character is the raw Weil distribution, with poles and zeros having opposite signed multiplicities. His §3.2, p. 17, descends suitable equivariant operators to weighted idele-class spaces. His Proposition 4.4, p. 26, gives Schwartz restriction and Fourier maps. These statements specify neither a bounded transport of N_{BC} nor the perturbation of an idele scaling operator. Passing between the raw character and $W = P - W_{\infty} - W_{\mathrm{fin}}$ requires the central twist, sign, and test-function normalization.

101.8 The Full Signed Trace Comparison

Theorem 101.8.1 *(Transfer on the specified arithmetic test algebra).* Suppose independently specified self-adjoint operators A_0, $A_1 = A_0 + V$, with $V = V^*$ trace class, satisfy

$$W(f) = \operatorname{Tr}(h_f(A_1) - h_f(A_0)) \qquad (f \in \mathscr{A}).$$

Then, for their normalized spectral shift ξ,

$$W(f * f^*) = \int_{\mathbb{R}} (|h_f|^2)'(\lambda)\xi(\lambda)d\lambda.$$

If this form is nonnegative on all $\mathscr{A}$, the trace functional vanishes on every Schwartz spectral test. In particular, a nonzero positive Weil functional cannot have this ordinary trace-class realization.

Proof. Apply the stipulated identity to $f * f^*$, use $h_{f*f^*} = h_f h_f^\sharp$, and apply the trace formula. The positivity obstruction forces $\xi = 0$, which makes the trace formula zero for every Schwartz function. Under Weil positivity, RH holds by Chapter 78.2.1. The zero-side formula then is a sum of $|h_f(\gamma_\rho)|^2$. It is nonzero for some f: choose a nontrivial zero ordinate γ_0, a compact smooth ϕ of integral one, and $f(u) = e^{-i\gamma_0 u}\phi(u)$. The term at γ_0 is positive, and the other terms are nonnegative. Existence of nontrivial zeros is part of Chapter 77.5.1. This contradicts vanishing and proves the last assertion. □

Remark 101.8.2 *(Required arithmetic data).* The trace identity in the theorem is additional arithmetic data. Trace-class estimates, wave completeness, and a functional equation do not imply it. A proposed regularized replacement must specify its carrier, scaling action, dense test domain, subtraction terms, and trace functional before imposing equality with W. If it uses Bost–Connes data, it must also construct the map from $\mathcal{H}_1$, or its stated occupation restriction, and prove which domains and operations that map preserves. Nuclear characters on locally convex spaces and Hilbert trace differences are distinct constructions.

PROPOSITION 101.8.3 *(Independent conditions on an arithmetic trace).* Let $\mathcal{T} : \mathscr{A} \to \mathbb{C}$ be a linear distribution obtained from a specified arithmetic trace construction. If $\mathcal{T}(f) = W(f)$ for every $f \in \mathscr{A}$, then $\mathcal{T}(f * f^*) \geq 0$ for every f is equivalent to A-TP, and hence to RH. Existence of $\mathcal{T}$, the comparison identity, and this positivity condition are separate requirements. The tensor and multiplication constructions above fail the wave requirement; the rank-one construction satisfies it but supplies no arithmetic trace identity.

Proof. Substitute $f * f^*$ in the stated identity and apply the Weil positivity criterion on $\mathscr{A}$. The final assertions are the tensor wave obstruction, the multiplication proposition, and the explicit rank-one construction, respectively. □

Remark 101.8.4 *(Comparison with the other analytic formulations).* The bounded-interval digamma inequality and the restricted automorphic comparison concern the same full signed distribution only when their stated test maps and residual terms agree with $P - W_\infty - W_{\mathrm{fin}}$. A scattering comparison additionally needs the trace identity above. Connes's cutoff trace and Meyer's virtual character supply precise alternative trace settings; neither is identified here with the critical BC generator by a unitary map. The non-Hausdorff quotient alone proves no impossibility theorem for other Hilbert realizations.

101.9 CONSEQUENCES FOR THE ARITHMETIC REALIZATION PROBLEM

THEOREM 101.9.1 *(Scaling and scattering constructions).* The idele scaling operator has the self-adjoint domain and Mellin realization specified above. Coupling it by tensor addition to the full critical BC generator gives self-adjoint dynamics but no full ordinary wave operators. Specified finite-rank perturbations do have complete scattering; their unitary matrices do not imply positivity of the trace difference. The ordinary entire-Mellin class $\mathrm{PW}^{\mathrm{TM}}$ is zero. A nonzero positive Weil trace therefore requires a construction beyond the ordinary trace-class comparison stated here, with its arithmetic test identity and positivity proved on all of $\mathscr{A}$.

Proof. Apply the Mellin-domain lemma, the tensor wave obstruction, the rank-one pair and signed-trace propositions, the entire-Mellin vanishing theorem, and the trace-comparison theorem. □

Remark 101.9.2 *(Arithmetic comparison problem).* An arithmetic BC comparison must realize $W = P - W_\infty - W_{\mathrm{fin}}$ on $\mathscr{A}$. Positivity of this trace is the full Weil condition.

Chapter 102

All-Genus Arithmetic Koszul Duality

The genus-zero arithmetic comparison concerns the identity $\kappa_{\mathsf{G}}^{\mathrm{Ar}} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar}} = 0$ and the Riemann functional equation $\xi(s) = \xi(1-s)$. The object $\mathcal{V}^{\mathrm{prim}}$ is the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2. Interpreting its levels requires the arithmetic realization in Theorem 43.5.1.

That theorem assumes a Mellin evaluation, a central-defect identity, and detection of the defect. Poisson summation and Satake parameters do not supply these maps. For rank $2g$, the corresponding question asks which internal identity has the motivic functional equation's sign and normalization.

The conditional answer is the same identity $\kappa_{\mathsf{G}}^{\mathrm{Ar},g} + (\kappa^{!})_{\mathsf{G}}^{\mathrm{Ar},g} = 0$, after the residual inputs of Chapter 102.6 are imposed. The genus does not deform the Koszul sum; it enters as the rank of the Heisenberg oscillators at each place, the archimedean Γ-factor $\Gamma_{\mathbb{C}}(s)^g$, and the motivic weight fixing the functional-equation center.

102.1 The Arithmetic Genus-g Datum

Definition 102.1.1 *(arithmetic genus-g datum).* . An *arithmetic genus-g datum* $\mathcal{D}_g$ is a triple $(\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$ specifying:

(i) $\mathcal{B}_g$, an arithmetic base: one of

   a) Arakelov-compactified $\overline{\operatorname{Spec} \mathcal{O}_K}$ for K totally imaginary of degree $2g$ (Window II);

   b) a proper flat regular arithmetic surface $X \to \operatorname{Spec} \mathcal{O}_K$ whose generic fibre X_K is a smooth projective curve of genus g, Arakelov-compactified via the archimedean Kähler form $\mu_{\mathrm{Ar},g}$ of Faltings 1984 (Windows I, V);

   c) a Shimura variety $\mathrm{Sh}_K(G, X)$ of a Shimura datum whose complex fibre is a moduli of abelian g-folds (Window VI).

(ii) $\mathcal{E}_g$, a rank-$2g$ arithmetic cohomology object: $H^1_{\mathrm{prim}}(\mathcal{B}_g)$ carrying Galois action (étale or crystalline), with Hodge structure of weight 1 at each archimedean place: $\mathcal{E}_g \otimes \mathbb{C} = \mathcal{E}_g^{1,0} \oplus \mathcal{E}_g^{0,1}$ with $\dim \mathcal{E}_g^{1,0} = \dim \mathcal{E}_g^{0,1} = g$ per place.

(iii) φ_g, a Frobenius-compatible endomorphism on $\mathcal{E}_g$ with square equal to the appropriate motivic involution: φ_g is either

   a) the archimedean Frobenius Φ_∞ of Deninger 1998 acting on the primitive Minkowski cohomology (Window II);

   b) the prismatic Frobenius φ of Bhatt–Scholze 2022 on the universal rank-$2g$ F-crystal over the ordinary crystalline locus of the Emerton–Gee stack $\mathcal{X}_{2g}$ (Window III);

   c) the Koszul duality operator J^{Koz} on chiral cohomology satisfying $(J^{\mathrm{Koz}})^2 = \tau$ for τ the motivic functional-equation involution (Window V).

At $g = 0$ the datum degenerates to the base $\overline{\operatorname{Spec}\mathbb{Z}}$ with $\mathcal{E}_0$ void and $\varphi_0 = \mathrm{id}$. The proposed scalar functional equation is then $\xi(s) = \xi(1-s)$, as in Theorem 43.5.1. Its arithmetic interpretation still requires that theorem's evaluation and detection hypotheses.

Remark 102.1.2 *(Frobenius as almost-complex substitute).* An endomorphism $J : TX \to TX$ satisfying $J^2 = -\mathrm{id}$ cannot exist on an arithmetic scheme: schemes over $\operatorname{Spec}\mathbb{Z}$ carry no real tangent bundle, and on a compact real 2-manifold Newlander–Nirenberg (1957) makes integrability of J automatic, so no genuinely almost-complex geometry survives. The Frobenius φ_g of Chapter 102.1.1 is the correct arithmetic substitute: on archimedean primitive cohomology it acts as Hodge rotation by $\pi/2$; on the prismatic F-crystal ordinary stratum it is the Newton–Hodge-polygon-aligned slope-decomposition Frobenius (Katz 1981, *Astérisque* 63); on chiral cohomology it is the Koszul duality operator J^{Koz} whose square equals the functional-equation involution τ. No non-integrable decoration is introduced.

102.2 Six Convergent Windows

The datum $\mathcal{D}_g$ admits six distinct geometric and automorphic presentations, each extracting a different structural feature of the rank-$2g$ arithmetic cohomology and the corresponding motivic functional equation.

Window I: Arakelov fibration

$\mathcal{B}_g^{\mathrm{I}} = X \to \operatorname{Spec} O_K$, proper flat regular with generic fibre of genus g, Arakelov-compactified. $\mathcal{E}_g^{\mathrm{I}} = H^1_{\mathrm{B}}(X(\mathbb{C}),\mathbb{Z})$ of rank $2g$ per archimedean place. φ_g^{I} the integrable complex structure J_∞ at each archimedean place. Arakelov 1974, Faltings 1984, Gillet–Soulé 1990 (Publ. IHES) supply the arithmetic intersection pairing on $\widehat{\mathrm{CH}}^1(X)$; Faltings–Hriljac 1984 the arithmetic Hodge index. Genus g enters via $\pi_*\omega_{X/S}$ of rank g, the Γ-factor $\Gamma_{\mathbb{C}}(s)^g$ of the Hasse–Weil L-function, the coefficient $2g-2$ in $\deg \omega_{X_K/K}$, and the δ-invariant correction in the arithmetic Noether formula $\widehat{\deg}\det R\pi_*\omega = \frac{1}{12}(\widehat{\omega}^2 + \delta_{\mathrm{Ar}})$ (Faltings 1984, Thm 5).

Window II: Minkowski torus / Bost–Connes–Marcolli

$\mathcal{B}_g^{\mathrm{II}} = \overline{\operatorname{Spec} O_K}$ for K totally imaginary of degree $2g$, with Minkowski lattice $\Lambda_K = j(O_K) \subset \mathbb{C}^g$ and Minkowski torus $T_K = \mathbb{C}^g/\Lambda_K$. This complex torus is an abelian variety only after choosing a CM type and a polarization satisfying the Riemann bilinear relations. $\mathcal{E}_g^{\mathrm{II}} = H^1(T_K,\mathbb{Z}) \cong \Lambda_K^\vee$ of $\mathbb{Z}$-rank $2g$; the primitive part equals the full H^1 only in that polarized abelian-variety subcase. $\varphi_g^{\mathrm{II}} = \Phi_\infty^{\mathrm{tw},K}$, the half-Tate-twisted archimedean Frobenius acting as $\sqrt{-1}$ on each complex embedding pair; equivalently the $\mathbb{C}^g$-structure on $\Lambda_K \otimes \mathbb{R}$. The genus is $g = r_2(K) = \frac{1}{2}[K:\mathbb{Q}]$. Bost–Connes–Marcolli 2004 (*Selecta Math.* 11) constructs the C_K^* quantum statistical system whose KMS_β partition function is $\zeta_K(\beta)$; Ha–Paugam 2005 and Laca–Neshveyev 2011 classify its KMS states.

Window III: Ordinary crystalline Emerton–Gee stack

$\mathcal{B}_g^{\mathrm{III}} = \mathcal{X}_{2g}^{\mathrm{crys,ord}}$, the ordinary crystalline locus of the Emerton–Gee stack $\mathcal{X}_{2g}$ (Emerton–Gee arXiv:1908.07185). Its dimension depends on the rank, the residual representation, and the imposed crystalline type; it is not a universal 2-dimensional Artin stack. A point in the ordinary crystalline stratum is a rank-$2g$ crystalline object with Hodge–Tate multiset $\{0,1\}^g$, together with the chosen ordinary filtration. $\mathcal{E}_g^{\mathrm{III}}$ is the universal rank-$2g$ bundle; φ_g^{III} is Frobenius together with this filtration. The analogy with $H^1(X(\mathbb{C}),\mathbb{C}) = H^{1,0} \oplus H^{0,1}$ is a Hodge analogy, not an archimedean tilting

theorem. Caraiani–Scholze supplies Shimura-variety Galois representations under its own genericity and signature hypotheses; it does not produce this rank-$2g$ window for all genus-g data.

Window IV: Hodge–Arakelov / arithmetic Teichmuller

$\mathcal{B}_g^{\mathrm{IV}} = [C, \vartheta] \in \mathcal{T}_g^{\mathrm{arith}}(\mathcal{O}_K)$, a closed point of the arithmetic Teichmüller space carrying a level-n theta-structure ϑ on the Jacobian $J(C)$. $\mathcal{E}_g^{\mathrm{IV}}$ is the n^g-dim Jet module over the theta-structure locus; φ_g^{IV} is Mochizuki's Hodge–Arakelov comparison isomorphism (Mochizuki 1999 *Publ. RIMS*; arXiv:math/0304054). The comparison is theorem-grade for $g = 1$; conjectural for $g \geq 2$. The Steinberg relation $\{p, 1-p\} = 0 \in K_2^M(\mathbb{Q})$ is preserved under every Frobenioid indeterminacy (anabelian invariant via Matsumoto 1969, Milnor 1970). The naïve speculation conflates the crystalline–étale comparison isomorphism with an almost-complex structure J on Spec $\mathbb{Z}$; the correct arithmetic object is the Hodge–Arakelov decoration φ_g^{IV} on the dense theta-generic open locus of $\mathcal{T}_g^{\mathrm{arith}}$ (Chapter 102.1.2).

Window V: E_2-chiral factorisation on the arithmetic surface

$\mathcal{B}_g^{\mathrm{V}} = \mathcal{S}_g^{\mathrm{Ar}}$, the arithmetic surface of Window I viewed through its E_2-chiral factorisation structure. $\mathcal{E}_g^{\mathrm{V}} = \mathcal{V}^{\mathrm{prim,surf},g} := \mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw,surf}}_{GL_{2g},\mathrm{glob}})$, the Hochschild trace class of the identity on the E_2-monoidal global Iwahori–Hecke category of GL_{2g} on the arithmetic surface. The E_2 structure arises via $E_1 \otimes E_1 = E_2$ Dunn additivity (Lurie *Higher Algebra* 5.1.2.2) from the horizontal E_1 (1-dim base factorisation on $\overline{C}$) and the vertical E_1 (fibre factorisation on X_K); the bar-cobar construction on this E_2 datum lifts to the 2-dim Parshin–Gersten complex with double residue (∂_1, ∂_2) (Parshin 1976; Kato 1980; Beilinson 1980). $\varphi_g^{\mathrm{V}} = J^{\mathrm{Koz}}$, the Koszul duality operator on chiral cohomology with $(J^{\mathrm{Koz}})^2 = \tau$ (the functional-equation involution). The genus enters via rank-$2g$ Fock oscillators per place, sourced from the ℓ-adic Tate module $T_\ell(\mathrm{Jac}(X_K))$; the holomorphic central charge is $c = g$, with g additional antiholomorphic oscillators, giving total Fock rank $2g$.

Window VI: Kudla–Rapoport / Shimura–Siegel Shimura variety

$\mathcal{B}_g^{\mathrm{VI}} = \mathrm{Sh}_K(G, X)$ a Shimura variety with $G \in \{\mathrm{GSp}_{2g}, \mathrm{Res}_{F/\mathbb{Q}}\mathrm{GL}_2 \text{ for } [F:\mathbb{Q}] = g, \mathrm{GU}(g,1)\}$. $\mathcal{E}_g^{\mathrm{VI}}$ the middle-degree cohomology decomposed under the Hecke algebra into rank-$2g$ (or $2g+1$, $4g$) Galois blocks per automorphic π of $G(\mathbb{A})$. φ_g^{VI} the integrable complex structure sourced from the Deligne torus $h : \mathbb{S} \to G_{\mathbb{R}}$. The Kudla–Rapoport generating series $\widehat{\phi}(\tau) = \sum_m \widehat{\mathcal{Z}}(m) q^m$ is a genus-g Siegel modular form valued in $\widehat{\mathrm{CH}}^1(\mathrm{Sh})_{\mathbb{C}}$ (Kudla 1997 *Ann. Math.* 146; Kudla–Rapoport 2011 *Algebra Number Theory* 5; Li–Liu 2021 arXiv:2101.09485). The g-fold arithmetic intersection of special cycles realises Fourier coefficients of a genus-g Siegel Eisenstein series' central derivative. The Langlands-dual group ${}^L G = \mathrm{GSpin}_{2g+1}$ carries a $(2g+1)$-dimensional standard representation and a 2^g-dimensional spin representation. The row below uses the standard L-function unless the spin representation is explicitly named.

102.3 Obstructed Candidate Readings

Six candidate readings of the phrase "genus-g arithmetic surface with almost-complex structure" meet distinct mathematical obstructions; the obstructions are recorded in Chapter B.7.

(i) $J^2 = -\mathrm{id}$ *on the tangent bundle of an arithmetic scheme.* Schemes over Spec $\mathbb{Z}$ carry no real tangent bundle; the phrase "almost-complex" is a category error at this level. The correct arithmetic substitute is the Frobenius φ_g on primitive cohomology (Chapter 102.1.2).

(ii) *Arithmetic Euler characteristic* $= 1 - g$. Gillet–Soulé 1992 arithmetic Riemann–Roch introduces Bismut–Gillet–Soulé analytic torsion; the arithmetic analog of $1 - g$ is the Faltings δ-invariant via the arithmetic Noether formula, not a simple integer.

(iii) *Künneth factorisation of the arithmetic surface.* Bost–Künnemann 2010 (*Adv. Math.* 223) shows the product formula has non-vanishing Bott–Chern archimedean correction terms; X does not factor as "genus-g curve $\times_{\operatorname{Spec}\mathbb{Z}} \operatorname{Spec}\mathbb{Z}$" in arithmetic Chow.

(iv) $\overline{\operatorname{Spec}\mathbb{Z}}$ *itself has finite genus.* Deninger's arithmetic-dynamical genus of $\operatorname{Spec}\mathbb{Z}$ is $+\infty$ (countably many critical zeros of ζ). Genus enters the arithmetic datum only through coefficient enhancement to a totally imaginary number field of degree $2g$.

(v) *Conflation of curve-genus g_c with Siegel-modular genus g_s.* For a modular curve $X_0(N)$: $g_c = g_0(N)$ and $g_s = 1$. For the Siegel threefold $\mathcal{A}_2$: g_c is undefined, $g_s = 2$. The genus g of the datum $\mathcal{D}_g$ is the symplectic rank of the Galois representation divided by 2; in the Shimura setting this is g_s, not g_c.

(vi) $\kappa + \kappa^! = 2 - 2g$ *as Euler-characteristic shift.* The Euler characteristic $2 - 2g$ is a topological invariant of the Riemann surface $X(\mathbb{C})$, not a Koszul invariant of the chiral datum. The identity $\kappa^{\mathrm{Ar},g} + (\kappa^!)^{\mathrm{Ar},g} = 0$ is the conditional Koszul-duality target at rank g; the genus enters through the Fock rank, the archimedean Γ-factor, and the motivic weight of the functional-equation center.

102.4 All-Genus Arithmetic Koszul Duality

Let $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$ be an arithmetic genus-g datum (Chapter 102.1.1). Attach to $\mathcal{D}_g$ the arithmetic Heisenberg $\mathcal{V}_{\mathrm{Heis}}^{\mathrm{prim},g}$ via the rank-$2g$ Fock on $\mathcal{E}_g$ at each place, and the Koszul dual via the genus-g Bost–Connes–Marcolli system of Consani–Marcolli 2006 (*J. Reine Angew. Math.* 597).

THEOREM 102.4.1 *(all-genus arithmetic Koszul duality). (on the residual conditions of Chapter 102.6).* For every $g \geq 0$ and every arithmetic genus-g datum $\mathcal{D}_g$, the arithmetic Heisenberg Koszul self-duality identity

$$\kappa_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) = 0$$

reproduces the normalization and sign of the motivic functional equation

$$\Lambda_{\mathcal{D}_g}(s) = \epsilon_{\mathcal{D}_g} \cdot \Lambda_{\mathcal{D}_g}\big(w_{\mathcal{D}_g} - s\big), \tag{102.1}$$

where $\Lambda_{\mathcal{D}_g}(s)$ is the completed L-function attached to $\mathcal{D}_g$ and $w_{\mathcal{D}_g}$ is the center parameter in the chosen motivic or automorphic normalisation, depending on the window but not on g alone. This statement does not derive analytic continuation or the functional equation from Koszul data alone. It is conditional on the Euler-product identification for the chosen datum, the appropriate genus-g Bost–Connes–Marcolli or Shimura input, the analytic continuation and functional equation of $\Lambda_{\mathcal{D}_g}$, the 2-dimensional arithmetic Positselski equivalence at $\Lambda_2 = \mathbb{Z}_p[[\Gamma_1 \times \Gamma_2]]$-coefficients (Window V), and Koszul–Petersson compatibility at rank g.

The four rows of (102.1), indexed by window, are recorded in Chapter 102.1.

Remark 102.4.2 *(weight structure).* The functional-equation center $w_{\mathcal{D}_g}$ is set by the motivic weight of the row, not by g itself. Window II (Dedekind ζ_K with archimedean $\Gamma_{\mathbb{C}}^g$ factor) is weight 0; the center stays at $s \mapsto 1 - s$ regardless of g, since ζ_K for K of degree $2g$ has the same $1 - s$ symmetry as ζ for any number field. Windows I, V (arithmetic surface with generic fibre of genus g) are weight 1 on the

Table 102.1: Rows of the all-genus arithmetic Koszul duality.

Window	$\Lambda_{\mathcal{D}_g}(s)$	$w_{\mathcal{D}_g}$	Motivic weight
II	$\xi_K(s) = \lvert d_K\rvert^{s/2}\Gamma_{\mathbb{C}}(s)^g\zeta_K(s)$	1	0 (Dedekind)
I, V	$\Lambda(s, X_K) = N_{X_K}^{s/2}\Gamma_{\mathbb{C}}(s)^g L(s, X_K)$	2	1 (Hasse–Weil)
VI	$\Lambda(s, \pi, \text{spin})$ for π on GSp_{2g}	$w_{\pi,\text{spin}}$	fixed by the chosen spin L-normalisation
III, IV	spectral refinements	indirect	refines above

Jacobian's H^1-motive; the center is $s \mapsto 2 - s$. Window VI (Siegel spin of genus-g cusp form) has centre determined by the chosen cohomological spin normalisation; the table records it as $w_{\pi,\text{spin}}$, not as a universal integer. All three rows share $\kappa + \kappa^! = 0$; the genus grading lives in the Γ-factor, the Fock rank, and the weight of the row.

Sketch. The following construction requires the stated comparison inputs. At $g = 0$, the arithmetic level criterion is Theorem 43.5.1, including its Mellin evaluation and detection hypotheses.

Step 1: Euler-product identification. Assume that at each prime p of good reduction for $\mathcal{D}_g$, writing $\alpha_1^{(p)}, \dots, \alpha_{2g}^{(p)}$ for the Frobenius eigenvalues on $\mathcal{E}_{g,p}$, the rank-$2g$ Heisenberg Fock partition function at inverse temperature $\beta = s$ factors as $\prod_{j=1}^{2g}(1 - \alpha_j^{(p)}p^{-s})^{-1} = \det(1 - p^{-s}\varphi_g|\mathcal{E}_{g,p})^{-1}$. The global Euler product (over primes of good reduction, with local factors at bad primes defined as in Serre 1970) gives $\Lambda_{\mathcal{D}_g}(s)$ in the respective window.

Step 2: Consani–Marcolli genus-g Koszul dual. Consani–Marcolli 2006 (*J. Reine Angew. Math.* 597) constructs the rank-$2g$ Bost–Connes–Marcolli system with KMS partition function $\zeta_K(\beta)$ in the number-field row. Identifying the Koszul dual of $\mathcal{V}_{\text{Heis}}^{\text{prim},g}$ with the row $\Lambda_{\mathcal{D}_g}$ outside that row is part of the residual input.

Step 3: rank-g Positselski pairing. Arithmetic Positselski (Positselski 2011 Mem. AMS 996; Chapter 46) at rank g, extended to Λ_2-coefficients for Window V. Pairs the bar coalgebra of the rank-$2g$ Heisenberg with the cobar algebra of the genus-g Bost–Connes system; total weight vanishes modulo the 2-dim μ-invariant vanishing condition (extending Ferrero–Washington 1979 *Ann. Math.* 109 for abelian at rank 1).

Step 4: adelic Fourier symmetry $s \mapsto w_{\mathcal{D}_g} - s$. Tate 1950 at $g = 0$ (Window II with $K = \mathbb{Q}$); Weil 1967 *Basic Number Theory* for totally imaginary base (Window II general); Bloch–Kato 1990 and Fontaine–Perrin-Riou 1994 for weight-1 motives on Jacobians (Windows I, V); and the automorphic theory available for the chosen Siegel or unitary datum (Window VI) are the inputs. Where these inputs do not give analytic continuation and the functional equation, they are part of the residual condition.

No step in the all-genus row is promoted to an unconditional theorem by this chapter. The result is a conditional reduction of the Koszul self-duality identity to the named Euler-product, functional-equation, and Positselski inputs. □

102.5 Reduction to $g = 0$ and the F-RH Axis

At $g = 0$:

- Window II: $K = \mathbb{Q}$, $\xi_K(s) = \xi(s)$, $\Gamma_{\mathbb{C}}(s)^0 = 1$, $\zeta_K = \zeta$. Functional equation $\xi(s) = \xi(1 - s)$.
- Windows I, V: $X_K = \mathbb{P}^1/K$, Jacobian trivial, $\Lambda(s, X_K)$ degenerates to $\xi(s)$ with center $s \mapsto 1 - s$; the weight-1 motive is void and the weight-0 Dedekind row takes over.

- Window VI: $\mathcal{A}_0 = \mathrm{pt}$, Siegel spin L-function collapses to ζ, center $s \mapsto 1 - s$.

At the level of the displayed scalar character, these specializations are intended to give $\xi(s) = \xi(1 - s)$. Recovering the arithmetic criterion of Theorem 43.5.1 additionally requires its central-defect and evaluation maps. A scalar specialization does not construct them.

COROLLARY 102.5.1 *(all-genus F-RH). (on Chapter 102.4.1 plus rank-g extensions of the P2, P3, VB pillars of Chapter 44).* For every $g \geq 0$ and every arithmetic genus-g datum $\mathcal{D}_g$ with rank-g Koszul–Petersson compatibility, a rank-g completed L-character, and a positive Hilbert–Pólya–Li trace, the non-trivial zeros of $\Lambda_{\mathcal{D}_g}(s)$ lie on the self-dual locus $\mathrm{Re}(s) = w_{\mathcal{D}_g}/2$.

Remark 102.5.2 *(specialisations).* Chapter 102.5.1 has as special cases the zero-placement clauses for the Riemann zeta function ($g = 0$, Window II), Hasse–Weil L-functions of Jacobians (Windows I,V), Dedekind zeta functions of totally imaginary fields (Window II at higher g), and Siegel-spin L-functions of cusp forms on $\mathrm{GSp}_{2g}(\mathbb{A}_{\mathbb{Q}})$ (Window VI). Each case still requires its rank-g spectral positivity input.

102.6 Residual Conditions

Chapter 102.4.1 reduces to ten residual conditions, each extending a Chapter-level $g = 0$ result to arbitrary g.

(i) *2-dim arithmetic Positselski equivalence* with $\mu_1 = \mu_2 = 0$ on $\Lambda_2 = \mathbb{Z}_p[[\Gamma_1 \times \Gamma_2]]$, extending Chapter 46. Condition: non-formal theorem. Precedents: Nekovář 2006 (Astérisque 310); Coates–Sujatha 2006 *Cyclotomic Fields and Zeta Values*.

(ii) *Rank-g Koszul–Petersson compatibility* replacing the scalar Petersson inner product with the genus-g Petersson pairing on weight-(k, g) automorphic forms, extending Chapter 47. It is a non-formal theorem.

(iii) *2-dim Parshin–Gersten bar construction* on the arithmetic surface with double residue (∂_1, ∂_2), extending Chapter 33. It is a non-formal theorem. Precedents: Parshin 1976, Kato 1980, Beilinson 1980.

(iv) *Rank-g arithmetic Ben-Zvi–Nadler* with target stack Σ_g^{Ar} replacing $B\widehat{\mathbb{Z}}$, extending Chapter 49. It is a non-formal theorem.

(v) *GL_{2g}-local geometric Langlands.* Fargues–Scholze arXiv:2102.13459 supplies the spectral action in broad reductive generality, while Emerton–Gee arXiv:1908.07185 is the GL_n Galois deformation-stack input. The categorical comparison at GL_{2g} is not a formal corollary of either source; it is the rank-g scaling of Chapter 42.1.1. Domain: determined by F1 scaled to rank $2g$.

(vi) *Perfectoid E_2-enhancement at rank g* via BD Grassmannians for $GL_{2g}/\mathbb{Q}_p$, extending F2 (Chapter 42.2.1). It is a non-formal theorem.

(vii) *Rank-g arithmetic Virasoro bootstrap* with central charge $c^{\mathrm{Ar},g} = g$ on the primary subspace of the rank-g archimedean Fock, extending Chapter 45. It is a non-formal theorem.

(viii) *Arithmetic Siegel–Weil at bad primes for $g \geq 3$*, extending Li–Liu 2021 arXiv:2101.09485. It is a non-formal theorem.

(ix) *Harder-Eisenstein-congruence prime at genus g* replacing $p = 691$ in F6 (Chapter 42.4.4). Systematic tabulation by Bergström–Faber–van der Geer 2014 (*Sel. Math.* 20) identifies the relevant Hecke-eigenvalue congruences. No genus-2 replacement prime is fixed here before that table is read. It is a non-formal theorem.

(x) *Arithmetic* B*-row genus-g ceiling.* F4 (Chapter 42.4.1) sharpens from the single integer $\kappa^{\mathrm{Ar}} + (\kappa^{!})^{\mathrm{Ar}} = 8$ to a genus-dependent Shimura-signature-indexed sum, via Bruinier–Heegner Chern-class reciprocity on $\mathrm{Sh}(\mathrm{O}(2, 2g-1))$ with accidental isomorphism $\mathrm{O}(2,3) \cong \mathrm{Sp}_4/\{\pm I\}$ at $g = 2$. It is a non-formal theorem.

The total residual condition is a non-formal theorem condition, organised as three to four mathematical blocks. Block (i): conditions 1–4 + 7 (Beilinson / Positselski / bar-cobar on 2-dim base plus Virasoro bootstrap). Block (ii): conditions 5, 6 (GL_{2g} Fargues–Scholze local plus global Arinkin–Gaitsgory). Block (iii): conditions 8, 10 (Kudla–Rapoport and Bruinier–Heegner at genus g). Block (iv): condition 9 and consolidation (Harder-Eisenstein congruences; all-genus F-RH corollary).

102.7 Orthogonal and Compatible Windows

The six windows are compatible but mathematically distinct: each captures a different facet of the datum $\mathcal{D}_g$, and their pairwise compatibility is an independent mathematical fact in each case. Pairwise compatibility:

- **Windows I and V** share the arithmetic surface as base and agree on the weight-1 Hasse–Weil functional equation. They differ on operadic dimension: Window I keeps the archimedean E_1-chiral structure; Window V lifts to E_2-chiral via Dunn. Compatibility is the content of Chapter 33's 2-dim extension.
- **Windows II and V** differ on arithmetic scheme dimension (1-dim vs. 2-dim). Window II encodes the genus as coefficient enhancement of the base field (totally imaginary K of degree $2g$); Window V keeps $K = \mathbb{Q}$ but lifts the base scheme to 2-dim via Dunn additivity. Compatibility passes through Tate 1950 adelic Fourier at number-field level.
- **Windows III and VI** are spectral: Window III gives the local (φ, Γ)-module moduli; Window VI gives the global automorphic side. Compatibility requires the relevant local-global comparison; it is not supplied by Fargues–Scholze alone.
- **Window IV** is moduli-theoretic: $\mathcal{T}_g^{\mathrm{arith}}$ carries the Hodge–Arakelov decoration on the theta-generic locus, and its point-by-point inputs supply Window I. Compatibility via the Torelli map: a genus-g curve's Jacobian is a point of $\mathcal{X}_{2g}^{\mathrm{crys,ord}}$ only after imposing the ordinary crystalline local condition, and a point of the Siegel moduli space $\mathcal{A}_g$ via its polarisation. The word "threefold" applies only at $g = 2$.

Orthogonal to these six windows: Deninger's $\mathbb{F}_1$ formalism (motivational context for the arithmetic-dynamical interpretation of Spec $\mathbb{Z}$, recorded in Chapter 24); the Caraiani–Scholze unitary-Shimura theory at genera where no Shimura model exists (moduli of curves $\mathcal{M}_g$ is not Shimura for $g \geq 4$); the Bethe-algebra heuristic presentation, which operates at the zero-Fock per-place level and does not carry g-dependence directly.

The conditional identity $\kappa^{\mathrm{Ar},g} + (\kappa^{!})^{\mathrm{Ar},g} = 0$ of Chapter 102.4.1 is the proposed rank-g fibre. The F-RH axis of Chapter 44 is the $g = 0$ fibre of the rank-graded family whose other fibres are the Hasse–Weil Riemann Hypothesis for Jacobians of curves of genus g, the generalised Riemann Hypothesis for Dedekind zeta of totally imaginary fields of degree $2g$, and the Siegel-spin Riemann Hypothesis for cusp forms on GSp_{2g}. The residual conditions of Chapter 102.6 quantify what must be proved before this conditional comparison becomes an unconditional theorem.

Chapter 103 considers arithmetic three-dimensional Chern–Simons theory. Its Kac–Moody comparison requires the current operations and normalized levels of Question 103.3.1. A conformal vector does not construct them.

Finite-level state sums are given by Theorem 103.4.2 from finite groupoids and action classes. A renormalized $GL_2(\widehat{\mathbb{Z}})$ limit is a separate construction, as stated in Conjecture 103.4.7. The equalities

$$Z_{\mathrm{ACS}^{\mathrm{qu}}} = \xi(k^{\mathrm{Ar}}), \qquad \mathrm{HH}_0(\partial\mathrm{ACS}^{\mathrm{qu}}) \simeq \mathcal{V}^{\mathrm{prim}}$$

are conditional on profinite renormalisation and the local trace comparison (Chapter 103.4.9). The ordered incidence model is computed by the normalised ordered bar construction on the auxiliary place order $\mathbb{P} \cup \{\infty\}$ (Chapter 103.5.4); the comparison with full Beilinson–Drinfeld / Costello–Gwilliam arithmetic chiral homology is conditional (Chapter 103.5.5). F-RH becomes a conditional spectral theorem on the partition-function zero locus (Chapter 103.7.1); the all-genus extension (Chapter 103.8.1) is formulated row by row on the corresponding residual hypotheses.

Chapter 103

3D Arithmetic Chern-Simons on Etale Spec(Z) and the Ordered Incidence Bar

An arithmetic Kac–Moody enhancement requires current operations and level comparisons beyond a conformal vector. The local vertex algebras constructed below make those additional inputs explicit. Finite arithmetic Chern–Simons state sums arise instead from finite local-system groupoids and their action classes.

The profinite $GL_2(\widehat{\mathbb{Z}})$ quantum theory, its boundary identification with $\mathcal{V}^{\mathrm{prim}}$, and its zeta partition function remain conditional. A supplied functor on ordered merged-place blocks has a simplicial replacement that computes its derived colimit. Identifying that complex with geometric arithmetic chiral homology is a further comparison. The associated Deninger construction requires a spectral-flow hypothesis beyond its explicit prime-orbit model.

103.1 Spec(Z) as Etale 3-Space

Mazur 1973 (*Notes on étale cohomology of number fields*, Ann. Sci. ENS 6) observed that $\operatorname{Spec} \mathcal{O}_K$ has étale cohomological dimension 3 for K a number field, with Artin–Verdier duality supplying a fundamental class $[\operatorname{Spec} \mathcal{O}_K] \in H^3_{\text{ét}}(\operatorname{Spec} \mathcal{O}_K, \widehat{\mathbb{Z}})$ analogous to a 3-manifold's orientation class. Morishita 2012 *Knots and Primes* (arXiv:0904.3399) systematizes the dictionary: primes $\mathfrak{p} \subset \mathcal{O}_K$ behave as knots in a closed 3-manifold; $\operatorname{Spec} \mathcal{O}_{K,\mathfrak{p}}$ is the tubular neighborhood; the inertia subgroup $I_{\mathfrak{p}} \subset \operatorname{Gal}(\overline{K}/K)$ is the meridian; linking numbers become Legendre symbols; the Alexander–Fox module becomes the Iwasawa module. For $K = \mathbb{Q}$, Arakelov compactification $\overline{\operatorname{Spec} \mathbb{Z}}$ closes the 3-space by adding the archimedean boundary component at ∞.

Remark 103.1.1 *(cohomological 3-dimensionality).* $\operatorname{Spec} \mathbb{Z}$ is not a smooth real 3-manifold. Its 3-dimensionality is cohomological: the étale site supports non-trivial H^1, H^2, H^3 computable via global class-field theory and Artin–Verdier. The Chern-Simons action functional below takes values in étale cohomology classes rather than in differential forms; its quantization is in Galois-representation-theoretic terms rather than path-integral terms in the differential-geometric sense.

103.2 Kim Classical Arithmetic Chern-Simons

Kim 2015 *Arithmetic Chern-Simons Theory I* (arXiv:1510.05818), and the non-abelian extension Chern-Dan-Kim-Park 2018 (arXiv:1609.03012), define the classical action

$$\mathrm{CS}^{\mathrm{Ar}}_{M,c}(\rho) := \langle \rho^* c, [M] \rangle \in \mathbb{Q}/\mathbb{Z}, \tag{103.1}$$

for $M = \operatorname{Spec} \mathcal{O}_K$, $\rho : \pi_1^{\text{ét}}(M) \to G$ a continuous representation into a finite group G, $c \in H^3(BG, \mathbb{Q}/\mathbb{Z})$ a level class, and $[M]$ the Artin–Verdier fundamental class. Summation over ρ gives the classical partition function $Z^{\mathrm{cl,Ar}}_{\mathrm{CS},c}(M) = \sum_\rho \frac{e^{2\pi i \mathrm{CS}^{\mathrm{Ar}}_{M,c}(\rho)}}{|\mathrm{Aut}(\rho)|}$. Chapter 37 already uses this classical

torsor as a boundary action-line input for $\mathcal{V}^{\mathrm{prim}}$; finite state sums and the profinite quantum-TQFT problem are developed in Chapter 103.4.

103.3 The Arithmetic Kac–Moody Lift

Chapter 45 supplies local Virasoro calculations on the finite Heisenberg covers and records the rank residue $r_\zeta = 2$. Chapter 102 upgrades per-window rank to g from the rank-g archimedean Fock. A conformal vector alone does not produce $\widehat{\mathfrak{gl}}_2$ currents. The Kac–Moody enhancement therefore requires the Satake current algebra as part of the input; the Sugawara construction then compares its Virasoro field with the Heisenberg conformal vector away from the critical level.

Question 103.3.1 *(arithmetic Kac–Moody enhancement).* Construct a state-field realization of the arithmetic Hochschild trace class and maps from independently defined local affine current algebras into it. Specify common coefficients, local levels, reference vacua, and the completion used to assemble the places. The Satake eigenvalues (α_p, β_p) do not supply a basis of $\mathfrak{gl}_2$ or its current commutators.

There is a local vertex-algebra construction once the inputs are given. Over $\mathbb{C}$, supply vertex algebras H_p and universal affine vacuum algebras $V^{b_p}(\mathfrak{gl}_2)$, where b_p is a chosen invariant bilinear form. Inserting the vacuum at each new place defines

$$\mathcal{A}_{\mathrm{loc}} := \varinjlim_{S \subset \mathbb{P},\ S \text{ finite}} \bigotimes_{p \in S} \big(H_p \otimes V^{b_p}(\mathfrak{gl}_2)\big).$$

Each vector involves finitely many places, so its field and every vertex identity are computed in a finite tensor product. Thus this algebraic colimit is a vertex algebra. An arithmetic identification and a continuous extension to a chosen completion remain extra maps.

Remark 103.3.2 *(the noncritical-level condition).* On the $\mathfrak{sl}_2$ factor, normalize the invariant form so that the dual Coxeter number is 2. The Sugawara coefficient is $1/(2(k+2))$, so this formula requires $k \neq -2$. The central one-dimensional current requires its own nonzero level to define the usual Heisenberg conformal vector.

The arithmetic scalar identity $\kappa + \kappa^! = 0$ gives no noncritical-level theorem. Even an additional identification $k = \kappa$ would allow $\kappa = -2$ and $\kappa^! = 2$. A comparison with an arithmetic conformal vector must therefore supply both the level normalization and the noncritical hypothesis.

103.4 3D Quantum Arithmetic Chern-Simons

Definition 103.4.1 *(finite arithmetic field groupoid).* . Let M be an arithmetic 3-space in the Mazur–Artin–Verdier sense, for example $\overline{\mathrm{Spec}\, O_K}$ with its compact-support fundamental class. Let G be a finite group and let $\alpha \in H^3(BG, \mathbb{C}^\times)$ be a level. The finite arithmetic field groupoid is

$$\mathcal{F}_G(M) := \mathrm{Map}_{\mathrm{cont}}\big(\Pi_1^{\text{ét}}(M), BG\big),$$

the groupoid of continuous G-local systems on the etale homotopy type of M. For a field $\rho \in \mathcal{F}_G(M)$, the action is

$$S_\alpha^{\mathrm{Ar}}(\rho) := \big\langle \rho^*\alpha, [M] \big\rangle \in \mathbb{C}^\times.$$

Theorem 103.4.2 *(finite-level arithmetic state sum and gluing).* . For a closed arithmetic 3-space M for which $\mathcal{F}_G(M)$ is a finite groupoid, the assignment

$$Z_{G,\alpha}^{\mathrm{Ar}}(M) := \int_{\mathcal{F}_G(M)} S_\alpha^{\mathrm{Ar}} = \sum_{[\rho] \in \pi_0 \mathcal{F}_G(M)} \frac{\langle \rho^*\alpha, [M] \rangle}{|\operatorname{Aut}(\rho)|}$$

is Kim's arithmetic Chern–Simons partition sum for the class α. If an arithmetic gluing $M = M_1 \cup_\Sigma M_2$ has finite field groupoids and satisfies étale descent

$$\mathcal{F}_G(M) \simeq \mathcal{F}_G(M_1) \times_{\mathcal{F}_G(\Sigma)} \mathcal{F}_G(M_2),$$

then $Z^{\mathrm{Ar}}_{G,\alpha}$ satisfies the corresponding finite-groupoid gluing formula.

Proof. The construction uses only finite homotopy types. To a closed arithmetic 3-space M, assign the finite groupoid $\mathcal{F}_G(M)$ and integrate the locally constant function S^{Ar}_α by groupoid cardinality. If

$$M = M_1 \cup_\Sigma M_2$$

is a gluing along an arithmetic boundary, then etale descent for local systems gives a homotopy pullback

$$\mathcal{F}_G(M) \simeq \mathcal{F}_G(M_1) \times_{\mathcal{F}_G(\Sigma)} \mathcal{F}_G(M_2).$$

The fundamental class is additive under gluing, so the action multiplies:

$$\langle \rho^* \alpha, [M] \rangle = \langle \rho_1^* \alpha, [M_1] \rangle \langle \rho_2^* \alpha, [M_2] \rangle.$$

Fubini for finite groupoid cardinality then gives the displayed gluing formula. Kim's action is exactly the same evaluation of a pulled-back degree-3 class on the Artin–Verdier fundamental class, written in $\mathbb{Q}/\mathbb{Z}$ and exponentiated here into $\mathbb{C}^\times$. □

Definition 103.4.3 *(finite-level boundary category).* . For an arithmetic boundary Σ, let $\tau_\Sigma(\alpha)$ be the transgression of $\alpha \in H^3(BG, \mathbb{C}^\times)$ to a 2-cocycle on the field groupoid $\mathcal{F}_G(\Sigma)$. The finite-level boundary category is

$$\mathcal{B}_{G,\alpha}(\Sigma) := \mathrm{Sh}_{\tau_\Sigma(\alpha)}\big(\mathcal{F}_G(\Sigma)\big),$$

the category of finite-dimensional $\tau_\Sigma(\alpha)$-twisted local systems on $\mathcal{F}_G(\Sigma)$.

The partition function $Z^{\mathrm{Ar}}_{G,\alpha}(M)$ is a scalar for closed M. For a manifold with boundary, the TQFT assignment must produce a category: the state category on the boundary. The finite boundary category provides this assignment.

Theorem 103.4.4 *(finite-level bulk-boundary span). (on a finite arithmetic cobordism category whose morphisms satisfy the gluing hypothesis of Chapter 103.4.2).* The finite-level theory $Z^{\mathrm{Ar}}_{G,\alpha}$ assigns $\mathcal{B}_{G,\alpha}(\Sigma)$ to the arithmetic boundary Σ. If M is a cobordism from Σ_0 to Σ_1, then M acts by the integral transform

$$\mathrm{Sh}_{\tau_{\Sigma_0}(\alpha)}\big(\mathcal{F}_G(\Sigma_0)\big) \longrightarrow \mathrm{Sh}_{\tau_{\Sigma_1}(\alpha)}\big(\mathcal{F}_G(\Sigma_1)\big)$$

whose kernel is the action local system on $\mathcal{F}_G(M)$. For a closed M, the categorical trace of this transform is $Z^{\mathrm{Ar}}_{G,\alpha}(M)$.

Proof. Restriction of local systems gives a span

$$\mathcal{F}_G(\Sigma_0) \leftarrow \mathcal{F}_G(M) \rightarrow \mathcal{F}_G(\Sigma_1).$$

The transgressed cocycle records the boundary anomaly of the degree-3 class α; tensoring by the action local system and then pushing forward along the right leg gives the displayed integral transform. Composition of cobordisms is composition of spans. The homotopy-pullback formula from Chapter 103.4.2 makes the two composite kernels canonically isomorphic. When the boundary is empty, the trace reduces to groupoid-cardinality integration over $\mathcal{F}_G(M)$, which is precisely $Z^{\mathrm{Ar}}_{G,\alpha}(M)$. □

Proposition 103.4.5 *(finite boundary Hochschild trace).* . For a finite groupoid $\mathcal{F}_G(\Sigma)$ over $\mathbb{C}$, the finite boundary category

$$\mathcal{B}_{G,\alpha}(\Sigma) = \mathrm{Sh}_{\tau_\Sigma(\alpha)}(\mathcal{F}_G(\Sigma))$$

has Hochschild trace equal to the twisted inertia trace of $\mathcal{F}_G(\Sigma)$:

$$\mathrm{HH}_0\big(\mathcal{B}_{G,\alpha}(\Sigma)\big) \cong \Gamma\big(\pi_0 I\mathcal{F}_G(\Sigma), L_{\tau_\Sigma(\alpha)}\big), \qquad \mathrm{HH}_{n>0}\big(\mathcal{B}_{G,\alpha}(\Sigma)\big) = 0.$$

Here $I\mathcal{F}_G(\Sigma)$ is the inertia groupoid, and $L_{\tau_\Sigma(\alpha)}$ is the transgressed local system on inertia.

Proof. A finite twisted sheaf category on a finite groupoid is Morita equivalent to modules over the corresponding finite-dimensional twisted groupoid algebra. Over $\mathbb{C}$ this algebra is separable: it is a finite product of twisted finite group algebras, hence semisimple. Hochschild homology of a separable algebra with coefficients in itself vanishes in positive degrees. Degree zero is the algebra modulo commutators, which is the space of twisted class functions on conjugacy classes, equivalently sections of the transgressed local system on the inertia groupoid. □

Corollary 103.4.6 *(Wilson lines at finite level).* . A prime p viewed as a knot in the Morishita dictionary supports Wilson defects labelled by representations of the local stabiliser group of a point of $\mathcal{F}_G(\mathrm{Spec}\,\mathbb{Q}_p)$. For a one-dimensional label χ, the Wilson expectation is the corresponding Frobenius trace $\chi(\mathrm{Frob}_p)$.

Proof. Removing the prime p and fixing monodromy around the meridian is the arithmetic analog of prescribing a conjugacy class around a knot. The defect category is the module category of the stabiliser of that local monodromy. A one-dimensional module evaluates a loop by its character, hence the meridian/Frobenius loop contributes $\chi(\mathrm{Frob}_p)$. □

Conjecture 103.4.7 *(renormalised $GL_2(\widehat{\mathbb{Z}})$ quantum arithmetic CS).* . Let $G_N = GL_2(\mathbb{Z}/N\mathbb{Z})$, and let $\alpha_N \in H^3(BG_N, \mathbb{C}^\times)$ be a compatible tower of finite levels whose inverse-limit class is the arithmetic level $k^{\mathrm{Ar}} = \kappa_{\mathsf{G}}^{\mathrm{Ar}}$. The finite theories $Z^{\mathrm{Ar}}_{G_N,\alpha_N}$ admit a renormalised profinite limit

$$\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}} := \varprojlim_{N}^{\mathrm{ren}} Z^{\mathrm{Ar}}_{G_N,\alpha_N}$$

on the etale 3-space $\overline{\mathrm{Spec}\,\mathbb{Z}}$. This limit satisfies three bulk-boundary axioms:

(i) (Boundary WZW.) The 2D factorization algebra on the archimedean fibre $\{\infty\}$ produced by canonical quantisation of $\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}$ has Hochschild trace $\mathcal{V}^{\mathrm{prim}}$:

$$\mathrm{HH}_0\big(\partial\,\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}\big) \simeq \mathcal{V}^{\mathrm{prim}}.$$

(ii) (Partition function.) The bulk partition function equals the completed zeta character at the level: $Z_{\mathrm{ACS}^{\mathrm{qu}}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}}) = \xi(k^{\mathrm{Ar}})$.

(iii) (Wilson lines as Frobenius traces.) For a prime $p \in \mathbb{P}$ viewed as a knot in the Morishita dictionary, the Wilson-line observable in representation $\rho : \pi_1^{\text{ét}} \to GL_2$ reproduces the Frobenius trace: $\langle W_\rho(K_p)\rangle_{\mathrm{ACS}^{\mathrm{qu}}} = \mathrm{tr}\,\rho(\mathrm{Frob}_p)$.

Remark 103.4.8 *(finite vs. profinite ACS: gap between theorem-grade and conjecture-grade).* The closed finite-level state sum is theorem-grade: Chapter 103.4.2 constructs it from étale local systems, the Artin–Verdier fundamental class, and finite groupoid cardinality. Functorial finite-level TQFT language still requires a specified arithmetic cobordism category. The larger residual is the renormalised profinite limit $G_N \to GL_2(\widehat{\mathbb{Z}})$, the comparison of its archimedean boundary category with $\mathcal{V}^{\mathrm{prim}}$, and the identification of its renormalised partition function with $\xi(k^{\mathrm{Ar}})$.

There is a concrete obstruction to treating the closed finite tower as the zeta partition function. On the closed base $\overline{\mathrm{Spec}\,\mathbb{Z}}$, finite etale local systems are trivial by Hermite–Minkowski, so the bare finite state sum for $G_N = GL_2(\mathbb{Z}/N\mathbb{Z})$ is the groupoid-cardinality scalar $|G_N|^{-1}$, or 1 after finite-gauge normalisation. This scalar does not contain prime weights p^{-s}, the archimedean $\Gamma_{\mathbb{R}}$-factor, or the polar correction. A zeta-valued profinite ACS theory therefore requires extra data: compatible continuous level classes, a counterterm or measure system on the congruence tower, a profinite boundary category, a Morita comparison with the local Iwahori trace factors, and a regularised character map.

Theorem 103.4.9 *(bulk-boundary comparison with $\mathcal{V}^{\mathrm{prim}}$). (on the renormalised profinite limit in Chapter 103.4.7 and on the local Satake/Iwahori trace identifications of Chapters 50 and 38).* Let

$$\mathcal{B}_\infty^{\mathrm{Ar}} := \overset{\mathrm{ren}}{\varprojlim_N} \mathcal{B}_{G_N,\alpha_N}(\{\infty\})$$

be the renormalised archimedean boundary category of the profinite ACS tower. If its finite-place compact generators identify with the local Iwahori Hecke generators and its archimedean vacuum sector identifies with the rank-2 Heisenberg Kac–Moody vacuum, then

$$\mathrm{HH}_\bullet(\mathcal{B}_\infty^{\mathrm{Ar}}) \simeq \mathcal{V}^{\mathrm{prim}}.$$

Equivalently, the boundary factorization algebra of $\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}$ is $\mathcal{V}^{\mathrm{prim}}$.

Proof. At finite level, Chapter 103.4.4 identifies the boundary state category with twisted sheaves on the boundary field groupoid. Passing through the congruence tower gives a renormalised inverse system of such categories. The stated compact-generation hypothesis is exactly the assertion that the local factors of this system are the Iwahori Hecke categories used in the definition of $\mathcal{V}^{\mathrm{prim}}$. Hochschild trace is local for the restricted tensor product under the compact-generation and spherical unit hypotheses of Chapter 50. Thus the finite places contribute the local trace factors $\mathcal{H}^{(p)}$, while the archimedean vacuum contributes $\mathcal{H}^{(\infty)}$. Their restricted tensor product is the Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ by Chapter 38. This proves the displayed boundary identification, conditional precisely on the profinite renormalisation and the local trace comparison. □

Remark 103.4.10 *(boundary trace form).* The finite boundary trace of Chapter 103.4.5 is theorem-grade, but it does not identify the boundary with $\mathcal{V}^{\mathrm{prim}}$. The comparison

$$\mathrm{HH}_\bullet(\mathcal{B}_\infty^{\mathrm{Ar}}) \simeq \mathcal{V}^{\mathrm{prim}}$$

requires an independent profinite Morita equivalence

$$\mathcal{B}_\infty^{\mathrm{Ar}} \simeq_{\mathrm{Morita}} \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}},$$

where $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}$ is the global arithmetic Iwahori–Hecke category (restricted tensor product of local Iwahori–Hecke categories with archimedean vacuum, defined in Chapter 38), compatible with the

chosen topology, completion, restricted tensor product, local Satake/Iwahori generators, archimedean vacuum, and the arithmetic Ben-Zvi–Nadler and wild-prime hypotheses. Until these data are proved, Chapter 103.4.9 is only a conditional implication.

Remark 103.4.11 *(Vol II cross-volume bridge).* Vol II Part VI states a 3D holomorphic-twist QFT on $C \times \mathbb{R}$ whose boundary factorization algebra on C is the complex $\mathcal{V}$. The arithmetic analog replaces the holomorphic twist by the Chern-Simons sector: the arithmetic base $\overline{\mathrm{Spec}\,\mathbb{Z}}$ has étale cohomological dimension 3 without a holomorphic structure in the differential-geometric sense. The 3D topological gauge theory over the arithmetic base is therefore Chern-Simons, not holomorphic twist. The complex $(HT)_{C\times\mathbb{R}} \to \partial = \mathcal{V}$ adjunction becomes an arithmetic boundary category whose Hochschild trace is $\mathcal{V}^{\mathrm{prim}}$.

103.5 The Ordered Incidence Bar

The discrete set of arithmetic places supplies no position diagonal. An ordered incidence category provides a coefficient model once its adjacent products have been specified: it encodes the primes of $\mathbb{Z}$ via the auxiliary total order $2 < 3 < 5 < 7 < \cdots < \infty$, with the archimedean place placed last. This order is not geometric structure on $\overline{\mathrm{Spec}\,\mathbb{Z}}$; the comparison with Beilinson–Drinfeld/Costello–Gwilliam arithmetic chiral homology is conditional (Chapter 103.5.5).

Definition 103.5.1 *(ordered incidence category).* . Put $V = \mathbb{P} \cup \{\infty\}$, with the order $2 < 3 < 5 < \cdots < \infty$. Let $\mathsf{Inc}_<(V)$ be the category whose objects are finite ordered block decompositions of finite ordered subsets of V. A singleton block is written v, and the merge of two adjacent blocks is written by concatenation. Morphisms are generated by order-preserving adjacent contractions

$$\{v_1 < \cdots < v_i < v_{i+1} < \cdots < v_n\} \longrightarrow \{v_1 < \cdots < (v_i v_{i+1}) < \cdots < v_n\},$$

where $v_i v_{i+1}$ denotes the formal merged block carrying the product operation of the coefficient system, not a new arithmetic place. The simplicial nerve of $\mathsf{Inc}_<(V)$ records chains of adjacent contractions. Its comparison with a geometric arithmetic configuration space is additional data.

Definition 103.5.2 *(ordered incidence homology).* . Specify cochain complexes $\mathcal{H}^{(B)}$ over $\mathbb{C}$ for every nonempty ordered block B, including $\mathcal{H}^{(v)}$ at a singleton, and compatible adjacent products. For singleton blocks these are

$$m_{v,w} \colon \mathcal{H}^{(v)} \otimes \mathcal{H}^{(w)} \longrightarrow \mathcal{H}^{(vw)} \qquad (v < w).$$

Here $\mathcal{H}^{(vw)}$ means the coefficient assigned to the merged block vw. Assume the products and their identities define a strict functor $F_{\mathcal{H}} \colon \mathsf{Inc}_<(V) \to \mathrm{Ch}_{\mathbb{C}}$, where $\mathrm{Ch}_{\mathbb{C}}$ denotes cochain complexes. It sends an ordered block decomposition $B_1|\cdots|B_r$ to

$$F_{\mathcal{H}}(B_1|\cdots|B_r) := \mathcal{H}^{(B_1)} \otimes \cdots \otimes \mathcal{H}^{(B_r)},$$

with contractions acting by the corresponding adjacent products. For a homotopy-coherent coefficient system, choose a strict diagram model before using this formula. Relative to this specified functor, the ordered incidence homology object is the derived colimit

$$\int^{\mathrm{ord}}_{\overline{\mathrm{Spec}\,\mathbb{Z}}} \mathcal{V}^{\mathrm{prim}} := \operatorname*{L\,colim}_{\mathsf{Inc}_<(V)} F_{\mathcal{H}}.$$

Definition 103.5.3 *(ordered incidence bar).* . Suppose the coefficient functor $F_{\mathcal{H}}$ of the preceding definition has been supplied, including coherent adjacent products on all merged blocks. A finite-place vacuum is a pointing, hence an underlying E_0-datum; it does not supply these products. The notation $\mathcal{V}^{\mathrm{prim}}$ for the arithmetic Hochschild trace class determines no such coefficient functor by itself. Relative to the chosen $F_{\mathcal{H}}$, the *ordered incidence bar* is the normalized chain complex of the simplicial replacement of $F_{\mathcal{H}}$:

$$B^{\mathrm{ord}}_{\bullet}(\mathcal{V}^{\mathrm{prim}}) := N_{\bullet}\,\mathrm{srep}_{\mathsf{Inc}_<(V)}(F_{\mathcal{H}}).$$

Here $\mathrm{srep}_{\mathsf{Inc}_<(V)}(F_{\mathcal{H}})$ is the simplicial replacement of $F_{\mathcal{H}}$ (the standard bar construction on a functor from a small category to chain complexes), and $N_{\bullet}$ is the normalized chain functor on simplicial chain complexes. In simplicial degree n, this is the direct sum over n-simplices $C_0 \to \cdots \to C_n$ of $\mathsf{Inc}_<(V)$ of $F_{\mathcal{H}}(C_0)$, modulo degeneracies. The first face applies $F_{\mathcal{H}}(C_0 \to C_1)$; an interior face composes two arrows, and the last face drops the last object. Thus all targets are coefficients of formal merged blocks, not new arithmetic places.

Its direct-sum total complex has

$$(\mathrm{Tot}^{\oplus}\, B^{\mathrm{ord}})^q = \bigoplus_{n\geq 0} (B^{\mathrm{ord}}_n)^{q+n}, \qquad d_{\mathrm{tot}}|_{B_n} = (-1)^n d_{\mathrm{int}} + \sum_{i=0}^{n} (-1)^i d_i.$$

The face sum is zero at $n = 0$. The notation $H_{\bullet}(B^{\mathrm{ord}}_{\bullet})$ means the homology of this total complex, with $H_m = H^{-m}$.

Theorem 103.5.4 *(ordered incidence homology via normalized bar).* . The ordered incidence homology of $\mathcal{V}^{\mathrm{prim}}$ is computed by the ordered incidence bar:

$$\int^{\mathrm{ord}}_{\overline{\mathrm{Spec}\,\mathbb{Z}}} \mathcal{V}^{\mathrm{prim}} \;\simeq\; \mathrm{Tot}^{\oplus}\, B^{\mathrm{ord}}_{\bullet}(\mathcal{V}^{\mathrm{prim}}).$$

Proof. For an object C of a small category $\mathcal{I}$, let $P_C(M)(D) = \bigoplus_{\mathcal{I}(C,D)} M$. This is the free diagram generated by a complex M at C. The simplicial free-diagram resolution of a functor F has degree n

$$\bigoplus_{C_0\to\cdots\to C_n} P_{C_n}(F(C_0)).$$

Its augmentation to F, evaluated at D, is contracted by appending the final arrow $C_n \to D$ and the identity of D. The usual alternating face differential makes this the extra-degeneracy contraction. Its degeneracies split, and over $\mathbb{C}$ its free diagram terms give a cofibrant simplicial resolution, also for unbounded coefficient complexes. Thus its realization computes the left derived colimit.

The colimit of $P_C(M)$ is M: every summand labelled by $C \to D$ is the image of the summand at the identity of C, with precisely these identifications. Taking colimits in the displayed resolution therefore gives the simplicial replacement of F. Quotienting the split degeneracies leaves its normalized complex. The internal and face differentials commute before totalization; $(-1)^n$ makes them anticommute, so its realization is the stated direct-sum total complex. Apply this construction to $\mathcal{I} = \mathsf{Inc}_<(V)$. □

Corollary 103.5.5 *(comparison with BD/CG chiral homology). (on constructing an arithmetic Beilinson–Drinfeld/Costello–Gwilliam Ran model for* $\overline{\mathrm{Spec}\,\mathbb{Z}}$*, finite-place collision thickenings, constructible descent, ordered-to-unordered descent, and completion exactness identifying the arithmetic chiral homology of Chapters 33 and 30 with the ordered incidence model).* One has

$$\int_{\overline{\mathrm{Spec}\,\mathbb{Z}}} \mathcal{V}^{\mathrm{prim}} \simeq \mathrm{Tot}^{\oplus}\, B^{\mathrm{ord}}_{\bullet}(\mathcal{V}^{\mathrm{prim}}).$$

Proof. The ordered theorem computes $\int^{\mathrm{ord}} \mathcal{V}^{\mathrm{prim}}$. The stated comparison hypothesis identifies the ordered incidence model with the independently specified arithmetic homology object. Substitution gives the displayed equivalence. □

Remark 103.5.6 *(form of the BD/CG comparison).* The ordered incidence bar computes the derived colimit over $\mathsf{Inc}_<(\mathbb{P} \cup \{\infty\})$ by Chapter 103.5.4. This is not full Beilinson–Drinfeld/Costello–Gwilliam arithmetic chiral homology. The comparison requires a non-terminal arithmetic Ran object, finite-place diagonal or collision thickenings, BD/CG descent, constructibility with an exit category homotopy-finally reached from the ordered incidence category, ordered-to-unordered descent, and exactness of the restricted products and completions used in the derived colimit. Until these hypotheses are supplied, Chapter 103.5.5 remains conditional.

Corollary 103.5.7 *(regularised character from the ordered bar). (on Chapter 103.4.7(1–2) and Chapter 103.5.5, and on a regularised character map* $\mathrm{ch}_{\mathrm{reg}}$ *from arithmetic chiral homology to scalar partition functions).* The partition function of the conjectural 3D quantum arithmetic Chern–Simons is the regularised character of the ordered-bar homology:

$$Z_{\mathrm{ACS}^{\mathrm{qu}}}\big(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}}\big) = \mathrm{ch}_{\mathrm{reg}}\, H_\bullet\big(B^{\mathrm{ord}}_\bullet(\mathcal{V}^{\mathrm{prim}})\big) = \xi(k^{\mathrm{Ar}}).$$

The character map is the missing type conversion: a scalar partition function is not identified with a homology object before applying $\mathrm{ch}_{\mathrm{reg}}$.

103.6 Deninger Skeleton from Arithmetic Chiral Homology

The ordered-bar computation of the finite Bost–Connes zero modes (Chapter 103.6.3) gives the prime-orbit Euler skeleton in the half-plane of absolute convergence. Deninger's missing cohomology requires an additional $\mathbb{R}_+^\times$-flow whose normal generator has regularised determinant divisor div $\xi_{\mathbb{R}}$ and Weil–Connes trace distribution. That additional flow is the Hilbert–Pólya/Connes–Deninger realisation; it is not produced by the Bost–Connes heat flow.

Definition 103.6.1 *(pre-Deninger arithmetic coefficient datum).* . The *pre-Deninger arithmetic coefficient datum* is the datum

$$\mathcal{A}_{\mathrm{Den}} := \Big(\mathcal{A}_{\mathrm{fin}} \otimes \mathcal{A}_\infty^{\mathrm{Tate}}\Big) \otimes \mathsf{P}^\bullet$$

with:

(i) finite Bost–Connes zero modes

$$\mathcal{A}_{\mathrm{fin}} := \bigotimes_p{}' \mathcal{H}_p^{\mathrm{BC}}, \qquad \mathcal{H}_p^{\mathrm{BC}} := \bigoplus_{r\geq 0} \mathbb{C}\delta_{p^r},$$

with $N_p\delta_{p^r} = r(\log p)\delta_{p^r}$ and $N_{\mathrm{BC}} = \sum_p N_p$ on the restricted tensor product;

(ii) the archimedean Tate-Gaussian sector $\mathcal{A}_\infty^{\mathrm{Tate}}$, whose Mellin character is $\Gamma_{\mathbb{R}}(s) := \pi^{-s/2}\Gamma(s/2)$ (the standard archimedean Euler factor);

(iii) a polar Tate complex $\mathsf{P}^\bullet = \mathbb{C}_0[0] \oplus \mathbb{C}_1[2]$, where the indicated subscripts record the formal Frobenius weights 0 and 1;

(iv) the Bost–Connes Euler flow $\phi^t_{\mathrm{BC}} := \exp(-tN_{\mathrm{BC}})$ on the finite zero modes, tensored with the usual Tate scaling on $\mathcal{A}_\infty^{\mathrm{Tate}}$.

The last flow records closed-orbit lengths $\log p$. It is not the Deninger Frobenius flow on the conjectural middle cohomology.

Definition 103.6.2 *(candidate chiral Deninger complex).* . Work in a fixed complete nuclear dg category where the restricted tensor products below and compactly supported continuous duals are defined. Put

$$C^{\bullet}_{\mathrm{core},\chi} := \mathrm{Hom}_{\mathrm{cont},c}\Big(B^{\mathrm{ord}}_{\bullet}(\mathcal{A}_{\mathrm{fin}}\widehat{\otimes}\mathcal{A}_{\infty}^{\mathrm{Tate}}),\ \mathbb{C}\Big).$$

The *candidate chiral Deninger complex* is the total direct sum

$$C^{\bullet}_{\mathrm{Den},\chi} := \mathrm{Tot}\Big(C^{\bullet}_{\mathrm{core},\chi} \oplus \mathsf{P}^{\bullet}\Big),$$

where $\mathsf{P}^{\bullet}$ has zero differential and contributes formal Tate lines in degrees 0 and 2. Its cohomology is denoted

$$H^{\bullet}_{\mathrm{Den},\chi} := H^{\bullet}(C^{\bullet}_{\mathrm{Den},\chi}).$$

The primitive middle part $H^{1}_{\mathrm{Den},\chi,\mathrm{prim}}$ is $H^{1}(C^{\bullet}_{\mathrm{core},\chi})$. No theorem is asserted here that the full complex has only the Deninger degrees 0, 1, 2, or that this dual agrees with compactly supported Artin–Verdier cohomology.

Proposition 103.6.3 *(unconditional Bost–Connes Euler skeleton).* . The finite Bost–Connes zero-mode sector has ordinary KMS character

$$\mathrm{Tr}\big(e^{-sN_{\mathrm{BC}}} \mid \mathcal{A}_{\mathrm{fin}}\big) = \prod_{p}\sum_{r\ge 0} p^{-rs} = \prod_{p}(1-p^{-s})^{-1} = \zeta(s) \qquad (\mathrm{Re}\, s > 1),$$

and logarithmic differentiation gives the prime-orbit sum

$$-\frac{\zeta'}{\zeta}(s) = \sum_{p}\sum_{r\ge 1}(\log p)\, p^{-rs}.$$

This is the raw non-archimedean Euler/log-prime skeleton in the half-plane of absolute convergence.

Proof. On $\mathcal{H}_p^{\mathrm{BC}}$, $\mathrm{Tr}(e^{-sN_p}) = \sum_{r\ge 0} e^{-sr\log p}$. The restricted tensor product multiplies these traces over primes, giving the Euler product for $\zeta(s)$ in the half-plane of convergence. Logarithmic differentiation turns each local factor into the Dirichlet series over iterates of the closed orbit at p, with length $\log p$. □

Remark 103.6.4 *(gap between Euler/log-prime skeleton and Weil–Guinand distribution).* Chapter 103.6.3 is not yet the Weil–Guinand distribution. Passing from $-\zeta'/\zeta(s)$ in $\mathrm{Re}\, s > 1$ to the finite-place term on critical-line test functions requires a separate contour shift, Fourier/Mellin convention, the $n^{-1/2}$ weight, the sign and factor 2, plus the archimedean and polar terms. Those analytic normalisations are part of the trace-formula residual, not part of the ordered-bar computation.

Conjecture 103.6.5 *(Deninger spectral-flow / Hilbert–Pólya hypothesis).* . There exists a Hilbert completion of $H^{1}_{\mathrm{Den},\chi,\mathrm{prim}}$ and a closed operator

$$\Theta_{\mathrm{Den}} = \frac{1}{2}\mathrm{id} + iH_{\mathrm{Den}}$$

with H_{Den} self-adjoint in the Petersson/GNS inner product, such that:

(i) regularised determinant:

$$\det_{\infty}\Big(s\mathrm{id} - \Theta_{\mathrm{Den}} \mid H^{1}_{\mathrm{Den},\chi,\mathrm{prim}}\Big) = \xi_{\mathbb{R}}(s);$$

(ii) Weil–Connes trace distribution:

$$\mathrm{Tr}_{\mathrm{reg}}\big(h(H_{\mathrm{Den}})\big) = \sum_{\rho} h(\gamma_{\rho}), \qquad \rho = \frac{1}{2} + i\gamma_{\rho},$$

for every admissible Paley–Wiener test function h;

(iii) the preceding notation is conditional on the determinant identity: the self-adjoint trace model and $\det_{\infty}(s\mathrm{id} - \Theta_{\mathrm{Den}}) = \xi_{\mathbb{R}}(s)$ force the zero divisor onto the critical line;

(iv) Lefschetz compatibility: the trace distribution in (2), after moving the contour across ξ'/ξ, equals the prime-orbit sum of Chapter 103.6.3, the archimedean Tate-Gamma correction, and the two polar terms from $\mathsf{P}^{\bullet}$.

This hypothesis is exactly the Hilbert–Pólya/Connes–Deninger determinant-trace realisation in the present chiral-homology language. In particular, self-adjointness of H_{Den} together with the determinant identity is already RH-strength zero-placement for $\xi_{\mathbb{R}}$.

Proposition 103.6.6 *(conditional formal Deninger datum). (on Chapter 103.6.5 and on the topological-dual choices in Chapter 103.6.2).* The candidate cohomology $H^{\bullet}_{\mathrm{Den},\chi}$, equipped with Θ_{Den} on its primitive middle part and with the two Tate polar lines in degrees 0 and 2, carries Deninger's formal regularised-determinant and Lefschetz-trace identities for $\overline{\mathrm{Spec}\,\mathbb{Z}}$.

Proof. The finite sector gives only the Euler/log-prime skeleton of Chapter 103.6.3. The archimedean and polar entries specify where the Tate-Gamma and $s = 0, 1$ terms would live in a cohomological Lefschetz formula. The spectral-flow hypothesis supplies the missing middle operator, its determinant, its zero-side trace distribution, and the Lefschetz comparison. Thus the claim is a conditional implication: once the spectral-flow data is assumed, the displayed cohomological object carries the formal slots required by Deninger's axioms. It is not an independent construction of Θ_{Den}. □

Proposition 103.6.7 *(what the construction does not prove).* . The ordered-bar construction of $C^{\bullet}_{\mathrm{Den},\chi}$ does not by itself construct Θ_{Den}, prove the determinant identity, prove the Weil–Guinand trace formula, fix the cohomological superdeterminant signs of the polar lines, or prove positivity/purity. These requirements are exactly the Hilbert–Pólya/Connes–Deninger obstruction of Chapter 44.3.2 plus the analytic trace-formula normalization.

Proof. The ordered bar is determined by the local factors $\{\mathcal{H}_p^{\mathrm{BC}}\}_p$, the archimedean Tate sector, and the polar complex. This data gives the Euler product and hence the prime side in $\mathrm{Re}\, s > 1$. The zero-side operator requires a self-adjoint determinant-trace realisation whose determinant is $\xi_{\mathbb{R}}$. Chapter 44 names that assertion H-P^{Ar} and records that it is not derivable from the character identity, the formal Virasoro action, or the Petersson form alone. Thus the chiral construction supplies a candidate complex and the prime-side Euler skeleton. The spectral-flow hypothesis is the remaining essential input and has RH-level strength. □

103.7 Arithmetic-Gravity Construction to F-RH

Witten 2007 (*Three-Dimensional Gravity Revisited*, arXiv:0706.3359) proposed that 3D quantum gravity admits a Chern-Simons formulation whose partition function's spectrum controls the zeros of arithmetically significant L-functions. Vol II Part VI states this as the complex-side 3D quantum gravity climax. The arithmetic base $\overline{\mathrm{Spec}\,\mathbb{Z}}$ supplies an analogous conditional formulation via the preceding ACS construction.

Theorem 103.7.1 *(arithmetic-gravity F-RH). (on Chapter 103.4.7, Chapter 103.4.9, Chapter 103.5.5, and Chapter 44's three-pillar + VB structure, including a holomorphic complex-level partition function).* The zeros of $Z_{\mathrm{ACS}^{\mathrm{qu}}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}})$ as a function of the level $k^{\mathrm{Ar}} \in \mathbb{C}$ coincide with the non-trivial zeros of $\xi(k^{\mathrm{Ar}})$. The zero-placement claim is RH-level: these zeros lie on the self-dual locus $\mathrm{Re}(k^{\mathrm{Ar}}) = 1/2$ exactly when the corresponding Riemann-hypothesis zero-placement statement holds. The stronger F-RH condition still includes the positive Hilbert–Pólya trace inputs of Chapter 44.

Remark 103.7.2 *(three-step construction).* The construction proceeds in three steps.

(i) *Bulk construction.* Finite-level ACS is constructed in Chapter 103.4.2. The open bulk step is the renormalised profinite limit $\varprojlim^{\mathrm{ren}}_{N} Z^{\mathrm{Ar}}_{G_N,a_N}$ and its zeta partition function, as stated in Chapter 103.4.7.

(ii) *Boundary identification and ordered-model computation.* Finite-level boundary categories are constructed in Chapter 103.4.4 after choosing the finite arithmetic cobordism category. The comparison with $\mathcal{V}^{\mathrm{prim}}$ is Chapter 103.4.9. The ordered-bar calculation is theorem-grade for the ordered incidence model by Chapter 103.5.4; the remaining comparison to BD/CG arithmetic chiral homology is Chapter 103.5.5.

(iii) *Positive trace.* Apply the Hilbert–Pólya–Li residual of Chapter 44. The ordered model and the completed-zeta character do not by themselves supply positivity; the missing input is the positive Hilbert–Pólya trace.

103.8 Genus-g Extension

A genus-g extension requires rank-$2g$ current operations and the arithmetic comparison requested in Question 103.3.1. A conformal vector alone does not provide this enhancement.

The proposed quantum CS family $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}}$ is parameterized by the datum $\mathcal{D}_g$ of Definition 102.1.1. Its proposed gauge group is $GL_{2g}(\widehat{\mathbb{Z}})$. The boundary identification with $\mathcal{V}^{\mathrm{prim},g}$ requires a separate construction. Given rank-$2g$ Fock coefficients and all adjacent products, one can form their ordered incidence bar on $\mathbb{P} \cup \{\infty\}$. The partition function is conjecturally $\Lambda_{\mathcal{D}_g}(k^{\mathrm{Ar},g})$ per Chapter 102.1: Dedekind $\xi_K(k^{\mathrm{Ar},g})$ for Window II, Hasse–Weil $\Lambda(k^{\mathrm{Ar},g}, X_K)$ for Windows I/V, Siegel spin $\Lambda(k^{\mathrm{Ar},g}, \pi, \mathrm{spin})$ for Window VI.

Corollary 103.8.1 *(all-genus arithmetic-gravity F-RH). (on the genus-g extensions of Chapter 103.4.7, Chapter 103.4.9, Chapter 103.5.5, plus Chapter 102.5.1).* The zeros of $Z_{\mathrm{ACS}^{\mathrm{qu},g}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar},g})$ coincide with the non-trivial zeros of $\Lambda_{\mathcal{D}_g}(s)$, and lie on the self-dual locus $\mathrm{Re}(k^{\mathrm{Ar},g}) = w_{\mathcal{D}_g}/2$ for $w_{\mathcal{D}_g}$ the motivic weight center of the relevant window: 1 for the zeta window, 2 for the curve H^1 window, and $w_{\pi,\mathrm{spin}}$ for the Siegel spin window.

103.9 Residual Conditions

Six conditions specific to the arithmetic-gravity construction, in addition to Chapter 102's residual list.

(i) *Finite arithmetic cobordism category.* . The closed finite-level state sum, gluing formula, and finite boundary trace are Chapter 103.4.2 and Chapter 103.4.5. A full finite-level TQFT still needs the arithmetic cobordism category and its finiteness hypotheses written explicitly.

(ii) *Profinite ACS renormalisation.* . Construct a canonical renormalised limit of the $GL_2(\mathbb{Z}/N\mathbb{Z})$ arithmetic CS tower, with compatible continuous level classes, counterterms, and scalar partition

$$Z_{\mathrm{ACS}^{\mathrm{qu}}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}}) = \xi(k^{\mathrm{Ar}}).$$

Finite closed state sums do not supply this data.

(iii) *Boundary trace comparison.* . Construct an independent Morita equivalence

$$\mathcal{B}_{\infty}^{\mathrm{Ar}} \simeq_{\mathrm{Morita}} \mathsf{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}},$$

compatible with restricted tensor products, spherical units, local Satake/Iwahori generators, and the archimedean vacuum.

(iv) *BD/CG ordered-model comparison.* . Construct arithmetic Ran/BD–CG descent whose exit or disk category is homotopy-finally computed by $\mathsf{Inc}_{<}(\mathbb{P} \cup \{\infty\})$, including finite-place collision thickenings, ordered-to-unordered descent, and completion exactness.

(v) *Positive trace/VB core.* . Prove the full positive Hilbert–Pólya trace, equivalently the full A-TP/VB input on the complete Paley–Wiener cone. The ordered model, Bost–Connes Euler skeleton, and formal Fock positivity away from the zero-mode sector do not supply this RH-strength positivity input.

(vi) *Deninger spectral-flow hypothesis.* . Upgrade the ordered-bar prime skeleton of Chapter 103.6.2 to a genuine middle cohomology Hilbert completion, with dense invariant core and a self-adjoint H_{HP} such that $\Theta_\xi = \frac{1}{2}\mathrm{id} + iH_{\mathrm{HP}}$ has determinant $\xi_{\mathbb{R}}$ and the Weil–Connes trace distribution. This is the Hilbert–Pólya/Connes–Deninger determinant-trace problem in chiral-homology form.

The arithmetic-gravity construction has two closed unconditional components: the closed finite-level state sums of Chapter 103.4.2 and the ordered incidence-bar calculation of Chapter 103.5.4. Together these yield the Euler/log-prime skeleton (Chapter 103.6.3) without further hypothesis. The remaining inputs are finite cobordism functoriality, profinite renormalisation, local trace comparison, BD/CG comparison, positivity, and the Deninger spectral-flow hypothesis (Chapter 103.9).

103.10 Ordered-Bar Boundary

Two first-principles results close unconditionally. First, closed finite-level arithmetic Chern–Simons state sums and their gluing law follow from étale local-system groupoids and Artin–Verdier integration alone (Chapter 103.4.2). Second, the ordered incidence bar computes the derived colimit of $\mathcal{V}^{\mathrm{prim}}$ over the auxiliary ordered place set via the normalized simplicial replacement (Chapter 103.5.4); this gives the Bost–Connes Euler/log-prime skeleton (Chapter 103.6.3) unconditionally.

The conditional structure has three layers. The profinite $GL_2(\widehat{\mathbb{Z}})$ quantum ACS, its boundary trace

$$\mathrm{HH}_0\big(\partial\,\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}\big) \simeq \mathcal{V}^{\mathrm{prim}},$$

and its zeta partition function $Z = \xi(k^{\mathrm{Ar}})$ are conjectural (Chapter 103.4.7, Chapter 103.4.9, Chapter 103.5.7). The comparison of the ordered incidence model with Beilinson–Drinfeld/Costello–Gwilliam arithmetic chiral homology requires finite-place collision thickenings, descent, and

completion exactness (Chapter 103.5.5). The Deninger spectral-flow hypothesis, equivalently the Hilbert–Pólya/Connes–Deninger determinant-trace realisation, is not produced by the ordered bar and has RH-level strength (Chapter 103.6.5, Chapter 103.6.7).

The arithmetic-gravity construction conditionally reformulates the analytic-number-theoretic F-RH question as a 3D topological-gauge-theoretic question on the étale 3-space $\overline{\mathrm{Spec}\,\mathbb{Z}}$. The reformulation acquires unconditional content only after the six residuals of Chapter 103.9 are supplied; the Deninger spectral-flow hypothesis carries the full Hilbert–Pólya weight.

Chapter 104

Deninger's Arithmetic Cohomology as a Chiral Candidate

Deninger's conjectural formalism demands a cohomology theory for $\overline{\mathrm{Spec}\,\mathbb{Z}}$ whose regularised Fredholm determinant equals the completed Riemann zeta function and whose closed orbits recover the explicit formula. The bar–cobar construction does not construct this cohomology. It constructs a candidate: the ordered-incidence homology of $\mathcal{V}^{\mathrm{prim}}$ (the Hochschild trace class of the identity on the global arithmetic Iwahori Hecke category of GL_2), two formal Tate polar lines, and the Bost–Connes Euler-prime-side character. Whether this candidate realizes Deninger's axioms depends on the spectral-flow hypothesis of Chapter 103.6.5. The central result of this chapter is the obstruction theorem: no unconditional triple identification exists among Deninger's conjectural cohomology, the ordered-incidence candidate, and the boundary homology of the arithmetic Chern–Simons bulk.

104.1 Deninger's Wish List

Deninger's formalism asks for a cohomology theory

$$H^\bullet_\Delta(\overline{\mathrm{Spec}\,\mathbb{Z}})$$

with three cohomological degrees, a Frobenius/flow operator Θ whose regularised determinant has the non-trivial zero divisor, a Lefschetz trace formula whose closed-orbit side is the prime side of the explicit formula, Poincaré duality, and purity. Under zero-placement this may be written as $\Theta = \frac{1}{2} + iH$ with H self-adjoint. For the Riemann zeta function the middle degree should carry the non-trivial zero divisor.

In the next display $\zeta(s)$ follows Deninger's convention: it is the completed zeta function, not the bare Euler product.

$$\zeta(s) \overset{?}{=} \det{}_\infty\big(s\cdot\mathrm{id} - \Theta \mid H^\bullet_\Delta\big)^{(-1)^\bullet}.$$

Here $\det_\infty$ is Deninger's regularised Fredholm determinant, $\zeta(s)$ denotes the completed Hasse–Weil zeta (including the archimedean factor), and the sign $(-1)^\bullet$ is the Euler-characteristic grading. The Lefschetz trace formula takes the form

$$\sum_\rho h(\rho) \overset{?}{=} \sum_\bullet (-1)^\bullet \operatorname{tr}\big(h(\Theta) \mid H^\bullet_\Delta\big) \overset{?}{=} \text{polar terms} + \text{archimedean term} - \sum_{p,k} (\log p)\, p^{-k/2}\widehat{h}(k\log p),$$

where h is a Schwartz test function on $\mathbb{R}$ and $\widehat{h}$ its Fourier transform.

Remark 104.1.1 *(absence of a construction).* The axioms above are not a construction. They specify what the missing arithmetic cohomology must do. The construction provides the prime-side Euler data (via Bost–Connes) and the formal polar lines (by insertion); the zero-side operator is not constructed.

Remark 104.1.2 *(Vol IV scoping).* Chapter 103 isolates the correct boundary: the ordered-incidence bar is theorem-grade as an algebraic model, while the comparison with genuine BD/CG chiral homology, the

profinite quantum ACS theory, and the Deninger spectral flow remain conditional. This chapter keeps that boundary fixed.

104.2 Surviving Inputs

The bar–cobar construction produces four inputs with theorem-grade form; the remainder of the Deninger axioms are either conditional or open.

(i) The finite-level arithmetic Chern–Simons state sum and gluing formula of Chapter 103.4.2. This is a closed finite groupoid state-sum statement, not a full profinite TQFT.

(ii) The ordered-incidence bar Chapter 103.5.3 and its normalized-bar computation Chapter 103.5.4. This computes the explicitly defined incidence model, not automatically BD/CG factorization homology on $\overline{\mathrm{Spec}\,\mathbb{Z}}$.

(iii) The Bost–Connes Euler skeleton Chapter 103.6.3. It gives the KMS character $\zeta(s)$ and the prime-power logarithmic derivative in $\mathrm{Re}(s) > 1$.

(iv) The Deninger spectral-flow hypothesis Chapter 103.6.5: the zero-side determinant divisor, trace distribution, and Hilbert–Pólya self-adjoint determinant-trace operator. This is the single missing piece that the bar–cobar construction does not supply.

104.3 The Chiral Candidate

Given the four inputs above, one may assemble a graded object that mimics Deninger's three-degree shape. The question is whether this assembly is genuinely Deninger's cohomology or only a formal approximation to it.

Let $B^{\mathrm{ord}}_\bullet(\mathcal{V}^{\mathrm{prim}})$ denote the ordered-incidence bar complex of Chapter 103.5.3 applied to $\mathcal{V}^{\mathrm{prim}}$.

Definition 104.3.1 *(arithmetic chiral homology candidate).* . The *arithmetic chiral homology candidate* is

$$H^\bullet_{\mathrm{ord}}(\overline{\mathrm{Spec}\,\mathbb{Z}}, \mathcal{V}^{\mathrm{prim}}) := H^\bullet\big(B^{\mathrm{ord}}_\bullet(\mathcal{V}^{\mathrm{prim}})\big).$$

It is an ordered-incidence model. Calling it genuine arithmetic chiral homology requires the separate BD/CG comparison of Chapter 103.5.5.

Definition 104.3.2 *(Deninger chiral candidate).* . The *Deninger chiral candidate* is the candidate complex of Chapter 103.6.2:

$$H^\bullet_{\Delta,\chi}(\overline{\mathrm{Spec}\,\mathbb{Z}}) := H^\bullet_{\mathrm{Den},\chi}(\overline{\mathrm{Spec}\,\mathbb{Z}}).$$

It consists of the ordered-incidence core, completed continuous duals, and formal Tate polar lines in degrees 0 and 2.

Remark 104.3.3 *(three labels, not one theorem).* Three nearby objects appear: Deninger's conjectural cohomology, the ordered-incidence chiral candidate, and the boundary state space of the conjectural 3D ACS bulk. Their equality is a conditional assertion, not a proved identification.

PROPOSITION 104.3.4 *(conditional Deninger comparison). (on Chapter 103.6.5, the BD/CG comparison Chapter 103.5.5, and the topological-dual choices in Chapter 103.6.2).* The chiral candidate $H^\bullet_{\Delta,\chi}$, together with the two Tate polar lines and the spectral-flow operator assumed in Chapter 103.6.5, carries Deninger's formal axioms for $\overline{\mathrm{Spec}\,\mathbb{Z}}$.

Proof. The finite-prime Euler terms are exactly the Bost–Connes series of Chapter 103.6.3. The polar lines are inserted by definition in Chapter 103.6.2. The zero-side operator, determinant identity, trace formula, and purity are precisely the extra data demanded by Chapter 103.6.5. Thus the statement is a conditional implication, not an independent construction of the missing cohomology. □

104.4 No Triple Identification Yet

Theorem 104.4.1 *(no unconditional triple identification).* . No unconditional equality holds among Deninger's conjectural cohomology, the ordered-incidence chiral candidate, and the boundary homology of $\mathrm{ACS}^{\mathrm{qu}}$.

Proof. The first object is conjectural. The second is an explicitly defined ordered-incidence homology object. The third depends on the profinite quantum ACS conjecture and on a boundary comparison with $\mathcal{V}^{\mathrm{prim}}$. The only theorem-grade equality is the normalized-bar computation of the ordered-incidence model. The BD/CG comparison and spectral-flow identifications are listed as residual conditions in Chapter 103.9. □

Corollary 104.4.2 *(conditional triangle). (on the profinite ACS conjecture, the BD/CG ordered-model comparison, a regularised character map, and the Deninger spectral-flow hypothesis).* These assumptions yield

$$Z_{\mathrm{ACS}^{\mathrm{qu}}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}}) = \xi(k^{\mathrm{Ar}}) = \mathrm{ch}_{\mathrm{reg}}\big(H^{\bullet}_{\Delta,\chi}\big)(k^{\mathrm{Ar}}), \tag{104.1}$$

where $\xi(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ is the completed Riemann zeta function satisfying $\xi(s) = \xi(1-s)$, k^{Ar} is the arithmetic level parameter, and $\mathrm{ch}_{\mathrm{reg}}$ denotes the regularised graded trace (the Θ-eigenvalue generating series with Deninger regularisation). Without those assumptions, (104.1) is a conditional shorthand.

104.5 Frobenius and Flow

The Bost–Connes Euler skeleton provides prime-length data at finite primes. Deninger's formalism requires a global Frobenius/flow operator acting on all three cohomological degrees. The question is whether the Euler skeleton and the archimedean scaling generator combine into such an operator.

Definition 104.5.1 *(finite Euler operators).* . At a finite prime p, the Bost–Connes Adams operation ψ_p records the prime length $\log p$ and contributes the Euler factor $(1-p^{-s})^{-1}$. It is denoted here by

$$F_p^{\mathrm{Euler}} := \psi_p.$$

This is an Euler-skeleton operator, not by itself Deninger's global Frobenius on middle cohomology.

Proposition 104.5.2 *(finite Wilson/Frobenius comparison is conditional). (on the Wilson-line axiom in Chapter 103.4.7).* A Wilson loop around the Morishita knot attached to p should recover the corresponding Frobenius trace. This is part of the conjectural ACS datum, not a consequence of the ordered bar.

Definition 104.5.3 *(archimedean scaling candidate).* . The archimedean scaling generator is the Mellin infinitesimal $-\partial_t$ on $\mathbb{R}_+$. The candidate archimedean flow on $H^{\bullet}_{\Delta,\chi}$ is denoted $\Theta_{\infty,\chi}$. In Deninger's

and Connes' formulation, the target operator has the form $\Theta_\xi = \frac{1}{2}\mathrm{id} + iH_{\mathrm{HP}}$, where H_{HP} is a self-adjoint Hilbert–Polya operator (to be constructed) whose normal determinant divisor is div $\xi_{\mathbb{R}}$. After zero-placement its Weil–Connes trace is supported at the ordinate multiset $\{\gamma_\rho\}$. The identification

$$\Theta_{\infty,\chi} \stackrel{?}{=} \Theta_\xi$$

is the spectral-flow hypothesis and is not available unconditionally.

PROPOSITION 104.5.4 *(Virasoro conjugacy is not available). (on the spectral-flow hypothesis).* Without the spectral-flow theorem of Chapter 103.6.5, the Virasoro L_0^{Ar}, the Bost–Connes logarithmic Hamiltonian, and the Hilbert–Polya operator H_{HP} remain distinct operators. Their identification requires the spectral-flow theorem as input.

Definition 104.5.5 *(formal global flow).* . The formal global flow symbol is

$$F_\chi := \Theta_{\infty,\chi} \oplus \bigoplus_p F_p^{\mathrm{Euler}}.$$

The notation records finite-prime lengths and archimedean scaling. It does not assert a well-defined Deninger Frobenius on a completed cohomology theory.

THEOREM 104.5.6 *(global Frobenius obstruction).* . The ordered-incidence bar and Bost–Connes Euler skeleton do not construct Deninger's global Frobenius operator.

Proof. The Bost–Connes side gives Euler factors and the prime-power series in the half-plane of convergence. Deninger's operator must act on the middle cohomology, must have regularised determinant divisor div $\xi_{\mathbb{R}}$, and must participate in a Lefschetz trace formula. That zero-side operator is exactly the missing spectral-flow input of Chapter 103.6.5. □

Remark 104.5.7 *(archimedean Wilson surface).* The phrase "archimedean Wilson surface" is useful only as a conditional dictionary entry inside the profinite ACS conjecture. It is not an independent construction of Θ_ξ.

104.6 CHARACTER, DEGREES, AND PURITY

The Frobenius obstruction theorem leaves open the question of what the candidate complex does compute. The regularised graded trace and the formal Tate structure answer this question partially: the Euler product and the polar lines are present; the zero-side is missing.

THEOREM 104.6.1 *(character identity is conditional). (on Chapter 103.5.7 and Chapter 103.6.5).* The regularised character of the Deninger chiral candidate is $\xi(s)$ only after the partition-function comparison and the zero-side spectral-flow operator are assumed.

$$\mathrm{ch}_{\mathrm{reg}}\big(H^\bullet_{\Delta,\chi}\big)(s) \stackrel{\mathrm{cond}}{=} \xi(s).$$

Remark 104.6.2 *(normalisation).* The additive determinant form $\det_\infty(s\cdot\mathrm{id} - \Theta)$ and the multiplicative Euler-character form are interchangeable only after the operator Θ, the polar signs, and the regularisation convention have been fixed.

PROPOSITION 104.6.3 *(formal Tate polar lines).* . The candidate complex contains formal one-dimensional Tate lines in degrees 0 and 2. This accounts for the polar terms in the Deninger skeleton but does not prove that the total complex has only Deninger's three degrees.

Proposition 104.6.4 *(middle cohomology is the hard part). (on Chapter 103.6.5).* The middle cohomology $H^1_{\Delta,\chi}$ admits a Hilbert-space completion with a self-adjoint generator having spectrum $\{\gamma_\rho\}$ only after Chapter 103.6.5 is assumed. This is the Hilbert–Polya hypothesis in cohomological form.

Remark 104.6.5 *(critical-line locus).* Purity of the middle degree is the assertion that the zero-side operator has real part 1/2. For zeta this is RH in cohomological language.

104.7 Duality and Positivity

Koszul duality for the arithmetic bar complex gives the functional-equation symmetry $s \leftrightarrow 1 - s$. The question is whether this duality implies Poincaré duality for the Deninger cohomology, and specifically whether it forces the middle degree to be positive definite.

Theorem 104.7.1 *(duality gives the functional equation, not positivity). (on the relevant Koszul and ACS comparison hypotheses).* The Koszul self-duality framework accounts for the functional-equation symmetry $s \leftrightarrow 1 - s$. It does not by itself imply positivity of the Deninger middle pairing or RH.

104.8 Purity as the RH-Level Input

Duality accounts for the functional equation but not for the zero-placement. Purity of the middle cohomological degree is the assertion that the zero-side operator Θ_ξ is self-adjoint with spectrum on the line $\mathrm{Re}(s) = 1/2$, which is RH.

Theorem 104.8.1 *(purity is RH-level). (on the spectral-flow/Hilbert–Polya realisation).* Deninger purity for $H^1_{\Delta,\chi}$, Hilbert–Polya self-adjointness for Θ_ξ, and the RH zero-placement statement are equivalent forms of the same missing input.

Corollary 104.8.2 *(Deninger-chiral RH construction).* . A proof of RH by this route is precisely a proof of the spectral-flow/positivity input. The ordered-incidence bar and the Bost–Connes Euler skeleton reduce the shape of the problem; they do not remove it.

104.9 All-Genus Extension

The preceding sections address $\overline{\mathrm{Spec}\ \mathbb{Z}}$ and the Riemann zeta function. In the notation of Chapter 102.1.1 this is the zeta fibre of the rank-graded arithmetic family, not a smooth surface of curve genus zero. Higher-rank arithmetic data occur in several distinct windows: arithmetic surfaces, totally imaginary number fields, crystalline deformation stacks, Hodge–Arakelov theta data, and Shimura varieties. The formal extension records only what the ordered candidate produces after such a datum has been fixed.

Definition 104.9.1 *(genus-g chiral Deninger candidate).* . A *genus-g arithmetic datum* $\mathcal{D}_g$ means the datum of Chapter 102.1.1. Thus it may be an arithmetic surface only in Windows I and V; in the other windows it is respectively a number-field, crystalline, Hodge–Arakelov, or Shimura datum. The corresponding $\mathcal{V}^{\mathrm{prim},g}$ is the row-specific Hochschild trace class of the identity on the indicated arithmetic Hecke category. In the surface, crystalline, and automorphic rows its oscillator sector has rank $2g$; in the Dedekind row g records the complex embedding rank of the coefficient field. The *genus-g chiral Deninger candidate* is

$$H^\bullet_{\Delta,\chi,g} := H^\bullet_{\mathrm{ord}}(\mathcal{D}_g, \mathcal{V}^{\mathrm{prim},g}).$$

The weight of $\mathcal{D}_g$, denoted $w_{\mathcal{D}_g}$, is the motivic weight of its L-function; purity is the assertion that $\mathrm{Re}(s) = w_{\mathcal{D}_g}/2$ for all non-trivial zeros.

THEOREM 104.9.2 *(all-genus Deninger comparison). (on the all-genus ACS, ordered-model comparison, and spectral-flow hypotheses).* The genus-g candidate carries the expected motivic functional-equation centre and prime-side Euler data. It does not construct the genus-g Deninger cohomology without the same spectral-flow input.

Remark 104.9.3 *(weight convention).* The expected purity line is $\mathrm{Re}(s) = w_{\mathcal{D}_g}/2$. This is a target condition, not a theorem of the ordered bar.

104.10 DICTIONARY

Table 104.1 records which Deninger axioms the chiral candidate supplies and which remain open or conditional.

Deninger target	Chiral/ACS object	Form
finite prime orbit lengths	Bost–Connes Euler skeleton	proved in $\mathrm{Re}(s) > 1$
cohomology object	ordered-incidence candidate plus polar lines	defined, not identified with Deninger cohomology
global Frobenius/flow	spectral-flow operator Θ_ξ	open, Hilbert–Polya strength
determinant = ξ	regularised character	conditional
Lefschetz trace formula	prime-power trace distribution	open
purity	real part 1/2 for middle spectrum	RH-level

TABLE 104.1: Surviving Deninger–chiral dictionary.

104.11 UNCONDITIONAL DENINGER–CHIRAL CONSEQUENCES

The ordered-incidence construction proves the four assertions below; the six remaining comparison maps require the stated hypotheses.

Unconditional consequences

(i) Ordered-incidence homology is computed by the normalized ordered bar.
(ii) The finite-prime Bost–Connes side gives the Euler product and logarithmic derivative in the convergence half-plane.
(iii) The formal Tate polar lines can be inserted as part of the candidate complex.
(iv) Koszul self-duality explains the functional-equation symmetry.

Conditional

(i) Profinite quantum arithmetic Chern–Simons.
(ii) Boundary comparison with $\mathcal{V}^{\mathrm{prim}}$.
(iii) BD/CG comparison with the ordered-incidence model.
(iv) Regularised character equality with ξ.
(v) Spectral flow/Hilbert–Pólya zero-divisor operator.
(vi) Positivity/purity of the middle degree.

104.12 Residual Conditions

The residue is a single mathematical obstruction: construct the middle operator and prove the trace formula with positivity. Equivalently, prove the spectral-flow hypothesis of Chapter 103.6.5. The remaining assertions are unconditional consequences or conditional consequences of that hypothesis.

Chapter 105

Trace Formula, Ordered Bar, and the Statistical Upside

105.1 The Trace Formula Target

Arithmetic Koszul duality assembles an ordered-incidence bar complex whose regularised character reproduces the Euler product of $\xi(s)$. The question it faces is: does this Euler-product data already determine the zero distribution of ξ, or does it leave open a spectral problem? To answer precisely, fix the target.

Definition 105.1.1 *(Weil test-function class).* . Let $\mathcal{H}$ be a standard Weil test-function class: even Schwartz functions $h : \mathbb{R} \to \mathbb{C}$ whose Fourier transforms $\widehat{h}(\tau) = \int_{-\infty}^{\infty} h(t) e^{i\tau t}\, dt$ are compactly supported and sufficiently regular for the explicit formula. The exact analytic class depends on the chosen normalization of the Weil–Guinand formula.

Theorem 105.1.2 *(Weil–Guinand explicit formula).* . Let ρ range over all nontrivial zeros of the completed Riemann zeta function $\xi(s)$, with no critical-line parametrization assumed. For $h \in \mathcal{H}$, the completed zeta function satisfies the distributional identity

$$\sum_{\rho} H(\rho) = W_{\infty}(h) + W_{\mathrm{pol}}(h) - \sum_{p} \sum_{k \geq 1} (\log p)\, p^{-k/2} \big(\widehat{h}(k \log p) + \widehat{h}(-k \log p) \big), \tag{105.1}$$

where H is the complex test function corresponding to h, and $W_{\infty}(h)$ is the archimedean gamma-factor contribution and $W_{\mathrm{pol}}(h)$ is the contribution of the polar and trivial zeros. Denote their sum by $W_{\mathrm{arch+pol}}(h) := W_{\infty}(h) + W_{\mathrm{pol}}(h)$.

Remark 105.1.3 *(three descriptions of the prime-power index set).* The geometric side of (105.1) is a sum over prime powers (p, k). In the Morishita dictionary this is a sum over iterates K_p^k of the prime knot K_p, with length $k \log p$. In a Gutzwiller language it is the periodic-orbit side. In the ordered-bar language it is the logarithmic derivative of the Euler-product character. These are three descriptions of the same prime-power index set; none supplies the zero-side determinant-trace operator.

105.2 Connes' Trace Formula

The Weil explicit formula is a distributional identity; the question is whether the zero sum on its left side admits a determinant-trace interpretation, i.e., whether some natural normal operator has determinant divisor div $\xi_{\mathbb{R}}$ and Weil–Connes trace supported at the ordinates γ_ρ after zero-placement. Connes' adele-class-space construction provides a partial answer.

THEOREM 105.2.1 *(Connes–Meyer scaling trace).* . Connes' adele-class-space construction, in Meyer's trace-formula formulation, realizes the Weil distribution as a distributional scaling trace on the appropriate cokernel space of the adele class space $\mathbb{A}/\mathbb{Q}^*$:

$$\mathrm{Tr}_{\mathrm{Connes}}(h) = \sum_{\rho} H(\rho)$$

distributionally, where ρ ranges over the non-trivial zeros and H is the Mellin transform paired with the test function h. The same prime-power and archimedean terms as (105.1) occur. The scaling operator is not thereby a self-adjoint Hilbert-space operator whose normal translate has determinant $\xi(s)$; the distributional trace is not by itself a spectral measure.

105.3 Ordered-Bar Euler Skeleton

The Connes–Meyer trace recovers the full Weil distribution (105.1) as an operator trace. The ordered-incidence bar complex approaches the same object from the Koszul-duality side: its regularised character computes the Euler product. The question is whether that character calculation closes the gap left by Connes.

PROPOSITION 105.3.1 *(ordered-bar Euler skeleton). (on the ordered-incidence model of Chapter 103.5.4 and on the chosen regularised character).* Let $\chi_\infty(s)$ denote the archimedean Euler factor arising from the regularisation at the archimedean place of $\overline{\mathrm{Spec}\,\mathbb{Z}}$. The ordered-incidence bar complex $B^{\mathrm{ord}}_\bullet(\mathcal{V}^{\mathrm{prim}})$, where $\mathcal{V}^{\mathrm{prim}}$ is the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2, has regularised character

$$\mathrm{ch}_{\mathrm{reg}}\, H_\bullet(B^{\mathrm{ord}}_\bullet(\mathcal{V}^{\mathrm{prim}})) = \chi_\infty(s) \prod_p (1 - p^{-s})^{-1}, \tag{105.2}$$

with the completed $\xi(s)$ obtained only after the archimedean and polar normalisations are inserted.

Proof. This is the Euler-character computation of the ordered-incidence model: finite prime factors contribute the Bost–Connes Euler factors, while the archimedean and polar pieces are part of the regularisation data. The statement is a character calculation, not a Lefschetz trace formula. □

Remark 105.3.2 *(canonical quantisation boundary).* If the profinite ACS theory and boundary comparison are assumed, the same regularised character can be read as a boundary partition function. That reading is conditional on Chapter 103.4.7 and Chapter 103.4.9.

105.4 Trace-Formula Equivalence

The Euler-product character of Proposition 105.3.1 yields $\xi(s)$ only after regularisation. Under the regularised character equality of Chapter 103.5.7, which sets $Z(s) = \xi(s)$ in the ACS framework, the argument principle converts the logarithmic derivative of ξ into the zero sum; the Weil–Guinand explicit formula then identifies this with the full Weil distribution. The three trace functionals are conditionally equal.

THEOREM 105.4.1 *(conditional equivalence of trace functionals). (on Chapter 103.4.7, Chapter 103.5.5, and the regularised character equality Chapter 103.5.7).* Let Γ_T be a positively oriented rectangle

enclosing the zeros of ξ with $|\operatorname{Im} s| \le T$, avoiding zeros on the boundary. The ACS argument-principle functional

$$\mathcal{Z}_h := \frac{1}{2\pi i}\int_{\Gamma_T} H(s)\frac{Z'(s)}{Z(s)}\,ds$$

converges, after the standard $T \to \infty$ limiting procedure and the polar and trivial-zero subtractions, to the Weil explicit-formula functional (105.1) whenever $Z(s) = \xi(s)$ is assumed.

Proof. Under the stated assumptions $Z = \xi$. Applying the argument principle to ξ'/ξ inside Γ_T gives the zero sum $\sum_{|\operatorname{Im}\rho|\le T} H(\rho)$, together with polar and trivial-zero residues. Expanding ξ'/ξ in the half-plane $\operatorname{Re}(s) > 1$ of absolute convergence and performing the standard explicit-formula contour shift yields the prime-power side of (105.1). The equality is inherited from the classical Weil–Guinand explicit formula. □

Corollary 105.4.2 *(equality of the ACS and Connes–Meyer distributions on $\mathcal{H}$). (on the hypotheses of Chapter 105.4.1).* For every $h \in \mathcal{H}$, the ACS functional $\mathcal{Z}_h$ and the Connes–Meyer scaling trace $\operatorname{Tr}_{\text{Connes}}(h)$ are equal.

105.5 The Bar Reorganises, Not Locates

The equivalence of the three trace functionals established conditionally in Section 105.4 raises a sharper question: does the ordered-bar construction supply an independent mechanism for placing the zero ordinates γ_n on the critical line, beyond what $\xi(s)$ itself encodes? The bar computation reorganises the zero data of ξ; it does not add new data.

Theorem 105.5.1 *(bar computation reorganises zero data).* . The ordered-incidence bar complex determines the individual zero ordinates γ_n only through the scalar function ξ: no additional self-adjoint operator or positivity mechanism is produced by the bar calculation.

Proof. The bar supplies the Euler-product character and, after conditional regularisation, the scalar function ξ. The zero ordinates are then the zero set of that scalar function. The bar calculation produces no self-adjoint operator, spectral theorem, or positivity input beyond what ξ already carries. □

Remark 105.5.2 *(the Hilbert–Pólya obstruction).* A self-adjoint operator with spectrum $\{\gamma_n\}$ would place the zeros on the critical line by the spectral theorem. Constructing such an operator is precisely the spectral-flow obstruction of Chapter 103.6.5.

105.6 Arithmetic Gutzwiller

The zero ordinates γ_n appear on the zero side of (105.1) and, conditionally, as the spectrum of the Hilbert–Pólya operator. The prime-power sum on the geometric side of (105.1) takes the same form as the periodic-orbit sum in the Gutzwiller trace formula: lengths $k \log p$ and amplitudes $(\log p)\,p^{-k/2}$. The prime-power side of the Weil formula is a periodic-orbit sum in Gutzwiller's sense, conditional on the existence of an arithmetic Hamiltonian whose primitive periodic orbits are the primes.

Theorem 105.6.1 *(classical Gutzwiller trace formula).* . Let H be a quantum Hamiltonian whose classical limit is chaotic with isolated primitive periodic orbits γ. Write $d_{\text{osc}}(E)$ for the oscillatory part of

the density of states $\sum_n \delta(E - E_n)$, T_γ for the period of orbit γ, A_γ for its stability amplitude (Maslov–Gutzwiller amplitude, incorporating the stability matrix determinant), and μ_γ for its Maslov index. Then

$$d_{\mathrm{osc}}(E) \sim \sum_\gamma A_\gamma \exp(iET_\gamma - i\mu_\gamma \pi/2),$$

asymptotically as $\hbar \to 0$.

THEOREM 105.6.2 *(arithmetic Gutzwiller hypothesis). (on a semiclassical ACS Hamiltonian, an arithmetic phase space, and a prime-orbit correspondence).* Call the amplitudes $A_p = (\log p)\, p^{-1/2}$ and lengths $T_p = \log p$ the *Weil amplitudes* for the prime p. If the ACS boundary Hamiltonian has a classical chaotic limit whose primitive periodic orbits are indexed by primes p with primitive period $\log p$ and stability amplitude A_p, then the periodic-orbit expansion has the desired form

$$\sum_p \sum_{k \geq 1} (\log p)\, p^{-k/2} e^{itk \log p} \quad + \quad \text{complex conjugate and archimedean terms.}$$

Proof. This is substitution of the assumed arithmetic orbit dictionary into the classical Gutzwiller formula. The proof is formal because the semiclassical ACS phase space, the chaotic flow, and the amplitude calculation are all hypotheses. □

105.7 Connes–Meyer and the Gutzwiller Gap

The arithmetic Gutzwiller hypothesis of the previous section requires a smooth symplectic Hamiltonian system with a chaotic classical limit. The question is whether the Connes–Meyer construction already supplies this structure, or whether the Gutzwiller construction is genuinely new input.

THEOREM 105.7.1 *(Connes–Meyer as distributional trace, not Gutzwiller system).* . The standard adele-class-space realization used in the Connes–Meyer trace formula is a noncommutative scaling trace construction. It is distinct from a smooth symplectic Hamiltonian system of the kind required by the classical Gutzwiller theorem.

Proof. The adele class space $\mathbb{A}/\mathbb{Q}^*$ is modeled by a noncommutative quotient; its C^*-algebraic description gives an operator-algebraic trace. The Gutzwiller formula requires a smooth symplectic phase space, a Hamiltonian flow, isolated primitive periodic orbits, and monodromy matrix determinants. None of these are part of the Connes–Meyer construction as stated. □

Remark 105.7.2 *(other geometrisations remain open).* Other geometrisations of the adele class space may supply a symplectic structure; the theorem records only that the standard Connes–Meyer trace formula is not itself a Gutzwiller mechanism. An arithmetic Gutzwiller system, if it exists, is new structure beyond Connes–Meyer.

105.8 Statistical Upside

The explicit formula (105.1) is a distributional identity; it does not determine the individual zero ordinates γ_n beyond what $\xi(s)$ already encodes. A Hilbert–Pólya operator, if it exists, would put the determinant divisor on the critical line by self-adjointness. The further statistical prediction, that the local spacing statistics of the γ_n follow the Gaussian Unitary Ensemble (GUE), is not implied by either the explicit formula or self-adjointness alone. It requires a dynamical mechanism: the Bohigas–Giannoni–Schmit

(BGS) principle connecting chaotic classical dynamics to random-matrix statistics. The relevant symmetry class is GUE because $\xi(s)$ has no anti-unitary time-reversal symmetry; the unitary symmetry class applies. Let $R_2(u)$ denote the two-point level spacing correlation function.

Theorem 105.8.1 *(Bohigas–Giannoni–Schmit principle).* . Quantum systems whose classical limits are chaotic are expected, after symmetry class is fixed, to exhibit random matrix local spectral statistics. For the unitary symmetry class (GUE), the two-point correlation function is

$$R_2(u) = 1 - \left(\frac{\sin \pi u}{\pi u}\right)^2. \tag{105.3}$$

Theorem 105.8.2 *(conditional statistical upside). (on Chapter 103.6.5, Chapter 105.6.2, arithmetic quantum chaos, and the BGS universality theorem Chapter 105.8.1).* If the ACS Hamiltonian of Chapter 103.6.5 has a chaotic semiclassical limit with prime periodic orbits, then the local statistics of the zero ordinates are governed by the corresponding random-matrix ensemble; in the expected zeta case by GUE statistics (105.3).

Proof. Spectral flow supplies the zero-divisor determinant and, after zero-placement, the Hamiltonian trace supported at the ordinates. Arithmetic Gutzwiller identifies the classical periodic orbits with prime powers. The BGS principle then transfers chaotic spectral statistics to the zero ordinates. Every substantive step is one of the stated hypotheses. □

Remark 105.8.3 *(GUE statistics as new content beyond the explicit formula).* The Weil explicit formula establishes a distributional equality between the zero ordinates and the prime-power sum; it implies neither Montgomery pair correlation nor GUE spacing statistics. A 3D Hamiltonian realization of the arithmetic ACS theory adds that statistical mechanism, conditional on the semiclassical and spectral-flow hypotheses of Chapter 103.6.5.

Remark 105.8.4 *(open conditions as explicit hypotheses).* Chapter 105.8.2 rests on seven open conditions: (1) the profinite quantum ACS on $\overline{\mathrm{Spec}\,\mathbb{Z}}$; (2) the Bezrukavnikov–Finkelberg and Costello–Gwilliam comparison with the ordered-incidence model; (3) the regularised character equality $Z = \xi$; (4) the spectral-flow operator realizing Hilbert–Pólya; (5) the full Weil–Guinand contour shift from the Euler skeleton; (6) the arithmetic semiclassical phase space and Hamiltonian flow; (7) chaos and random-matrix universality for that flow. These are the explicit hypotheses of Chapter 105.8.2. The ordered bar supplies the finite Euler skeleton (105.2); the equality $Z = \xi$ also requires the archimedean, polar, and regularised character inputs. Conditions (1), (4), (6), and (7) constitute the spectral-flow problem of Chapter 103.6.5.

Chapter 106

The Wilson Line–Frobenius Identity on $\overline{\mathrm{Spec}\,\mathbb{Z}}$

The prime knot $K_p \subset \overline{\mathrm{Spec}\,\mathbb{Z}}$ is the codimension-two defect at a rational prime p; the Wilson loop $W_\rho(K_p)$ is the holonomy of a flat G-connection around that defect, evaluated in a representation ρ. The fundamental question of this chapter is whether, for an unramified ρ, the Wilson expectation equals the Frobenius trace: whether $\langle W_\rho(K_p)\rangle = \mathrm{tr}\,\rho(\mathrm{Frob}_p)$. Witten's 1989 path-integral construction, transplanted via the Morishita dictionary to the arithmetic 3-space, reduces the Wilson integral to a character evaluation on the Frobenius conjugacy class in the punctured tubular category. On the closed base the finite etale torsor is trivial; non-trivial Frobenius data enter after the defect is retained. This identification is finite-level local and is conditional at the profinite limit (Theorem 106.5.1(2)), with the single residual being the renormalised inverse limit of Chapter 103.4.7.

106.1 Setup and Conventions

The arithmetic 3-space is $M = \overline{\mathrm{Spec}\,\mathbb{Z}}$, the Arakelov compactification of $\mathrm{Spec}\,\mathbb{Z}$ by the archimedean place $\{\infty\}$. By Mazur 1973 and Artin–Verdier, M is etale cohomologically 3-dimensional with fundamental class $[M] \in H^3_{\text{ét}}(M, \widehat{\mathbb{Z}})$ (Chapter 103.1).

Definition 106.1.1 *(prime knot in the Morishita dictionary).* . For a rational prime p, the *prime knot* $K_p \subset M$ is the codimension-two etale closed embedding $\mathrm{Spec}\,\mathbb{F}_p \hookrightarrow \mathrm{Spec}\,\mathbb{Z} \subset M$. Its tubular neighborhood is $\mathrm{Spec}\,\mathbb{Z}_p$. Its complement is $M \setminus K_p \cong \mathrm{Spec}\,\mathbb{Z}[1/p] \cup \{\infty\}$. Under the Mazur 1973 / Morishita 2012 (arXiv:0904.3399) dictionary, K_p plays the role of a framed knot: the meridian is the inertia subgroup $I_p \subset G_{\mathbb{Q}_p}$; the longitude and Frobenius class carry the decomposition quotient $G_{\mathbb{Q}_p}/I_p = \widehat{\mathbb{Z}} \cdot \mathrm{Frob}_p$.

Remark 106.1.2 *(the arithmetic loop is a Frobenius, not a geometric loop).* $\mathrm{Spec}\,\mathbb{Z}$ is not a smooth 3-manifold; the loop around K_p is not a smooth curve. Following Chapter 103.1.1, *loop around the knot* K_p is a name for the generator of the etale fundamental group of the tubular neighbourhood $\mathrm{Spec}\,\mathbb{Z}_p \setminus K_p = \mathrm{Spec}\,\mathbb{Q}_p$; this fundamental group is the absolute Galois group $G_{\mathbb{Q}_p}$, whose inertia quotient $\widehat{\mathbb{Z}}$ is topologically generated by the arithmetic Frobenius Frob_p. Wilson-line observables on K_p in the arithmetic theory evaluate functions on conjugacy classes of $G_{\mathbb{Q}_p}$, not on free-homotopy classes of a geometric circle.

Convention 106.1.3 *(Frobenius normalisation).* . We use the *arithmetic* Frobenius $\mathrm{Frob}_p \in G_{\mathbb{Q}_p}/I_p$, acting on residue-field points by $x \mapsto x^p$. At a ramified prime, Frob_p means the image in the tame quotient; the residual obstruction at wild places is recorded in Chapter 106.7. Traces $\mathrm{tr}\,\rho(\mathrm{Frob}_p)$ are unnormalised. The geometric Frobenius is $\mathrm{Frob}_p^{\mathrm{geom}} = \mathrm{Frob}_p^{-1}$. Euler factors below are written with geometric Frobenius. The analytic shift by $p^{1/2}$ required to match $W_\rho(K_p)$ with the local L-factor is fixed in Chapter 106.6.

Definition 106.1.4 *(boundary WZW representation).* . The boundary Chern–Simons theory of Chapter 103 requires representations of $G_{\mathbb{Q}_p}$ that are compatible with the global boundary data at $\{\infty\}$. A

boundary WZW representation at p is a continuous representation $\rho\colon G_{\mathbb{Q}_p} \to GL_n(\overline{\mathbb{Q}}_\ell)$ arising as the local restriction of a global representation $\rho\colon \pi_1^{\text{ét}}(M) \to GL_n$ together with the datum of a compatible module of the (finite-level) boundary category $\mathcal{B}_{G_N,\alpha_N}(\{\infty\})$ of Chapter 103.4.3, in the sense that the Tate-restricted tensor of its local spherical parameters recovers the generating class of $\mathcal{V}^{\text{prim}}$ (the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category; Chapter 103).

106.2 Classical Wilson Loops (Kim ACS)

The unconditional footing is the abelian classical theory of Kim arXiv:1510.05818, where the Wilson loop expectation is a finite groupoid sum and the Frobenius trace identity is a direct evaluation.

Definition 106.2.1 *(classical Kim Wilson loop).* . Let A be a finite abelian group, $c \in H^3(BA, \mathbb{R}/\mathbb{Z})$ a level cocycle, and $\chi\colon A \to \mathbb{C}^\times$ a character. For a prime p, the *Kim classical Wilson loop along K_p in representation χ* is the functional

$$W^{\text{cl}}_{\chi,A,c}(K_p)(\rho) \;:=\; \chi\big(\rho(\mathrm{Frob}_p)\big)\cdot \exp\!\big(2\pi i\,\mathrm{CS}^{\mathrm{Ar}}_{M,c}(\rho)\big), \tag{106.1}$$

for $\rho\colon \pi_1^{\text{ét}}(M) \to A$ in the field groupoid $\mathcal{F}_A(M)$ (the groupoid of continuous A-torsors on M, i.e. continuous homomorphisms $\pi_1^{\text{ét}}(M) \to A$ with isomorphisms as morphisms; Chapter 103), with $\mathrm{CS}^{\mathrm{Ar}}_{M,c}(\rho) \in \mathbb{Q}/\mathbb{Z}$ the Kim arithmetic Chern–Simons invariant ((103.1)).

THEOREM 106.2.2 *(closed-base classical Wilson expectation).* . Let $M = \overline{\mathrm{Spec}\,\mathbb{Z}}$, A finite abelian, $c \in H^3(BA, \mathbb{R}/\mathbb{Z})$ a level cocycle (with $\exp(2\pi i\,\cdot)\colon \mathbb{R}/\mathbb{Z} \to \mathbb{C}^\times$ used throughout). Since the closed arithmetic curve has no non-trivial finite etale A-torsor, every $\rho \in \mathcal{F}_A(M)$ is trivial. For any character $\chi\colon A \to \mathbb{C}^\times$, the Kim classical action satisfies

$$\langle W^{\text{cl}}_{\chi,A,c}(K_p)\rangle_{Z^{\text{cl,Ar}}_{\mathrm{CS},c}(M)} \;=\; \frac{1}{Z^{\text{cl,Ar}}_{\mathrm{CS},c}(M)} \sum_{\rho\in\pi_0\mathcal{F}_A(M)} \frac{\chi(\rho(\mathrm{Frob}_p))\,\exp(2\pi i\,\mathrm{CS}^{\mathrm{Ar}}_{M,c}(\rho))}{|\mathrm{Aut}(\rho)|}. \tag{106.2}$$

Thus the closed-base value is the trivial-torsor value $\chi(1)$, up to the explicit Kim normalisation. Non-trivial Frobenius traces live on the punctured tubular category $M_p^\circ := \overline{\mathrm{Spec}\,\mathbb{Z}} \setminus K_p$ with prescribed local monodromy.

Proof. The expectation (106.2) is the groupoid-cardinality integral from Chapter 103.4.2, the Wilson insertion $\chi(\rho(\mathrm{Frob}_p))$ being a locally-constant function of $\rho \in \mathcal{F}_A(M)$. Hermite–Minkowski gives triviality of finite etale torsors over the closed arithmetic curve. Hence $\rho(\mathrm{Frob}_p) = 1$ on the closed base. The residue-field quotient factorisation for unramified local monodromy is Kim arXiv:1510.05818 §3, restated in Chapter 103.4.6; it belongs to M_p°, not to a non-trivial closed torsor. □

Remark 106.2.3 *(abelian A is unconditional).* Unlike the conjectural profinite $GL_2(\widehat{\mathbb{Z}})$ theory, finite abelian A has no renormalisation residual: the state sum Chapter 103.4.2 is finite and (106.2) is a direct evaluation. The classical theory is the unconditional footing.

Remark 106.2.4 *(independence of sources and domain of the classical identity).* The derivation of Theorem 106.2.2 draws on three independent constructions: Kim arXiv:1510.05818 and Chern–Dan–Kim–Park arXiv:1609.03012 provide the classical action and finite state sum; Borger arXiv:0906.3146 §8 provides the Bost–Connes ψ_p as Frobenius trace in the λ-ring language. These are independent from one another. Kim works in $\mathbb{Q}/\mathbb{Z}$-valued Chern–Simons; the exponentiation lands in $\mathbb{C}^\times$; the character χ

is unitary. All conventions match Chapter 103.1. The ambient category is finite groupoids of continuous A-local systems on $\pi_1^{\text{ét}}(M)$. Unramified χ at p is required for the residue-field collapse; wild and ramified χ carry extra data recorded in Chapter 106.7. Pullback along $\operatorname{Spec}\mathbb{Z}_p \hookrightarrow M$ preserves the Wilson insertion because Frob_p generates the meridian after localisation and χ is a class function. The classical state sum admits independent verification through the Bost–Connes partition calculation of Chapter 77, independent from Kim's level-cocycle construction.

106.3 Quantum Extension Framework (Ch. 103 Conditional)

The abelian classical theory has a non-abelian quantum extension for $G = GL_2(\widehat{\mathbb{Z}})$, defined as a renormalised inverse limit over the finite-level theories of Section 106.2. The existence and properties of this limit are the content of Chapter 103.4.7; the present section records the definitions used in Theorem 106.5.1.

Definition 106.3.1 *(quantum Wilson loop, profinite GL_2).* . Let $G_N = GL_2(\mathbb{Z}/N\mathbb{Z})$ and let α_N be a compatible tower of levels as in Chapter 103.4.7. For a prime p not dividing N and an unramified representation $\rho\colon G_{\mathbb{Q}_p} \to GL_2(\mathbb{Z}/N\mathbb{Z})$, the *level-$N$ Wilson loop along K_p in representation ρ* is

$$W_\rho^{\mathrm{qu},N}(K_p) \;:=\; \frac{Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M, K_p, \rho)}{Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M)}, \tag{106.3}$$

with $Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M, K_p, \rho)$ the finite state sum of Chapter 103.4.2 with a Wilson defect of type ρ along K_p. The *profinite Wilson loop* is the renormalised limit

$$W_\rho^{\mathrm{qu}}(K_p) \;:=\; \operatorname*{ren\,lim}_{\longleftarrow N} W_{\rho_N}^{\mathrm{qu},N}(K_p), \tag{106.4}$$

when the tower of reductions $\rho_N\colon G_{\mathbb{Q}_p} \to G_N$ is compatible.

Remark 106.3.2 *(quantum form).* Each $W_\rho^{\mathrm{qu},N}(K_p)$ is a finite sum (Chapter 103.4.2) and carries no renormalisation issue. The residual is purely in the *limit* step: Chapter 103.4.7 states that the renormalised inverse limit exists, agrees with the canonical-quantisation definition of the continuous-group path integral, and reproduces the boundary datum $\mathcal{V}^{\mathrm{prim}}$ (the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category; Chapter 103). Finite-N Wilson identities below are unconditional; the continuous-group statement is conditional on that limit.

106.4 Morishita Functoriality

For Theorem 106.5.1, the Wilson observable must be a well-defined class function on Frobenius conjugacy classes; this requires functoriality of the Frobenius-class assignment under change of prime. The Morishita dictionary provides this functoriality on the unramified locus.

Theorem 106.4.1 *(Morishita functor for Wilson observables).* . Let $\mathrm{Knot}^{\mathrm{Ar}}$ denote the category of prime-knot data $(K_p, \pi_1^{\text{ét}}(\mathrm{tube}_p))$ on $\overline{\operatorname{Spec}\mathbb{Z}}$ with morphisms the Galois-equivariant embeddings of tubular neighbourhoods. The assignment

$$\begin{aligned} \Phi_{\mathrm{Mor}}\colon \mathrm{Knot}^{\mathrm{Ar}} &\longrightarrow \mathrm{Conj}(G_N) \\ K_p &\longmapsto [\mathrm{Frob}_p^{K_p}] \end{aligned}$$

is a well-defined functor on the unramified locus, where $\mathrm{Conj}(G_N)$ is the set of conjugacy classes of G_N (viewed as a discrete category) and $[\mathrm{Frob}_p^{K_p}]$ is the conjugacy class of the Frobenius generator of $G_{\mathbb{Q}_p}/I_p$ under the ambient representation $\rho\colon \pi_1^{\text{ét}}(M) \to G_N$. The functor Φ_{Mor} intertwines the classical Wilson observable (106.1) with the character evaluation $[\mathrm{Frob}_p^{K_p}] \mapsto \chi([\mathrm{Frob}_p^{K_p}])$.

Proof. We verify the three functorial properties. Object-level: on the unramified locus, ρ factors through the tame quotient $G_{\mathbb{Q}_p}/I_p = \widehat{\mathbb{Z}}$; the image of a topological generator is $\rho(\mathrm{Frob}_p) \in G_N$, whose conjugacy class is well defined independently of the choice of lift (standard: change of lift differs by I_p, which acts trivially by the unramifiedness hypothesis). Morphism-level: a Galois-equivariant embedding of tubular neighbourhoods $\operatorname{Spec}\mathbb{Z}_p \hookrightarrow \operatorname{Spec}\mathbb{Z}_q$ induces a restriction of local systems and hence a map of Frobenius classes by functoriality of the inertia-quotient assignment. Compatibility with Wilson observable: the classical Wilson insertion $\chi(\rho(\mathrm{Frob}_p))$ depends on ρ only through the conjugacy class $[\rho(\mathrm{Frob}_p)]$, since χ is a class function. This is functoriality of the Wilson-character correspondence. □

Remark 106.4.2 *(meridian and longitude).* At a rational prime p, the local fundamental group $G_{\mathbb{Q}_p}$ fits in the Morishita dictionary as follows: the meridian is I_p (topologically a $\widehat{\mathbb{Z}}(1)$ at tame primes); the longitude is a fixed lift of $\mathrm{Frob}_p \in G_{\mathbb{Q}_p}/I_p$. The Wilson holonomy around the meridian records the ramification; the Wilson holonomy along the longitude records the Frobenius trace. In the unramified case, ρ factors through the longitude and the Wilson loop reads the Frobenius trace cleanly.

106.5 Main Theorem

THEOREM 106.5.1 *(Wilson line = Frobenius trace on unramified locus). (conditional on Chapter 103.4.7 for the continuous-group step, and on the renormalised profinite limit therein; unconditional at finite level in the punctured local category).* Let $M_p^\circ = \overline{\operatorname{Spec}\mathbb{Z}} \setminus K_p$ and let p be an unramified rational prime. For each continuous unramified local representation $\rho\colon G_{\mathbb{Q}_p} \to GL_2(\overline{\mathbb{Q}}_\ell)$ factoring through a finite quotient tower $\rho_N\colon G_{\mathbb{Q}_p} \to G_N = GL_2(\mathbb{Z}/N\mathbb{Z})$ with N coprime to p:

(i) *Finite-level identity (unconditional).* For every N coprime to p, the level-N Wilson loop of Chapter 106.3.1 satisfies

$$W_{\rho_N}^{\mathrm{qu},N}(K_p) \;=\; \frac{1}{Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M_p^\circ)} \sum_{\sigma\in\pi_0\mathcal{F}_{G_N}(M_p^\circ)} \frac{\operatorname{tr}\rho_N(\sigma(\mathrm{Frob}_p))\,\exp(2\pi i\,\mathrm{CS}^{\mathrm{Ar}}_{M_p^\circ,\alpha_N}(\sigma))}{|\mathrm{Aut}(\sigma)|}. \tag{106.5}$$

At level $\alpha_N = 0$ and for ρ_N the inclusion $G_N \hookrightarrow GL_2(\mathbb{Z}/N\mathbb{Z})$ specialised at the prescribed unramified local field $\sigma = \rho_N$, this specialises to $W_{\rho_N}^{\mathrm{qu},N}(K_p) = \operatorname{tr}\rho_N(\mathrm{Frob}_p)$.

(ii) *Profinite identity (conditional on the renormalised limit of Chapter 103.4.7).* The profinite Wilson loop (106.4) equals the Frobenius trace

$$W_\rho^{\mathrm{qu}}(K_p) \;=\; \operatorname{tr}\rho(\mathrm{Frob}_p), \tag{106.6}$$

as an element of $\overline{\mathbb{Q}}_\ell$ (identified with $\mathbb{C}$ under a chosen embedding), where the right side is the trace of the arithmetic Frobenius acting on the underlying finite-rank module of ρ.

Proof. (1) Start from Chapter 103.4.2: the state sum $Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M)$ integrates by groupoid cardinality over $\mathcal{F}_{G_N}(M)$ (the groupoid of continuous G_N-torsors on M, the non-abelian analogue of $\mathcal{F}_A(M)$ from

Definition 106.2.1). Insertion of a Wilson defect of type ρ_N along K_p multiplies the integrand by the class function $\sigma \mapsto \operatorname{tr} \rho_N(\sigma(\mathrm{Frob}_p))$, well defined on $\mathcal{F}_{G_N}(M)$ by Chapter 106.4.1 and unramifiedness of p with respect to G_N (the coprimality $\gcd(N, p) = 1$). The ratio (106.3) is then (106.5). The specialisation at $\alpha_N = 0$ uses the level-zero collapse: the phase $\exp(2\pi i \operatorname{CS}^{\mathrm{Ar}}_{M,0}(\sigma)) = 1$ for every σ, so the sum reduces to the character of G_N averaged on $\mathcal{F}_{G_N}(M)$. On the locus where ρ_N is the unique G_N-torsor up to isomorphism (the generic case), $\mathcal{F}_{G_N}(M)$ is concentrated at the point $\sigma = \rho_N$ and the average reduces to $\operatorname{tr} \rho_N(\mathrm{Frob}_p)$; on the non-generic locus where multiple isomorphism classes of G_N-torsors exist, the average is a weighted sum over the classes and the right side of (106.5) must be read with these multiplicities.

(2) Take the renormalised inverse limit $\varprojlim^{\mathrm{ren}}$ of (106.5) as $N \to \infty$ along a tower compatible with ρ_N. The right side is the trace of $\rho(\mathrm{Frob}_p)$ by continuity of the trace: each ρ_N is the mod-N reduction of ρ; the limit of $\operatorname{tr} \rho_N(\mathrm{Frob}_p)$ is $\operatorname{tr} \rho(\mathrm{Frob}_p)$ in $\overline{\mathbb{Q}}_\ell$ by definition of the $\varprojlim$-topology on compact-generator traces. The left side is $W^{\mathrm{qu}}_\rho(K_p)$ by definition (106.4). Existence of the renormalised limit is exactly Chapter 103.4.7; its conclusion includes the Wilson-line axiom Chapter 103.4.7(3). Under that conjecture, (106.6) holds. □

Remark 106.5.2 *(what the proof provides and what it does not).* Part (1) is a fully unconditional identity at each finite level N coprime to p, for each unramified ρ_N, with the Frobenius trace appearing as a class-function insertion in the finite state sum. It upgrades the Wilson-line evaluation from axiom Chapter 103.4.7(3) at the finite level to an arithmetic-geometric theorem. Part (2) is conditional on the continuous-group renormalised limit of Chapter 103.4.7. The Frobenius-trace side is classical (Deligne–Serre–Lafforgue); the Wilson side depends on the continuous-group construction of Ch. 103. The residual is the limit step, not the identity itself.

Remark 106.5.3 *(independence of sources and domain of the main theorem).* The derivation of Theorem 106.5.1 rests on five independent constructions: Witten 1989 *Commun. Math. Phys.* 121 (path integral for Wilson loops in 3D Chern–Simons); Morishita 2012 arXiv:0904.3399 (knots-primes dictionary); Kim 2015 arXiv:1510.05818 and Chern–Dan–Kim–Park 2018 arXiv:1609.03012 (classical arithmetic Chern–Simons); Borger 2009 arXiv:0906.3146 §8 (ψ_p = Frobenius trace in the λ-ring language); Fargues–Scholze 2021 arXiv:2102.13459 (local geometrisation). These are pairwise independent and disjoint from the derivation path of Chapter 103.

The geometric-versus-arithmetic Frobenius distinction is fixed in Convention 106.1.3; the character is unitary; cohomological and etale conventions are bridged by the Artin–Verdier fundamental class. At each finite level the ambient category is finite groupoids; the continuous-group step is a $\varprojlim$ in nuclear complete topological objects (Remark 106.3.2). Unramifiedness of p with respect to N (i.e. $\gcd(N, p) = 1$) and unramifiedness of ρ at p are both required for the Frobenius class to be well defined; ramified and wild cases are Section 106.7. Wilson evaluation is a class function, hence preserved by conjugation; Morishita pullback preserves the Frobenius class by Theorem 106.4.1. The renormalised $\varprojlim$ over $G_N \to GL_2(\widehat{\mathbb{Z}})$ is open (Chapter 103.4.7). The finite state-sum calculation (Chapter 103.4.2) is independent from the Bost–Connes partition calculation of Chapter 77, which provides an independent numerical check on the finite-level identity.

Remark 106.5.4 *(reconciliation with the finite-abelian case).* At $n = 1$ with A finite abelian, Chapter 106.5.1(1) specialises to Chapter 106.2.2: the trace of the one-dimensional representation χ at Frob_p is $\chi(\mathrm{Frob}_p)$ itself, confirmed by the Kim classical state sum. This reconciliation pins the normalisation.

106.6 Local Langlands Compatibility

The identity $W_\rho^{\mathrm{qu}}(K_p) = \operatorname{tr}\rho(\mathrm{Frob}_p)$ of Theorem 106.5.1 connects the gauge-theory Wilson expectation to a Galois-side datum. The Euler factor uses the inverse conjugacy class $\rho(\mathrm{Frob}_p^{\mathrm{geom}})$; the translation from the Galois side to the automorphic Satake parameter fixes this normalisation.

THEOREM 106.6.1 *(local L-factor via Wilson loop). (conditional on Chapter 106.5.1(2), hence on Chapter 103.4.7).* Let ρ be unramified at p. Then

$$L_p(\rho, s) \;=\; \det\!\big(1 - \rho(\mathrm{Frob}_p^{\mathrm{geom}})\, p^{-s}\big)^{-1} \;=\; \exp\!\left(\sum_{r\geq 1} \frac{\operatorname{tr}(\rho(\mathrm{Frob}_p^{\mathrm{geom}})^r)}{r}\, p^{-rs}\right),$$

where the Wilson data must include the full conjugacy class, or equivalently all power traces. The single scalar $W_\rho^{\mathrm{qu}}(K_p) = \operatorname{tr}\rho(\mathrm{Frob}_p)$ determines only the linear coefficient of the characteristic polynomial. Under the unramified local Langlands correspondence of Tate 1979 (*Number theory past and present*, Corvallis II, §3) for GL_1 and Satake 1963 / Borel 1976 (Corvallis II, §3) for GL_n, the RHS equals the Satake-parameter expression of the local L-factor of an unramified automorphic representation π_p with parameter $\rho(\mathrm{Frob}_p^{\mathrm{geom}})$.

Proof. The determinant formula is the definition of the unramified Euler factor attached to the conjugacy class $\rho(\mathrm{Frob}_p^{\mathrm{geom}})$. The exponential identity is the formal equality $-\log\det(1 - Ax) = \sum_{r\geq 1} \operatorname{tr}(A^r)x^r/r$. The Wilson loop determines this factor only when the Wilson datum is the full conjugacy class, equivalently the compatible system of power traces. The Satake/Borel identification of the characteristic-polynomial expression with the unramified local L-factor is Tate 1979 / Borel 1976. □

COROLLARY 106.6.2 *(global L-function from Wilson loops). (on Chapter 106.5.1(2), Chapter 103.4.7, and the archimedean Wilson-surface identification of Chapter 104.5.7).* The global L-function of ρ decomposes over the prime knots:

$$L(\rho, s) \;=\; \prod_p L_p(\rho, s) \;=\; \prod_p \det\!\big(1 - \rho(\mathrm{Frob}_p^{\mathrm{geom}})\, p^{-s}\big)^{-1}\, L_\infty(\rho, s),$$

with $L_\infty(\rho, s)$ supplied by the archimedean Wilson-surface expectation at $\{\infty\}$ (Ch. 104.5).

Proof. Finite-part product: Theorem 106.6.1 for each finite prime times the archimedean completion. The archimedean factor $L_\infty(\rho, s)$ is a Γ-factor whose 3D-ACS incarnation is the Wilson-*surface* expectation along the archimedean boundary $\{\infty\}$, cf. Chapter 104.5.7, tied to the Arakelov area form. □

Remark 106.6.3 *(triviality of the Frobenius analytic shift).* Convention 106.1.3 leaves the trace unnormalised: if ρ is of motivic weight w, the natural analytic shift for a self-dual L-function places the critical line at $\operatorname{Re} s = (w+1)/2$; the Wilson expectation then carries an implicit $p^{-w/2}$ factor relative to the trace. For the weight-zero sheaf $\mathbb{C}_o$ (Deninger H^0) the shift is trivial; for the weight-one Tate twist (Deninger H^2) the shift is $p^{-1/2}$. Identity (106.6) is stated unnormalised; the analytic shift is implicit in the $W_\rho^{\mathrm{qu}}(K_p)$ notation when embedding into the global L-function.

Remark 106.6.4 *(independence of sources and domain of the Langlands compatibility).* Theorem 106.6.1 draws on three independent constructions: Witten 1989 (Wilson trace as holonomy trace); Tate 1979 and Borel 1976 together with Satake 1963 (unramified local Langlands). These are independent from the

Chapter 103 construction path. The geometric-versus-arithmetic Frobenius distinction is fixed in Convention 106.1.3; the motivic-weight analytic shift is recorded in Remark 106.6.3. The ambient category is finite-dimensional $\overline{\mathbb{Q}}_\ell$-vector spaces tensored with the category of meromorphic functions in s. Unramifiedness at p is required; at ramified primes the L-factor carries local epsilon factors (see Section 106.7). The Satake isomorphism is functorial in ρ; the Wilson insertion is functorial via the class-function lift. The archimedean $L_\infty(\rho, s)$ identification with a Wilson-surface expectation is a definition-level identification in Chapter 104.5.7; its analytic content depends on the Arakelov area form and is conditional on the renormalised profinite construction. The Satake-eigenvalue calculations of Chapter 66 are independent from the Kim Chern–Simons state-sum calculations, providing an independent numerical check.

106.7 Residual Obstructions

Theorem 106.5.1 is proved on the unramified locus and for GL_2; four boundary conditions fall outside this domain.

(i) *Ramified and wild primes.* At ramified (but tame) primes, the Frobenius class is replaced by a representation of the tame inertia quotient, and the Wilson expectation picks up a monodromy factor along the meridian. At wild primes the arithmetic tubular neighbourhood carries ramification filtration data beyond the tame quotient; the Wilson identity becomes a local epsilon-factor equation (Deligne–Laumon; Laumon 1987 Publ. IHES 65). The tame-ramified extension is a direct generalisation via the tame-inertia quotient; the wild locus is treated in Chapter 78.

(ii) *Profinite renormalisation.* The $\varprojlim^{\mathrm{ren}}$-step in Theorem 106.5.1(2) is exactly Chapter 103.4.7. The Wilson–Frobenius identity is unconditional at each finite level; the continuous-group limit is the open problem of Chapter 103, recorded here without modification.

(iii) *Archimedean Wilson-surface realisation.* Corollary 106.6.2 requires identification of the archimedean Γ-factor with a Wilson-surface expectation at $\{\infty\}$ via the Arakelov area form (Chapter 104.5.7). This analytic continuation is treated in Chapter 104.

(iv) *GL_n for $n \geq 3$.* Theorem 106.5.1 is stated for GL_2, matching the gauge-group choice of Chapter 103. Extension to GL_n proceeds via Chapter 102's genus-g extension with $G = GL_{2g}(\widehat{\mathbb{Z}})$; the Morishita functor of Theorem 106.4.1 extends directly to $G = GL_n(\widehat{\mathbb{Z}})$ by replacing tr with the appropriate class function. The profinite-renormalisation obstruction of item (2) is carried over.

Remark 106.7.1 *(the abelian case is closed unconditionally).* On the closed base, Chapter 106.2.2 gives the trivial-torsor value. On the punctured unramified local category, the finite abelian Wilson loop reads $\chi(\mathrm{Frob}_p)$ unconditionally. Under Chapter 103.4.7, the identity extends to the continuous-group $GL_n(\widehat{\mathbb{Z}})$ and produces the finite-prime Frobenius-trace input used by the Deninger skeleton. It does not construct Deninger's global Frobenius flow on the middle cohomology. The chapter discharges the finite-level unramified Wilson calculation and leaves the continuous-group axiom Chapter 103.4.7(3) as part of the profinite ACS renormalisation datum.

106.8 Wilson–Frobenius Boundary

(i) The prime knot $K_p \subset \overline{\mathrm{Spec}\,\mathbb{Z}}$ is the Morishita avatar of a codimension-two defect; its meridian is I_p and its longitude is Frob_p (Chapter 106.1.1, Chapter 106.4.2).

(ii) Classical Kim ACS Wilson loops on the closed base have only the trivial finite etale torsor. Non-trivial unramified Frobenius characters are read in the punctured tubular category $\mathcal{M}_p^\circ$: $\langle W_\chi^{\mathrm{cl}}(K_p)\rangle = \chi(\mathrm{Frob}_p)$ there (Chapter 106.2.2).

(iii) The Morishita dictionary lifts to a functor $\Phi_{\mathrm{Mor}}\colon \mathrm{Knot}^{\mathrm{Ar}} \to \mathrm{Conj}(G_N)$ on the unramified locus; this functor intertwines Wilson insertion with Frobenius-class evaluation (Chapter 106.4.1).

(iv) At each finite level N coprime to p, the finite-level Wilson-loop expectation is a finite state sum, with the Frobenius trace appearing as a class-function insertion (Chapter 106.5.1(1)), unconditionally.

(v) At the profinite limit, the Wilson-loop identity $W_\rho^{\mathrm{qu}}(K_p) = \mathrm{tr}\,\rho(\mathrm{Frob}_p)$ holds conditionally on Chapter 103.4.7 (the continuous-group renormalisation), but unconditionally once that conjecture is granted; no additional open problem appears in the limit step (Chapter 106.5.1(2)).

(vi) The local L-factor $L_p(\rho, s) = \det(1 - \rho(\mathrm{Frob}_p^{\mathrm{geom}})p^{-s})^{-1}$ equals the unramified Satake L-factor when the Wilson datum records the full conjugacy class, or equivalently all power traces. The single scalar $W_\rho^{\mathrm{qu}}(K_p)$ gives only the first trace. The global L-function is a product of such conjugacy-class Wilson data plus an archimedean Wilson-surface factor (Chapter 106.6.1, Chapter 106.6.2).

(vii) Residual obstructions: ramified and wild primes (where the identity becomes a local epsilon-factor equation); the profinite renormalised limit (Chapter 103.4.7, open); the archimedean Γ-factor identification; and the GL_n-extension (Chapter 106.7).

The chapter proves the unramified finite-level Wilson/Frobenius calculation and conditionally transports it to the continuous-group limit. In the Deninger chiral candidate of Chapter 104, this supplies only the finite-prime trace component. The global Deninger flow, archimedean factor, and zero-side spectral operator remain the spectral-flow/profinite-renormalisation conditions; this chapter does not resolve them.

Chapter 107

Primary Fock Determinant: Rank Residue 2

Chapter 35 separates the local conformal charge from the global arithmetic determinant. The naive sum $\sum_p c^{(p)}$ diverges, and the log *p-weighted arithmetic Hamiltonian is not a Virasoro zero mode. The determinant assertion is the following: the primary Fock Euler product has rank residue 2 at $s = 1$. It does not construct a global Virasoro action on V^{prim}, and it does not close Conjecture 44.3.5.*

107.1 Local Virasoro and Arithmetic Hamiltonian

The per-prime chiral Heisenberg Fock

Definition 107.1.1 *(per-prime Heisenberg and arithmetic Hamiltonian).* At each finite place $p \in \mathbb{P}$ the *per-prime chiral Heisenberg* is the complex rank-2 Heisenberg vertex algebra $\mathcal{H}^{(p)}$ with generators $a^{(p)}$, $b^{(p)}$, OPE $a^{(p)}(z)a^{(p)}(w) \sim (z-w)^{-2}$, $b^{(p)}(z)b^{(p)}(w) \sim (z-w)^{-2}$, mixed OPE vanishing, and Fock vacuum $|0\rangle_p$ (Chapter 26; Kac 1998, §3.5). The local conformal vector is

$$\omega_p^{\mathrm{conf}} \;:=\; \tfrac{1}{2}\big(a_{-1}^{(p)}a_{-1}^{(p)} + b_{-1}^{(p)}b_{-1}^{(p)}\big)|0\rangle_p.$$

The state-field correspondence produces conformal modes

$$L_m^{\mathrm{conf},(p)} \;=\; \tfrac{1}{2}\sum_{k\in\mathbb{Z}} :a_{m-k}^{(p)}a_k^{(p)}: \;+\; \tfrac{1}{2}\sum_{k\in\mathbb{Z}} :b_{m-k}^{(p)}b_k^{(p)}:.$$

The arithmetic Hamiltonian is

$$N_p \;:=\; (\log p)\,L_0^{\mathrm{conf},(p)}. \tag{107.1}$$

Remark 107.1.2 *(convention:* log *p is archimedean).* The factor log p is archimedean-real scaling data, not an internal $\mathbb{Q}_p$-coefficient (Section 26.2.2). Observation 35.1.1 shows that rescaling $T \mapsto \lambda T$ breaks the Virasoro OPE unless $\lambda = 1$. Thus N_p is a Hamiltonian used in the Mellin character, not a Virasoro generator.

Per-prime central charge

Proposition 107.1.3 *(per-prime central charge is 2).* For every prime p and every pair m, n with $m + n = 0$ the Virasoro commutator on $\mathcal{H}^{(p)}$ satisfies

$$[L_m^{\mathrm{conf},(p)}, L_{-m}^{\mathrm{conf},(p)}] \;=\; 2m\,L_0^{\mathrm{conf},(p)} \;+\; \frac{c^{(p)}}{12}\,m(m^2-1)\cdot\mathrm{id}, \qquad c^{(p)} \;=\; 2.$$

Proof. Two independent Sugawara-type Heisenbergs tensor multiplicatively at the level of Virasoro central charge: the single chiral $u(1)$ Heisenberg has $c = 1$ by Kac–Raina §3.5 / Frenkel–Ben-Zvi Chapter 2. The rank-2 Heisenberg is the product, so $c^{(p)} = 1 + 1 = 2$. The arithmetic Hamiltonian N_p in (107.1) is external to this Virasoro calculation. □

Remark 107.1.4 *(independence of p).* Theorem 35.1.3 records $c^{(p)} = 2$ as a Polyakov observation. Proposition 107.1.3 derives it from the Sugawara tensor rule. The log p-weighted Hamiltonian enters only the determinant.

107.2 Divergent Sum and Per-State Finiteness

The naive global sum diverges

Observation 107.2.1 *(full global conformal central sum is $+\infty$).* The naive *full* sum of local conformal central charges

$$c_{\text{full}} := \sum_{p\in\mathbb{P}} c^{(p)} = \sum_{p\in\mathbb{P}} 2 = +\infty$$

diverges. Equivalently, the formal stress tensor $\sum_p \omega_p^{\text{conf}}$ is not a vector of the restricted tensor product, and no Virasoro central extension with a finite scalar acts on $\mathcal{V}^{\text{prim}}$ (Chapter 35, Corollary 35.2.2).

The primary core

Definition 107.2.2 *(primary Heisenberg core).* The *primary Heisenberg core* of $\mathcal{V}^{\text{prim}}$ is

$$\mathcal{V}^{\text{prim}}_{\text{Heis,prim}} := \operatorname{span}_{\mathbb{C}}\Big\{ v=\bigotimes_p v_p \;\Big|\; v_p=|0\rangle_p \text{ for all but finitely many } p \Big\},$$

with $|0\rangle_p \in \mathcal{H}^{(p)}$ the per-prime Fock vacuum (Definition 77.3.1). Each $v \in \mathcal{V}^{\text{prim}}_{\text{Heis,prim}}$ has a finite *support set* $\operatorname{supp}(v)\subset\mathbb{P}$, $|\operatorname{supp}(v)|<\infty$.

Remark 107.2.3 *(primary = finite-support).* The primary core is the algebraic restricted tensor product, before any Hilbert completion: the dense subspace on which every per-prime mode acts by zero at all but finitely many places. It is a $\mathbb{C}$-vector space (not a $\mathbb{Q}_p$-module) carrying the $\mathbb{N}^\times$-action by Adams operations ψ_n (Adams-Frobenius; Definition 25.2.1 and Theorem 25.2.2).

Finite Positive Modes and Divergent Negative Modes

PROPOSITION 107.2.4 *(finite positive modes).* For every $v \in \mathcal{V}^{\text{prim}}_{\text{Heis,prim}}$ and every $m \geq -1$ the conformal mode action

$$L_m^{\geq -1} v := \sum_{p\in S_v(m)} L_m^{\text{conf},(p)} v, \qquad S_v(m) \subset \mathbb{P}, \quad |S_v(m)|<\infty,$$

is a finite sum. For $m \leq -2$, the sum $\sum_p L_m^{\text{conf},(p)}$ is not defined on the vacuum. Consequently the global Virasoro commutator is not an operator on the restricted tensor product. Only the local commutators exist, and their central scalar has divergent prime sum.

Proof. Fix $v=\otimes_p v_p$ with $\operatorname{supp}(v)\subset\mathbb{P}$ finite. For $p\notin\operatorname{supp}(v)$, $v_p=|0\rangle_p$ and $L_m^{\text{conf},(p)}|0\rangle_p=0$ for every $m\geq -1$ (Kac–Raina §3.5; the standard creation-annihilation normal ordering places any positive-mode on the vacuum to zero, and the L_{-1}, L_0 annihilation on vacuum is the standard vertex-algebra axiom). Thus only finitely many summands act non-trivially for $m\geq -1$. For $m\leq -2$, each vacuum factor contributes the non-zero descendant $L_m^{\text{conf},(p)}|0\rangle_p$. The sum over primes is then an infinite sum of mutually orthogonal one-prime descendants, not an element of the algebraic restricted tensor product. The local identity

$$[L_m^{\text{conf},(p)}, L_{-m}^{\text{conf},(p)}]|0\rangle_p = \frac{c^{(p)}}{12} m(m^2-1)|0\rangle_p$$

therefore produces the divergent scalar $\sum_p c^{(p)}$ when summed over all primes. This scalar is not an operator before regularisation. □

Remark 107.2.5 *(finite action, divergent scalar).* Proposition 107.2.4 proves only finite action of the conformal modes $m \geq -1$. The formal central term

$$\frac{1}{12} m(m^2-1) \cdot \Big(\sum_p c^{(p)} \Big) \cdot \mathrm{id}$$

contains $\sum_p c^{(p)} = \infty$. The residue calculation below assigns a scalar to the determinant; it does not turn the formal commutator into a Virasoro action.

107.3 Dirichlet-Series Regularisation

The naive prime-zeta attempt fails

Observation 107.3.1 *(naive prime-zeta regularisation is not well-posed).* Define the formal series

$$c_{\mathbb{P}}(s) \;:=\; \sum_{p \in \mathbb{P}} c^{(p)}\, p^{-(s-1)} \;=\; 2 \sum_p p^{-(s-1)} \;=\; 2\zeta_{\mathbb{P}}(s-1).$$

This series converges absolutely exactly for $\operatorname{Re} s > 2$. Along the real axis,

$$c_{\mathbb{P}}(s) = 2 \log \frac{1}{s-2} + O(1) \qquad (s \downarrow 2).$$

Indeed, for real $w > 1$, the Euler logarithm gives $\log \zeta(w) = \sum_p p^{-w} + \sum_p \sum_{k \geq 2} p^{-kw}/k$. The second sum stays bounded as $w \downarrow 1$, by comparison with $\sum_{n \geq 2} n^{-2}/(1-n^{-1})$. The simple pole of ζ then gives the displayed logarithmic asymptotic. For $1 < s \leq 2$ the positive prime series already diverges; there is no convergent real-series limit at $s = 1$. Analytic continuation is a separate question: the natural boundary of $\zeta_{\mathbb{P}}(w)$ at $\operatorname{Re} w = 0$, as in Theorem 35.3.1, corresponds to $\operatorname{Re} s = 1$, not to the real divergence threshold.

Remark 107.3.2 *(prime-zeta sum vs. Riemann-zeta residue).* The Dirichlet series $c_{\mathbb{P}}(s)$ uses the prime-index set $\mathbb{P}$ as its summation domain. The determinant-rank scalar is instead read from the Euler product for the Riemann zeta $\zeta(s)$, which is meromorphic on $\mathbb{C}$. The prime zeta $\zeta_{\mathbb{P}}$ has a natural boundary at $\operatorname{Re}(w) = 0$, and therefore cannot define the value at $w = 0$. The finite-mode statement Proposition 107.2.4 gives only an algebraic domain for the modes $m \geq -1$; the residue at $s = 1$ belongs to the determinant, not to a Virasoro commutator.

Arithmetic black-hole motivation: primon gas as the first determinant

The partition function $Z(s) = \prod_p \prod_{n \geq 1} (1 - p^{-sn})^{-2}$ defined in §107.3 is the arithmetic-Chern–Simons thermal determinant over prime knots before the zero-side trace formula is available. The following heuristic identifies its origin in the primon-gas thermodynamics of Julia; no black-hole existence theorem enters the proof of Lemma 107.3.5, and no positivity statement is inferred from the calculation.

In ordinary three-dimensional gravity written as Chern–Simons theory, a black-hole sector is not a propagating local graviton. It is a flat connection with non-trivial holonomy around the cycles of a solid torus. Its one-loop determinant is built from the closed geodesics of the filling. The arithmetic replacement used throughout Chapters 103–106 is:

$$\text{closed geodesic} \quad \rightsquigarrow \quad \text{prime knot } K_p, \qquad \ell(K_p) = \log p, \qquad \mathrm{hol}(K_p) = \mathrm{Frob}_p.$$

At the level relevant here, the arithmetic Chern–Simons thermal determinant is computed around a holonomy saddle, with the primitive closed orbits indexed by primes.

The elementary thermodynamic step is the whole primon-gas calculation. A single bosonic occupation mode over the orbit K_p has energy

$$E_p = \ell(K_p) = \log p.$$

At inverse temperature s, its local partition function is the geometric series

$$\sum_{m\geq 0} e^{-smE_p} \;=\; \sum_{m\geq 0} p^{-sm} \;=\; (1-p^{-s})^{-1}.$$

Multiplying the independent local factors over all prime knots gives Julia's primon gas:

$$Z_{\text{primon}}(s) \;=\; \prod_{p}(1-p^{-s})^{-1} \;=\; \zeta(s), \qquad \operatorname{Re}(s) > 1. \tag{107.2}$$

For a rank-r free Heisenberg sector the same calculation gives $\zeta(s)^r$. Here $r = 2$, because the local arithmetic Heisenberg is generated by two commuting $u(1)$ fields.

The oscillator refinement adds the usual Fock levels. Instead of only one occupation energy E_p, the n-th oscillator over K_p has energy $nE_p = n\log p$. Therefore the rank-2 local factor is

$$\prod_{n\geq 1}(1-e^{-sn\log p})^{-2} \;=\; \prod_{n\geq 1}(1-p^{-sn})^{-2}. \tag{107.3}$$

Multiplication over all primes gives exactly the global Fock partition function defined below:

$$\prod_{p}\prod_{n\geq 1}(1-p^{-sn})^{-2}. \tag{107.4}$$

The primon gas is the $n = 1$ factor in the oscillator product: setting $n = 1$ in (107.3) and taking $r = 1$ recovers $(1-p^{-s})^{-1}$. The full rank-2 Fock product (107.4) is the arithmetic Chern–Simons thermal determinant used for the determinant rank-residue extraction in §107.3.

The limitation is as important as the calculation. Equations (107.2)–(107.4) recover the prime-side Euler product in its convergence half-plane. They do not construct Deninger's middle cohomology, do not locate the non-trivial zeros, and do not prove a trace formula. Those require the spectral-flow and positivity inputs isolated in Chapters 104 and 105.

The partition function regularisation

Definition 107.3.3 *(per-prime Fock partition).* For each prime p and complex parameter s with $\operatorname{Re}(s) > 0$ the *per-prime Fock partition* is

$$Z^{(p)}(s) \;:=\; \operatorname{Tr}_{\mathcal{H}^{(p)}}\left(e^{-sN_p}\right) \;=\; \operatorname{Tr}_{\mathcal{H}^{(p)}}\left(p^{-sL_0^{\mathrm{conf},(p)}}\right) \;=\; \prod_{n\geq 1}(1-p^{-sn})^{-2},$$

the final equality holding formally because $L_0^{\mathrm{conf},(p)}$ on the rank-2 Heisenberg Fock has generating function η-type with two commuting copies (Chapter 35, §35.4; Kac–Raina §3.5 for the rank-1 generating series).

Definition 107.3.4 *(global Fock partition: Euler product).* The *global Fock partition* is the formal Euler product

$$Z(s) \;:=\; \prod_{p\in\mathbb{P}} Z^{(p)}(s) \;=\; \prod_{p}\prod_{n\geq 1}(1-p^{-sn})^{-2}, \tag{107.5}$$

convergent for $\operatorname{Re}(s) > 1$ by convergence of the log-sum $\sum_{p,n} p^{-sn}$ (standard Euler-product estimate, Serre 1973 Ch. VI).

Lemma 107.3.5 *(partition function is squared zeta product).* In the region $\mathrm{Re}(s) > 1$,

$$Z(s) \;=\; \prod_{n\geq 1} \zeta(ns)^2.$$

Proof. Interchange the two products in (107.5):

$$Z(s) \;=\; \prod_{n\geq 1}\prod_{p}(1-p^{-sn})^{-2} \;=\; \prod_{n\geq 1}\Big(\prod_{p}(1-p^{-sn})^{-1}\Big)^2 \;=\; \prod_{n\geq 1}\zeta(ns)^2.$$

Each inner factor is the standard Euler product of $\zeta(ns)$ for $\mathrm{Re}(ns) > 1$, valid since $\mathrm{Re}(s) > 1$ implies $\mathrm{Re}(ns) > 1$ for every $n \geq 1$. The interchange of infinite products is justified by absolute convergence of the double sum $\sum_{p,n} p^{-\mathrm{Re}(s)n}$ on compact subsets of $\{\mathrm{Re}(s) > 1\}$. □

Remark 107.3.6 *(logarithmic derivative of Z and the rank pole).* From $\log Z(s) = 2\sum_{n\geq 1}\log\zeta(ns)$, the logarithmic derivative is

$$-\frac{d}{ds}\log Z(s) \;=\; 2\sum_{n\geq 1}\frac{n\,\zeta'(ns)}{\zeta(ns)}\cdot(-1) \;=\; 2\sum_{n\geq 1} n\,\frac{-\zeta'(ns)}{\zeta(ns)},$$

convergent for $\mathrm{Re}(s) > 1$. The leading pole of $-\frac{d}{ds}\log Z$ at $s = 1$ arises from the $n = 1$ term via $\frac{-\zeta'(s)}{\zeta(s)} \sim (s-1)^{-1}$ near $s = 1$, with the higher-n terms holomorphic at $s = 1$. In the corrected Polyakov convention (§35.4), this residue is the rank scalar of the determinant, not a global central charge.

The Dirichlet-series rank residue

Definition 107.3.7 *(zeta rank residue).* The *zeta rank residue* is

$$r_\zeta \;:=\; \mathrm{Res}_{s=1}\Big(-\frac{d}{ds}\log Z(s)\Big). \tag{107.6}$$

Equivalently, if $\log Z(s) = -r\log(s-1) + $ holomorphic near $s = 1$, then $r_\zeta := r$, where r is the order of the logarithmic singularity.

Remark 107.3.8 *(rationale for the residue definition).* For the stated Polyakov-rank comparison (Chapter 35, Theorem 35.4.1), the rank prescription is the residue of $-\partial_s \log Z(s)$ at the global partition function's $s = 1$ pole. The definition (107.6) places this residue at the $s = 1$ pole of ζ, which is the dominant pole of Z since $Z(s) = \zeta(s)^2 \cdot \prod_{n\geq 2}\zeta(ns)^2$ and the $n \geq 2$ factors are holomorphic at $s = 1$ (with $\zeta(2n) \in \mathbb{Q}\pi^{2n}$ for $n \geq 1$).

107.4 Local Expansion at $s = 1$

Decomposition of $\log Z$ *near* $s = 1$

Theorem 107.4.1 *(local Laurent expansion of* $\log Z$ *at* $s = 1$*).* In a punctured neighbourhood of $s = 1$ on a fixed logarithm branch, the function $\log Z(s) = 2\sum_{n\geq 1}\log\zeta(ns)$ has expansion

$$\log Z(s) \;=\; -2\log(s-1) \;+\; 2\sum_{n\geq 2}\log\zeta(n) \;+\; 2\left(\gamma_E + \sum_{n\geq 2} n\,\frac{\zeta'(n)}{\zeta(n)}\right)(s-1) \;+\; O((s-1)^2), \tag{107.7}$$

where $\gamma_E = \lim_{N\to\infty}(\sum_{k=1}^{N} 1/k - \log N)$ is the Euler–Mascheroni constant.

Proof. Write $\log Z(s) = 2\log\zeta(s) + 2\sum_{n\geq 2}\log\zeta(ns)$. For $n \geq 2$ and s in a sufficiently small complex neighbourhood of 1, $\mathrm{Re}(ns) > 1$, so $\zeta(ns)$ is holomorphic and nonzero at $s = 1$ (since $\zeta(2), \zeta(3), \ldots$ are positive real and greater than 1). The tail bound $\sum_{n\geq 2} |\log\zeta(ns)| \leq C\sum_{n\geq 2} 2^{-n\mathrm{Re}(s)}$ is uniform on $\mathrm{Re}(s) \geq 1/2 + \epsilon$, so $\sum_{n\geq 2}\log\zeta(ns)$ is holomorphic at $s = 1$ and has first derivative $\sum_{n\geq 2} n\,\zeta'(n)/\zeta(n)$ there.

For the $n = 1$ term: the Laurent expansion $\zeta(s) = (s-1)^{-1} + \gamma_E + O(s-1)$ (Edwards 1974, §1.6) gives

$$\log\zeta(s) = \log\big((s-1)^{-1}(1 + \gamma_E(s-1) + O((s-1)^2))\big) = -\log(s-1) + \gamma_E(s-1) + O((s-1)^2),$$

using $\log(1+x) = x + O(x^2)$. Therefore

$$\log Z(s) = -2\log(s-1) + 2\sum_{n\geq 2}\log\zeta(n) + 2\left(\gamma_E + \sum_{n\geq 2} n\,\frac{\zeta'(n)}{\zeta(n)}\right)(s-1) + O((s-1)^2),$$

which is (107.7). □

Remark 107.4.2 *(why the rank residue is 2).* The leading term $-2\log(s-1)$ in (107.7) has a -2 coefficient because $Z(s) = \zeta(s)^2 \cdot \mathrm{hol}$ near $s = 1$, and the double factor in ζ comes from the rank-2 Heisenberg: per-prime two-commuting-Heisenberg implies per-prime $Z^{(p)}$ has a *squared* $(1-p^{-s})^{-1}$ factor leading at $n = 1$, and on the Euler-product reshuffle this makes $Z = \zeta^2 \cdot \mathrm{hol}$. The power of ζ at $s = 1$ is the per-prime rank, here 2. This rank agrees with the local Sugawara central charge prime by prime, but it is not a global central charge.

Residue extraction

THEOREM 107.4.3 *(residue at $s = 1$).* With the decomposition (107.7),

$$\mathrm{Res}_{s=1}\left(-\frac{d}{ds}\log Z(s)\right) = 2,$$

and the zeta rank residue of Definition 107.3.7 evaluates to

$$r_\zeta = 2.$$

Proof. Differentiate (107.7):

$$-\frac{d}{ds}\log Z(s) = \frac{2}{s-1} - 2\left(\gamma_E + \sum_{n\geq 2} n\,\frac{\zeta'(n)}{\zeta(n)}\right) + O(s-1)$$

near $s = 1$. The residue at $s = 1$ is 2. By Definition 107.3.7, $r_\zeta = \mathrm{Res}_{s=1}(-\frac{d}{ds}\log Z) = 2$. □

COROLLARY 107.4.4 *($r_\zeta = 2\cdot\mathrm{Res}_{s=1}\zeta(s)$).* Since $\mathrm{Res}_{s=1}\zeta(s) = 1$,

$$r_\zeta = 2\cdot\mathrm{Res}_{s=1}\zeta(s) = 2. \tag{107.8}$$

Remark 107.4.5 *(Dirichlet-series form of regularisation).* The prime-indexed function $2\zeta_{\mathbb{P}}(s-1)$ and the logarithmic derivative $-\partial_s\log Z(s)$ are distinct analytic functions. The first has its real logarithmic divergence at $s = 2$ and a continuation boundary at $\mathrm{Re}\,s = 1$. The second has a simple pole at $s = 1$ with residue two, since $Z(s) = \zeta(s)^2 A(s)$ and $A(1) \neq 0$. The stated rank prescription extracts this latter residue, as in (107.8). This calculation establishes its value, not uniqueness among every possible regularization rule, and does not construct a global Virasoro action.

107.5 Polyakov Anomaly Connection

The Polyakov stress tensor and anomaly

Theorem 107.5.1 *(Polyakov anomaly on the archimedean chiral Heisenberg).* (Polyakov 1981; Belavin–Polyakov–Zamolodchikov 1984; Friedan–Shenker 1987; archimedean Heisenberg: Kac 1998 §3.5). On the archimedean Heisenberg $\mathcal{H}^{(\infty)}$ with rank-2 free-field presentation, the Polyakov conformal anomaly coefficient is

$$c^{(\infty)}_{\text{anomaly}} \;=\; 2,$$

extracted from the $T(z)T(w)$ OPE central term with $T = \frac{1}{2}(a^{(\infty)}_{-1}a^{(\infty)}_{-1} + b^{(\infty)}_{-1}b^{(\infty)}_{-1})$, independently from trace-anomaly $\langle T^{\mu}_{\mu}\rangle = -cR/24\pi$ and from Friedan–Shenker modular-invariance bootstrap.

Remark 107.5.2 *(archimedean vs. determinant).* $c^{(\infty)}_{\text{anomaly}} = 2$ is the anomaly of the *archimedean* Heisenberg alone. Each per-prime place also satisfies $c^{(p)} = 2$, so the per-place charges are uniformly 2. The finite-prime determinant residue also equals 2. Equality of these two numbers is a rank comparison; it is not an addition of local central charges.

The Polyakov–regularisation identity

Theorem 107.5.3 *(Polyakov-rank comparison).* The zeta rank residue of Definition 107.3.7 equals the Polyakov conformal anomaly coefficient of the archimedean rank-2 Heisenberg:

$$r_\zeta \;=\; c^{(\infty)}_{\text{anomaly}} \;=\; 2.$$

Equivalently, for the global Fock partition $Z(s) = \prod_p \prod_{n\geq 1}(1-p^{-sn})^{-2}$, the residue of $-\partial_s \log Z(s)$ at $s=1$ has the same value as the rank-2 Polyakov-Friedan-Shenker anomaly computed on the archimedean completion $\mathcal{H}^{(\infty)}$.

Proof. Combine Corollary 107.4.4 ($r_\zeta = 2$) with Theorem 107.5.1 ($c^{(\infty)}_{\text{anomaly}} = 2$): both sides equal 2 independently, and their common value is $2 \cdot \operatorname{Res}_{s=1}\zeta(s) = 2$.

The two sides arise from different constructions: the left-hand side from a global partition-function Euler product over all finite primes, regularised through the residue of ζ at its pole; the right-hand side from a Lagrangian stress-tensor computation on the archimedean fibre, regularised through Polyakov's short-distance anomaly. The identity is the arithmetic-branch expression of Polyakov's principle in the residue form (Theorem 35.4.1): the finite-prime determinant and the archimedean free-field anomaly have the same rank 2. No global Virasoro action on $\mathcal{V}^{\text{prim}}$ is produced. □

Remark 107.5.4 *(global compatibility).* Distinguish the meromorphic completion and its entire version:

$$\Lambda(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s), \qquad \xi_{\mathbb{R}}(s) = \tfrac{1}{2}s(s-1)\Lambda(s).$$

Since $\zeta(s) = (s-1)^{-1} + \gamma_E + O(s-1)$ and $\pi^{-1/2}\Gamma(1/2) = 1$, Λ has residue $+1$ at 1. The functional equation $\Lambda(s) = \Lambda(1-s)$ gives residue -1 at 0. The prefactor cancels both poles: $\xi_{\mathbb{R}}$ is entire, with value $1/2$ at both points. It has no residue pole at zero.

For the partition function defined here, write $Z(s) = \zeta(s)^2 A(s)$, with $A(s) = \prod_{n\geq 2}\zeta(ns)^2$ holomorphic and nonzero near 1. Thus Z has a pole of order two. Its residue is $2\gamma_E A(1) + A'(1)$, whereas

$$-\partial_s \log Z(s) = \frac{2}{s-1} + O(1), \qquad \operatorname{Res}_{s=1}(-\partial_s \log Z) = 2.$$

The rank scalar is this logarithmic-derivative residue, not the residue of Z. Its equality with the local rank-two free-field central charge is the scalar equality stated in Theorem 107.5.3; a global action requires additional comparison maps.

Local Central Charge and the Global Residue

Remark 107.5.5 *(the two scalar calculations).* The local chiral calculation uses Kac–Raina *Bombay Lectures on Highest Weight Representations of Infinite-Dimensional Lie Algebras* (World Scientific 1987), §3.5 (Sugawara central charge for bosonic Fock); Kac *Vertex Algebras for Beginners* 2nd ed. (AMS 1998), Chapter 3 (rank-n Heisenberg vertex algebra and Virasoro central charge formula). The global residue calculation uses Edwards *Riemann's Zeta Function* (Academic Press 1974), §1.6 (Laurent expansion of ζ at $s = 1$) for the residue-extraction half; Serre *Cours d'Arithmétique* (PUF 1970) Ch. VI (Euler product) for the global partition rewriting. Both displayed calculations give the scalar 2. Equality of these scalars does not by itself construct a map between the local vertex-algebra carrier and the global determinant object.

107.6 MAIN THEOREM: $r_\zeta = 2$

Statement

THEOREM 107.6.1 *(primary Fock determinant has rank residue 2).* Let $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ denote the primary Heisenberg core of Definition 107.2.2. Then:

(a) *Finite positive modes.* For every $v \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ and every $m \geq -1$, the mode action $L^{\geq -1}_m v = \sum_{p \in S_v(m)} L^{\mathrm{conf},(p)}_m v$ is a finite sum over $|S_v(m)| < \infty$ primes. The modes $m \leq -2$ do not form global operators on the restricted vacuum (Proposition 107.2.4).

(b) *Divergent conformal scalar.* The formal Virasoro central-term coefficient $\sum_p c^{(p)}$ is $+\infty$ as a naive sum (Observation 107.2.1).

(c) *Zeta rank residue.* The Dirichlet-series residue of the scalar via the global Fock partition $Z(s) = \prod_p Z^{(p)}(s)$ yields

$$r_\zeta \;=\; \mathrm{Res}_{s=1}\Big(-\frac{d}{ds}\log Z(s)\Big) \;=\; 2.$$

(d) *Polyakov-rank comparison.* The rank residue equals the Polyakov conformal anomaly coefficient of the archimedean rank-2 Heisenberg $c^{(\infty)}_{\mathrm{anomaly}} = 2$ (Theorem 107.5.3).

Proof. (a) is Proposition 107.2.4. (b) is Observation 107.2.1. (c) is Theorem 107.4.3 with Corollary 107.4.4. (d) is Theorem 107.5.3. □

Regularization, Rescaling, and Determinant Rank

Remark 107.6.2 *(prime-zeta sum does not regularise the determinant rank).* The prime sum $c(s) = 2\zeta_{\mathbb{P}}(s-1)$ is absolutely convergent for $\mathrm{Re}\, s > 2$, and diverges logarithmically as real $s \downarrow 2$, as proved in Observation 107.3.1. The continuation boundary at $\mathrm{Re}\, s = 1$ is a separate obstruction. The determinant-rank prescription of Definition 107.3.7 uses instead the logarithmic derivative of the meromorphic partition function.

Remark 107.6.3 *(*$(\log p)$*-weighting is not a Virasoro rescaling).* **Objection.** "The $(\log p)$-rescaling changes the central charge $c^{(p)} \mapsto (\log p)^2 \cdot c^{(p)}$." **Answer.** The local stress tensor is not rescaled.

The factor $\log p$ defines $N_p = (\log p) L_0^{\mathrm{conf},(p)}$, the Hamiltonian in the Mellin determinant. The local conformal charge remains $c^{(p)} = 2$, and N_p is not a Virasoro zero mode.

Remark 107.6.4 *(the universal scalar is not per-state-finite).* **Objection.** "Proposition 107.2.4 establishes a global Virasoro commutator." **Answer.** It establishes finite action only for $m \geq -1$. For $m \leq -2$ the global mode is not defined on the vacuum, and the formal central scalar is ∞. The residue in §107.3 targets the determinant scalar, not a commutator on a dense domain (Remark 107.2.5).

Remark 107.6.5 *(the residue prescription is uniquely determined).* **Objection.** "The regularisation $r_\zeta = 2$ is arbitrary: many Dirichlet-series prescriptions yield different numbers." **Answer.** The prescription (107.6) is fixed by two requirements: (i) the regularisation runs through the global Fock partition $Z(s)$ whose pole structure is uniquely determined by the Euler product of ζ^2 at $s = 1$; (ii) the regularisation must match the Polyakov anomaly on the archimedean completion (Theorem 107.5.3). Together these single out the residue prescription; the prime-zeta prescription fails (i): $\zeta_{\mathbb{P}}$ has a natural boundary at $\mathrm{Re}(w) = 0$; the sum-at-zero prescription fails (ii): a sum indexed by primes is not the same as a residue of the Riemann zeta at $s = 1$, which runs over all positive integers via the Euler product.

Remark 107.6.6 *(the archimedean fibre enters through the completed-zeta* Γ*-factor).* **Objection.** "The partition $Z(s) = \prod_p Z^{(p)}(s)$ omits the archimedean fibre $\mathcal{H}^{(\infty)}$." **Answer.** The archimedean contribution enters through the Γ-factor in the completed zeta $\xi_{\mathbb{R}}(s) = \frac{1}{2} s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$; on the stress-tensor side it is built into the Polyakov-anomaly identification. Theorem 107.5.3 states only a rank equality between the finite-prime residue and the archimedean anomaly. It does not add two central charges.

Remark 107.6.7 *(the order of the pole of* $\log Z$ *at* $s = 1$ *is not a free parameter).* **Objection.** "The residue prescription is circular: the residue is 2 because the rank is chosen to be 2." **Answer.** The order of the pole is *not* a free parameter. It is computed from the Euler product: $Z^{(p)}(s) = \prod_{n \geq 1}(1 - p^{-sn})^{-2}$ has rank-2 because the per-prime Heisenberg is rank-2 (two free bosons); this is a *fixed input* from the construction. The resulting $Z(s) = \zeta(s)^2 \cdot \mathrm{hol}$ near $s = 1$ has a pole of order 2 in ζ, hence a leading $-2\log(s-1)$ term in $\log Z$, hence $\mathrm{Res}_{s=1}(-\frac{d}{ds}\log Z) = +2$. The input is the rank-2 Heisenberg determinant. The output is the same rank read from the pole of $\zeta(s)^2$.

Remark 107.6.8 *(rank in a specified Iwasawa coefficient model).* Let $\Lambda_p = \mathbb{Z}_p[[T]]$ and $M = \Lambda_p^{\oplus r}$. Its (p, T)-adic completion is again M, and specialization along $\Lambda_p \to \mathbb{Q}_p$, $T \mapsto 0$, gives $M \otimes_{\Lambda_p} \mathbb{Q}_p \cong \mathbb{Q}_p^r$. Thus this finite free coefficient model retains its rank.

Applying the calculation to an arithmetic Heisenberg requires an identification with that coefficient model and its current operators. The lifting criterion in Theorem 46.1.5 does not make Λ_p a Heisenberg algebra or construct that identification. A local conformal charge still requires the specified Heisenberg fields and stress tensor.

Relation to the conditional Virasoro-bracket question

Remark 107.6.9 *(what is proved and what is not).* Theorem 107.6.1 proves the determinant scalar $r_\zeta = 2$. It does *not* prove that a per-prime sum $\sum_p L_m^{\mathrm{conf},(p)}$ satisfies a Virasoro bracket with this scalar. Two obstructions remain:

(i) *Domain.* The modes $m \leq -2$ must first exist as dense operators on a completion of $\mathcal{V}_{\mathrm{Heis,prim}}^{\mathrm{prim}}$ (the Petersson completion, Theorem 43.7.1). The closure is not automatic: finite-support states do not form an invariant core unless a commutator estimate is given.

(ii) *Bracket identity.* After closure, the identity $[L_m, L_n] = (m-n)L_{m+n} + (c/12)(m^3 - m)\delta_{m+n,0} \cdot \mathrm{id}$ would still be a new theorem. The determinant scalar r_ζ does not supply it.

Both obstructions are open for the primary-Virasoro reconciliation.

Domain and logical form

Remark 107.6.10 *(determinant domain).* The determinant-rank identity is $r_\zeta = 2$. It does not prove either half of Conjecture 44.3.5. The open content remains operator closure plus bracket identity on a dense domain (Remark 107.6.9). The operator closure requires operator estimates on $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis,prim}}$ with respect to the Petersson inner product of Theorem 43.7.1.

Chapter 108

Modular Generators, Zero Divisors, and Operator Domains

The critical Bost–Connes generator, the occupation Hamiltonian, and the idele scaling operator have different spectral measures. The arithmetic realization problem asks for a self-adjoint operator with the completed zeta divisor and the full signed Weil trace. An intertwiner preserves eigenvalues on every source eigenvector in its domain, while a unitary multiplication chart preserves continuous spectral type. These elementary restrictions determine which proposed comparisons can represent that divisor. The explicit formula and the graph-domain calculations below give separate distributional and operator statements.

108.1 Setup: N_{BC} and Θ_ξ as Target Operators

The proposed operator comparison starts with the critical BC generator and asks for a zero-divisor target. Their distinct Hilbert carriers and spectra determine its domain requirements.

Source: The Bost–Connes Log-Prime Operator

Definition 108.1.1 *(Critical generator and occupation restriction).* On the critical GNS space $\mathcal{H}_1$, use the basis of Chapter 77.2.2:

$$\mathcal{H}_1 = \ell^2(\mathbb{Q}_{>0})\widehat{\otimes}\ell^2(\mathbb{Q}/\mathbb{Z}), \quad N_{\mathrm{BC}} v_{q,r} = \tfrac{1}{2}\log q\, v_{q,r}, \quad \mathrm{Dom}\, N_{\mathrm{BC}} = \{c : \sum_{q,r} |\log q|^2 |c_{q,r}|^2 < \infty\}.$$

Its eigenvalues have infinite multiplicity and their closure is $\mathbb{R}$. Let $\mathcal{H}_{\mathrm{BC}} := K_2 = \overline{\mathrm{span}}\{v_{m^2,0} : m \geq 1\}$ when discussing occupation coordinates. This reducing subspace carries $N_{\mathrm{occ}} = N_{\mathrm{BC}}|_{K_2}$, whose simple eigenvalues are $\log m$. The full and restricted operators remain distinct.

Remark 108.1.2 *(Occupation coordinates).* Let e_m be the coordinate vector of norm $m^{-1/2}$ in $L_w = \ell^2(\mathbb{N}^\times, dm/m)$. The map $v_{m^2,0} \mapsto \sqrt{m}\, e_m$ is unitary. Prime factorization identifies the orthonormal occupation basis with the restricted tensor product of the bases indexed by $v_p(m)$, with vacuum index zero at every prime. In these coordinates N_{occ} is the closure of $\sum_p v_p(m) \log p$ on finite-support vectors. This Hilbert tensor decomposition is not a map from the full critical generator to the continuous idele scaling representation.

Target: The Hypothetical Zeta-Zero Divisor Operator

Definition 108.1.3 *(target Hilbert space and zero-divisor operator).* Let $\mathcal{Z}$ denote the multiset of nontrivial zeros $\rho = \beta_\rho + i t_\rho$ of $\xi_{\mathbb{R}}$, with each occurrence indexed once, and write $\gamma_\rho := t_\rho$ for the ordinate. The *formal target Hilbert space* is

$$\mathcal{H}_\xi^{\mathrm{formal}} := \bigoplus_{\rho \in \mathcal{Z}} \mathbb{C},$$

with inner product making the one-dimensional summands orthonormal. The *formal ordinate multiplier* is the diagonal symmetric operator

$$H_{\mathrm{ord}}^{\mathrm{formal}} \;:\; (\xi_\rho)_\rho \;\mapsto\; (t_\rho \xi_\rho)_\rho$$

on the maximal domain

$$\left\{ c \in \ell^2(\mathcal{Z}) : \sum_{\rho \in \mathcal{Z}} t_\rho^2 |c_\rho|^2 < \infty \right\}.$$

This real diagonal operator is self-adjoint; its adjoint domain is exactly the displayed square-summability domain. Coordinate truncations show that finite-support vectors form a graph core. Its point spectrum is the ordinate set, with one coordinate per zero occurrence. Distinct zeros with the same ordinate add their multiplicities. The *critical-line projection operator* is

$$\Theta_\xi^{\mathrm{proj}} = \tfrac{1}{2}\mathrm{id} + i H_{\mathrm{ord}}^{\mathrm{formal}}.$$

Its divisor is the projection of the zero divisor to the critical line; it is the actual zero divisor of $\xi_{\mathbb{R}}$ exactly under RH.

Remark 108.1.4 *(why "formal").* The triple $(\mathcal{H}_\xi^{\mathrm{formal}}, H_{\mathrm{ord}}^{\mathrm{formal}}, \Theta_\xi^{\mathrm{proj}})$ exists trivially as a diagonal construction. It carries no intrinsic arithmetic structure: the enumeration of $\{t_\rho\}$ is read from the zero set itself, and the diagonal operator realises its spectrum by fiat. If one replaces β_ρ by $1/2$, one has already projected the divisor to the critical line. The content of the Hilbert–Pólya problem is not the existence of $\mathcal{H}_\xi^{\mathrm{formal}}$; it is the existence of a Hilbert space *with independent structure* whose spectral data force the original zero divisor to equal this projected divisor.

Definition 108.1.5 *(non-formal target).* A *non-formal target* is a pair $(\mathcal{H}_\xi, H_{\mathrm{HP}})$ where $\mathcal{H}_\xi$ is a Hilbert space carrying structure inherited from the Bost–Connes framework (restricted-tensor adelic factorisation, Petersson inner product on cuspidal cores, GNS modular data, or another independently specified structure) and H_{HP} is a self-adjoint operator on $\mathcal{H}_\xi$ whose spectral resolution is canonical with respect to the inherited structure and whose regularised determinant

$$\det{}_\infty\big(s\mathrm{id} - (\tfrac{1}{2}\mathrm{id} + i H_{\mathrm{HP}})\big)$$

has the non-trivial zero divisor of $\xi_{\mathbb{R}}$.

Remark 108.1.6 *(domain of "canonical").* "Canonical" means: the spectral resolution of H_{HP} is determined by the inherited structure up to a unitary equivalence whose parameters are themselves determined by that structure. A diagonal construction with eigenvalues labelled by an arbitrary enumeration is not canonical; a diagonal construction whose eigenvectors are explicit functions of arithmetic data (adelic characters, automorphic forms, spectral projectors of a globally defined operator) is.

Spectral Flow as Intertwining Operator

Definition 108.1.7 *(An operator comparison).* Choose explicitly either $N = N_{\mathrm{BC}}$ on $\mathcal{H}_1$ or $N = N_{\mathrm{occ}}$ on K_2. An intertwining datum consists of a self-adjoint H on a complex Hilbert space $\mathcal{L}$, a dense N-invariant subspace $\mathcal{D} \subset \mathrm{Dom}\, N$, and an injective linear map $A : \mathcal{D} \to \mathrm{Dom}\, H$ with dense range, satisfying

$$HAu = ANu \qquad (u \in \mathcal{D}).$$

A zero-divisor realization additionally requires a complete orthonormal eigenbasis of H whose eigenvalue multiset obeys

$$\{\tfrac{1}{2} + i\lambda : \lambda \text{ an eigenvalue of } H\} = \{\rho : \xi_{\mathbb{R}}(\rho) = 0\},$$

with multiplicities, and a separately normalized determinant. The existence of such a target is not an assertion that the intertwining datum exists for either source.

Proposition 108.1.8 *(Eigenvectors under an intertwiner).* If $Nv = \lambda v$, $v \in \mathcal{D}$, and A is an intertwining datum, then $Av \neq 0$ and $HAv = \lambda Av$. No such datum containing a nonzero zero-energy source vector can have the zero-divisor target above. In particular, an injective intertwiner on the eigenvector core of either source is impossible.

Proof. Injectivity gives $Av \neq 0$, and the intertwining identity gives the eigenvalue equation. Both source cores contain $v_{1,0}$ of energy zero, whereas $\xi_{\mathbb{R}}(1/2) \neq 0$. Indeed, the alternating series $\eta(1/2) = \sum_{n\geq 1}(-1)^{n-1}n^{-1/2}$ converges and is positive: grouping consecutive pairs gives positive terms and the first pair is positive. The alternating-series continuation $\eta(s) = (1 - 2^{1-s})\zeta(s)$ on $\Re s > 0$ then gives $\zeta(1/2) = \eta(1/2)/(1 - \sqrt{2}) \neq 0$. The other completed factors at $1/2$ are finite and nonzero. Unboundedness of A does not alter this eigenvector argument. □

108.2 Prime-Zero Mangoldt-Hadamard Duality Recap

The Riemann–von Mangoldt explicit formula and the Hadamard product relate prime data to the zero divisor. In the Fourier formulation below, the prime terms act on compact smooth time tests and the zero functional acts on their entire Fourier transforms. This identity does not by itself identify Hilbert-space operators.

Hadamard Factorisation of $\xi_{\mathbb{R}}$

Proposition 108.2.1 *(Hadamard factorisation). (Hadamard 1893; Chapter 77.4).* The completed Riemann zeta $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$ is entire of order 1, of genus 1, and admits the factorisation

$$\xi_{\mathbb{R}}(s) \;=\; \xi_{\mathbb{R}}(0)\, e^{Bs} \prod_{\rho}\Big(1 - \frac{s}{\rho}\Big)e^{s/\rho}, \tag{108.1}$$

with ρ ranging over non-trivial zeros with multiplicity and

$$B = \frac{\xi_{\mathbb{R}}'(0)}{\xi_{\mathbb{R}}(0)} = -1 - \frac{\gamma}{2} + \frac{1}{2}\log(4\pi),$$

where γ is Euler's constant and $\xi_{\mathbb{R}}(0) = 1/2$. See Edwards 1974, §2.7, and the normalization in Chapter 77.5.2.

Proof. The function here is exactly the completed function of Chapter 77.5.2. Its identity $\xi_{\mathbb{R}}(s) = (s-1)\Gamma(1 + s/2)\pi^{-s/2}\zeta(s)$ gives

$$\frac{\xi_{\mathbb{R}}'(0)}{\xi_{\mathbb{R}}(0)} = -1 - \frac{\gamma}{2} - \frac{1}{2}\log\pi + \log(2\pi),$$

using $\Gamma'(1) = -\gamma$, $\zeta(0) = -1/2$, and $\zeta'(0) = -\frac{1}{2}\log(2\pi)$, as evaluated there. Each genus-one factor has logarithmic derivative zero at the origin, so this logarithmic derivative is the constant B in (108.1). □

Riemann-von Mangoldt Explicit Formula

PROPOSITION 108.2.2 *(Riemann-von Mangoldt explicit formula). (von Mangoldt 1895; Edwards 1974 §3).* For $x > 1$ non-integer,

$$\sum_{n \le x} \Lambda(n) \;=\; x \;-\; \sum_{\rho} \frac{x^{\rho}}{\rho} \;-\; \frac{\zeta'(0)}{\zeta(0)} \;-\; \tfrac{1}{2}\log(1 - x^{-2}),$$

where $\Lambda(n) = \log p$ if $n = p^k$ and 0 otherwise. The zero sum means $\lim_{T\to\infty} \sum_{|\operatorname{Im}\rho| \le T} x^{\rho}/\rho$, with multiplicities and symmetric height truncation.

Mellin-Dual Measures

Definition 108.2.3 *(prime and zero counting measures).* The *prime-counting distribution* is

$$\mu_{\mathrm{prime}} \;:=\; \sum_{m \in \mathbb{N}^{\times}} \Lambda(m)\, \delta_{\log m} \;=\; \sum_{p \in \mathbb{P}} \sum_{k \ge 1} (\log p)\, \delta_{k \log p}$$

on $\mathbb{R}_{>0}$. The *ordinate shadow* of the zero-counting distribution is

$$\mu_{\mathrm{ord}} \;:=\; \sum_{\rho \in \mathcal{Z}} \delta_{\gamma_\rho}$$

on $\mathbb{R}$. The actual Weil zero functional acts on $\mathscr{P} = \mathcal{F}_{+} C_c^{\infty}(\mathbb{R})$, with $(\mathcal{F}_{+} f)(z) = \int f(u) e^{izu}\, du$:

$$\mathfrak{Z}_{\xi}(h) := \sum_{\rho \in \mathcal{Z}} h(z_\rho), \qquad z_\rho := -i(\rho - \tfrac{1}{2}).$$

The equality $\mathfrak{Z}_{\xi}(h) = \int_{\mathbb{R}} h\, d\mu_{\mathrm{ord}}$ for every $h \in \mathscr{P}$ is equivalent to RH. Indeed, equality on Fourier images of convolution squares makes the Weil form nonnegative; apply the Weil criterion. Conversely, RH gives $z_\rho = \gamma_\rho$ term by term.

PROPOSITION 108.2.4 *(Mellin-dual form of the explicit formula). (Weil 1952; Patterson 1988 Ch. 3).* Let $\mathscr{A} = C_c^{\infty}(\mathbb{R}; \mathbb{C})$, with its usual inductive-limit topology, and let $\mathscr{P} = \mathcal{F}_{+}\mathscr{A}$ have the transported topology. For $\varphi \in \mathscr{A}$, set

$$h(z) = \mathcal{F}_{+}\varphi(z) = \int_{\mathbb{R}} \varphi(t) e^{izt}\, dt, \qquad \varphi(t) = \frac{1}{2\pi} \int_{\mathbb{R}} h(u) e^{-iut}\, du.$$

Write $\psi_{\Gamma} = \Gamma'/\Gamma$ and define

$$k(u) = \log \pi - \mathfrak{R}\psi_{\Gamma}(\tfrac{1}{4} + iu/2),$$

$$P(\varphi) = h(i/2) + h(-i/2), \qquad W_{\infty}(\varphi) = \frac{1}{2\pi} \int_{\mathbb{R}} h(u) k(u)\, du,$$

$$W_{\mathrm{fin}}(\varphi) = \sum_{m \ge 2} \frac{\Lambda(m)}{\sqrt{m}} \big(\varphi(\log m) + \varphi(-\log m)\big).$$

Then, with zeros counted with multiplicity,

$$\mathfrak{Z}_{\xi}(h) = \sum_{\rho \in \mathcal{Z}} h(z_\rho) = P(\varphi) - W_{\infty}(\varphi) - W_{\mathrm{fin}}(\varphi). \tag{108.2}$$

The prime sum is finite and the zero sum converges absolutely. For even φ, the finite term is $2\mu_{1/2}(\varphi)$, where $\mu_{1/2} = \sum_{m \ge 2} \Lambda(m) m^{-1/2} \delta_{\log m}$. Under RH, $z_\rho = \gamma_\rho$ and $\mathfrak{Z}_{\xi}(h) = \int_{\mathbb{R}} h\, d\mu_{\mathrm{ord}}$. Without RH, replacing z_ρ by γ_ρ discards the real-part information and does not give the explicit formula.

Proof. The Fourier convention and test carrier are those of Chapter 78.1.1. Apply Chapter 77.5.6 to $f = \varphi$. Its polar terms are $h(\pm i/2)$; its real-line density is $\Re\psi_\Gamma(1/4 + iu/2) - \log\pi = -k(u)$. This gives (108.2), with the sign convention of Chapter 78.1.2. Compact support makes the prime sum finite. Repeated integration by parts gives rapid decay of h in the strip $|\Im z| \le 1/2$; the zero count in Chapter 77.5.1 gives absolute convergence of the zero sum. Evenness identifies the two prime evaluations. Finally, $z_\rho = \gamma_\rho - i(\Re\rho - 1/2)$, proving the stated specialization under RH. □

Remark 108.2.5 *(the distributional identity and Hilbert realizations).* The Mellin–Hadamard identity in Chapter 108.2.4 relates the continuous zero functional on $\mathscr{P}$ to the full polar, signed gamma and prime functionals on $\mathscr{A}$. The locally finite measures $\mu_{\text{prime}} = \mu_0$ and $\mu_{1/2}$ define distributions on compact smooth tests. Neither is tempered, by Chapter 77.5.4; their Fourier transforms cannot be taken in $\mathscr{S}'(\mathbb{R})$ by this construction.

There is nevertheless a signed Hilbert-space realization: Chapter 78.9.3 constructs the continuous map $E : \mathscr{A} \to K_Z = \ell^2(Z)$ and the self-adjoint involution J, with $(Ef)_\rho = (\mathcal{F}_+ f)(z_\rho)$, such that

$$\langle Ef, JEg\rangle = P(f * g^*) - W_\infty(f * g^*) - W_{\text{fin}}(f * g^*), \qquad g^*(t) = \overline{g(-t)}.$$

Here Z indexes occurrences of zeros, including multiplicity. This signed pairing does not supply a positive arithmetic-sector unitary comparison. Realizing the prime and zero expressions as spectral data of a single self-adjoint operator requires that additional comparison, including the operator domains and the spectral measures; the distributional identity alone supplies none of these identifications.

108.3 Formal Spectral Flow A as Mellin-Inversion Symbol

Mellin transformation followed by residue extraction defines a sequence-valued map on compact smooth multiplicative tests. Square summability and compatibility with a source operator require separate proofs.

The Mellin-Hadamard Inversion Symbol

Definition 108.3.1 *(formal Mellin-Hadamard inversion).* The *formal Mellin-Hadamard inversion* is the composite symbol

$$A^{\text{sym}} := \mathcal{I}_{\text{Had}} \circ \mathcal{M}$$

where $\mathcal{M}$ is the Mellin transform $(\mathcal{M}f)(s) = \int_0^\infty f(x)x^{s-1}dx$ on a suitable function class and $\mathcal{I}_{\text{Had}}$ is the Hadamard-inversion formal symbol

$$(\mathcal{I}_{\text{Had}}F)(\gamma_\rho) := \operatorname*{Res}_{s=\rho} \frac{F(s)}{\xi_{\mathbb{R}}(s)}$$

reading the residue of $F/\xi_{\mathbb{R}}$ at each non-trivial zero and writing it into the ρ-component of a formal sequence indexed by $\mathcal{Z}$.

Remark 108.3.2 *(Domains for a residue map).* The Mellin-residue prescription gives coordinates indexed by zeros. To obtain a Hilbert-space operator, one must specify a source Hilbert space, a dense domain on which the residue sequence is square summable, and a proof of closability. The occupation space is not a subspace of multiplicative Haar L^2 through the atomic prescription. A comparison with its generator requires an additional map and a domain intertwining identity.

Formal Mellin–Hadamard Obstruction

LEMMA 108.3.3 *(formal Mellin–Hadamard obstruction).* Suppose $f \in C_c^\infty(\mathbb{R}_{>0})$ and let $Lf(x) = -\log x\, f(x)$. Suppose f has Mellin transform $F(s) = (\mathcal{M}f)(s)$ entire, and suppose $\rho \in \mathcal{Z}$ is a simple zero of $\xi_{\mathbb{R}}$. Then

$$A^{\mathrm{sym}}(Lf)(\gamma_\rho) = -\frac{F'(\rho)}{\xi_{\mathbb{R}}'(\rho)}, \qquad A^{\mathrm{sym}}(f)(\gamma_\rho) = \frac{F(\rho)}{\xi_{\mathbb{R}}'(\rho)}.$$

Consequently the bare residue intertwining relation

$$A^{\mathrm{sym}} L \stackrel{?}{=} M_\gamma A^{\mathrm{sym}}$$

holds at ρ only under the additional interpolation condition

$$F'(\rho) = -\gamma_\rho F(\rho).$$

This interpolation condition concerns the test function and is not a consequence of RH. No map identifying L with either BC generator has been specified.

Proof. Define $(Lf)(x) = -\log x\, f(x)$ on $C_c^\infty(\mathbb{R}_{>0})$. Mellin transform gives $(\mathcal{M}(Lf))(s) = -F'(s)$, where F' is the derivative in the spectral variable. Since ρ is a simple zero,

$$\operatorname*{Res}_{s=\rho} \frac{F(s)}{\xi_{\mathbb{R}}(s)} = \frac{F(\rho)}{\xi_{\mathbb{R}}'(\rho)}, \qquad \operatorname*{Res}_{s=\rho} \frac{-F'(s)}{\xi_{\mathbb{R}}(s)} = -\frac{F'(\rho)}{\xi_{\mathbb{R}}'(\rho)}.$$

Multiplication by the zero ordinate would instead give $\gamma_\rho F(\rho)/\xi_{\mathbb{R}}'(\rho)$. Equality is exactly the displayed first-order interpolation condition. This is not an identity on compact tests: take $f(x) = x^{1-\rho}\psi(x)$, where ψ is nonnegative, nonzero, and compactly supported in an interval on which $\log x + \gamma_\rho$ has one strict sign. Then $F'(\rho) + \gamma_\rho F(\rho) = \int (\log x + \gamma_\rho)\psi(x)\,dx \neq 0$. □

Remark 108.3.4 *(RH is not enough for formal intertwining).* Chapter 108.3.3 shows that the continuous multiplier $L = -\log x$ differentiates the Mellin numerator before Hadamard residue extraction. RH would place ρ on the critical line, but it would not imply $F'(\rho) = -\gamma_\rho F(\rho)$ for the Mellin transforms in the source class. Thus the bare symbol A^{sym} is not a spectral-flow operator. A genuine operator construction must supply a new domain theorem or boundary condition that converts derivative residue data into zero-ordinate multiplication without inserting that conclusion by definition.

108.4 OBSTACLE I: HILBERT-SPACE COMPLETIONS ON BOTH SIDES

A sequence-valued residue prescription needs a source completion and estimates in the chosen target norm. Abstract Hilbert isomorphisms do not settle these domain or spectral requirements.

Source-Side Completion

Definition 108.4.1 *(Occupation source completion).* Use $L_w = \ell^2(\mathbb{N}^\times, dm/m)$ for occupation coordinates, with $N_{\mathrm{occ}} e_m = (\log m) e_m$. Its maximal domain is $\{c : \sum_m (\log m)^2 |c_m|^2/m < \infty\}$, and finite-support vectors form a core. This is the restriction in Chapter 77.3.2.

LEMMA 108.4.2 *(The atomic Mellin prescription).* Sending e_m to the additive Dirac distribution $\delta_{x=m}$ does not embed L_w in $L^2(\mathbb{R}_{>0}, dx/x)$. Its ordinary distributional Mellin transform is m^{s-1}, which is not square integrable on any vertical line.

Proof. A point mass is singular relative to dx/x, so it has no L^2 density. Pairing the additive Dirac distribution with x^{s-1} gives m^{s-1}. On $\Re s = c$ its modulus is the positive constant m^{c-1}, proving the second assertion. □

Remark 108.4.3 *(Atomic and continuous carriers).* The atomic prescription fails on each basis vector before any infinite Dirichlet-series convergence question arises. Abstract Hilbert-space isometries still exist between the separable infinite-dimensional spaces. An isometry preserving their stated generators cannot exist, because the occupation generator has an eigenvector basis and continuous scaling has no eigenvectors.

Target-Side Completion

Definition 108.4.4 *(Distinct target constructions).* The idele carrier is $\mathcal{K} = L^2(C_{\mathbb{Q}}, d^\times x)$ of Chapter 101.2.1. The weighted adele-class Hilbert completion in Chapter 101.7.1 and its quotient representation are different spaces. A Petersson completion, when supplied by an automorphic construction, is a third carrier. Neither these names nor abstract Hilbert isomorphisms specify a generator-domain map between any two of them.

Lemma 108.4.5 *(Mellin transform on the idele norm).* The transform

$$(\mathcal{M}g)(\tau) = (2\pi)^{-1/2} \int_0^\infty g(x) x^{-i\tau}\, dx/x$$

is unitary from $L^2(\mathbb{R}_{>0}, dx/x)$ to $L^2(\mathbb{R}, d\tau)$. Tensoring with the identity on $L^2(C_{\mathbb{Q}}^1)$ gives the idele transform. It carries $-i\partial_{\log x}$, with logarithmic H^1 domain, to M_τ, with its maximal domain.

Proof. Substitute $u = \log x$ and apply Fourier Plancherel and Chapter 101.2.2. □

Remark 108.4.6 *(Representations and completions).* The Mellin transform diagonalizes the continuous scaling representation, not the occupation or critical BC representation. An injective map on their eigenvector cores cannot intertwine these generators. A different completion or a distributional map must state which operators, domains, and pairings it preserves.

108.5 Obstacle 2: Kernel of A as Bounded/Unbounded Operator

A residue prescription must define an operator on a stated domain. An integral kernel is one possible construction; closability requires an independent estimate.

The Hadamard Inversion Kernel

Definition 108.5.1 *(Residue integrals and a line-kernel candidate).* For a distinct zero ρ, take a positively oriented small circle C_ρ containing no other zero. The actual residue is

$$r_\rho(F) = \frac{1}{2\pi i} \int_{C_\rho} \frac{F(s)}{\xi_{\mathbb{R}}(s)} ds.$$

A different proposed line kernel is $K_{\mathrm{Had}}(\rho, s) = (2\pi i)^{-1}[\xi_{\mathbb{R}}(s)(s-\rho)]^{-1}$. It does not give the preceding residue by the same circle integral: the additional factor changes the Laurent coefficient extracted. Its integrability on the critical line can nevertheless be tested.

LEMMA 108.5.2 *(the Hadamard kernel is not a Hilbert-Schmidt kernel).* For the critical-line Mellin completion compatible with the spectral-flow condition, the Hadamard kernel K_{Had} is not Hilbert–Schmidt. Its Hilbert-Schmidt norm

$$\|K_{\mathrm{Had}}\|_{\mathrm{HS}}^2 = \frac{1}{4\pi^2} \sum_{\rho} \int_{\mathbb{R}} \frac{d\tau}{|\xi_{\mathbb{R}}(1/2 + i\tau)|^2 |1/2 + i\tau - \rho|^2}$$

diverges at every zero ρ lying on the critical line.

Proof. Let $m_\rho \geq 1$ be the order of vanishing at ρ. If ρ lies on the critical line, then $|\xi_{\mathbb{R}}(s)|^{-2} \sim C_\rho |s - \rho|^{-2m_\rho}$ along the contour near $s = \rho$. The integrand is then $|s - \rho|^{-2m_\rho - 2}$, non-integrable on a one-dimensional contour for $m_\rho \geq 1$. Hardy's theorem gives infinitely many zeros on the critical line. Hence the critical-line Hadamard residue kernel is not Hilbert–Schmidt. Off-line zeros do not give this local contour singularity; they are not needed for the conclusion. □

Remark 108.5.3 *(Limits of the Hilbert–Schmidt obstruction).* Chapter 108.5.2 rules out a Hilbert–Schmidt Hadamard-residue kernel in the critical-line completion. A bounded non-Hilbert–Schmidt operator is not thereby excluded. The unbounded spectral-flow problem is the stronger demand imposed by the pole residue prescription together with the zero-divisor determinant and trace identities; it requires a closed densely defined operator and a specified domain.

The Domain Problem

PROPOSITION 108.5.4 *(Dirichlet-series and residue domains).* Finite-support sequences and sequences satisfying $|c_m| = O_N(m^{-N})$ for every N are dense subspaces of L_w. For the latter sequences, $F_c(s) = \sum_m c_m m^{s-1}$ is entire, with derivatives converging normally on compact sets. This does not imply vertical rapid decrease. The sequence-valued residue map on this class lands in ℓ^2 exactly on the subspace

$$\mathcal{D}_R = \{c : \sum_{\rho} |r_\rho(F_c)|^2 < \infty\},$$

where one coordinate is used per distinct zero. Density and closability of this restricted map require further estimates.

Proof. Finite sequences lie in both source classes and are dense in L_w by coordinate truncation. On a compact set with $\Re s \leq B$, each derivative is bounded termwise by $|c_m| m^{B-1} (\log m)^k$; choosing $N > B + k + 2$ proves normal convergence. The sequence $c_1 = 1, c_m = 0$ for $m > 1$ gives $F_c = 1$, refuting vertical rapid decrease. The final criterion is the definition of the ℓ^2 norm. At multiple zeros, residue extraction uses a finite Taylor jet; it does not itself supply one independent coordinate per zero multiplicity. □

Remark 108.5.5 *(Additional domain requirements).* A different Mellin growth space, including a Beurling-type space, requires an explicitly defined norm and comparison map before it can replace $\mathcal{D}_R$. Coefficient decay alone supplies neither the residue estimates nor a generator intertwiner. For any closed densely defined operator A, A^*A is self-adjoint and the polar decomposition exists. These general facts do not imply that its partial isometry preserves the source and target generators or has the required arithmetic range.

108.6 Adele-Class and Virtual Trace Constructions

Definition 108.6.1 *(Weighted adele-class comparison).* For $\delta > 1$, use the map $E\phi(x) = |x|^{1/2} \sum_{q \neq 0} \phi(qx)$ and Hilbert seminorm of Chapter 101.7.1. Its completion embeds isometrically in $L^2(C_{\mathbb{Q}}, (1 + \log^2 |x|)^{\delta/2} d^\times x)$. The cokernel of this closed image carries the quotient of the left regular idele-class representation. The norm-direction action is polynomially bounded; this weighted representation is not asserted to be unitary.

Proposition 108.6.2 *(Critical-zero trace).* Connes's §III, Theorem 1 and Corollary 2, pp. 13–14, identify the quotient spectrum and integrated trace with the critical zeros, with the δ-dependent multiplicities stated in Chapter 101.7.2. This is a statement about that quotient representation. It does not identify the full critical BC generator with its scaling generator.

Global trace comparison

Definition 108.6.3 *(A full arithmetic trace identity).* For a specified trace construction, let $\mathcal{T} : \mathscr{A} \to \mathbb{C}$ be its distribution on compact smooth logarithmic tests. The full comparison requirement is

$$\mathcal{T}(f) = P(f) - W_\infty(f) - W_{\mathrm{fin}}(f) \qquad (f \in \mathscr{A}).$$

If a cutoff or regularized trace defines $\mathcal{T}$, its subtraction, convergence, and normalization are part of the construction. The positivity requirement is separately $\mathcal{T}(f * f^*) \geq 0$ for every $f \in \mathscr{A}$.

Remark 108.6.4 *(The source map).* The identity map is not a map between the BC GNS space and Connes's quotient Hilbert space. To compare their dynamics one must specify a map and its domain. The eigenvector obstruction excludes an injective exact intertwiner on the BC eigenvector core with a zero-divisor target. Connes's global cutoff comparison in §VIII is distinct from the critical-zero quotient theorem.

Proposition 108.6.5 *(Trace comparison and positivity).* Under the full trace identity above, positivity of $\mathcal{T}$ on convolution squares is equivalent to Weil positivity, and hence to RH. This implication does not construct an intertwiner.

Proof. Apply the identity to $f * f^*$ and use Chapter 78.2.1. □

Remark 108.6.6 *(Weighted and unweighted spaces).* Connes's completion uses a Schwartz summation seminorm and a cokernel. It is not quotient Haar L^2 on a non-Hausdorff space. A comparison with the unweighted idele space must account for this weight, quotient, and the action on the quotient.

108.7 Meyer's Virtual Character

Definition 108.7.1 *(Virtual representations).* A virtual representation $\pi_+ \ominus \pi_-$ has character $\mathrm{Tr}\, \pi_+(a) - \mathrm{Tr}\, \pi_-(a)$ on test functions for which both integrated operators have a trace. In Meyer's construction the carriers are smooth locally convex representations with the summability structure of his §5. They are not defined as a single self-adjoint perturbation pair on $L^2(C_{\mathbb{Q}})$.

Theorem 108.7.2 *(The virtual Weil character).* Meyer's Theorems 5.8 and 5.11 identify the character of his smooth summable virtual representation with the raw Weil distribution. Its spectral multiplicities are the orders of poles minus the orders of zeros of the relevant L-functions.

The source is Meyer, pp. 43 and 47. His Proposition 4.4, p. 26, instead concerns Schwartz restriction and Fourier maps.

Positive and signed traces

Remark 108.7.3 *(A character is not an operator intertwiner).* The virtual character theorem supplies no unitary $\mathcal{H}_1 \to L^2(\mathbb{R})$ intertwining the BC generator with a zero-divisor operator. Its signed trace also supplies no positivity theorem for the difference. The central twist and sign converting its raw character to W must be specified before using the normalized Weil criterion.

PROPOSITION 108.7.4 *(A positive trace comparison).* Let H be self-adjoint. Suppose that, for every $f \in \mathscr{A}$, $|h_f|^2(H)$ is trace class and

$$\operatorname{Tr}(|h_f|^2(H)) = W(f * f^*).$$

Then Weil positivity holds. The hypothesis includes the full arithmetic trace identity; it is not supplied by a virtual character formula.

Proof. The spectral theorem makes $|h_f|^2(H)$ positive. A positive trace-class operator has nonnegative trace. □

Remark 108.7.5 *(Trace ideals and summability).* Smooth summability on locally convex representation spaces and trace-class differences on a Hilbert space require different operator estimates. Neither condition changes point spectrum into continuous spectrum under an exact intertwiner.

108.8 OBSTRUCTIONS TO THE PROPOSED OPERATOR COMPARISONS

THEOREM 108.8.1 *(Specified comparison obstructions).* An injective intertwiner on the full BC or occupation eigenvector core cannot produce the zero-divisor target. The common tensor construction $M_\tau \otimes 1 + 1 \otimes N_{\mathrm{BC}}$ has no full ordinary wave operators relative to $M_\tau \otimes 1$. The literal entire-Mellin class $\mathrm{PW}^{\mathrm{TM}}$ is zero. These statements restrict the displayed constructions, not all possible arithmetic realizations.

Proof. The first assertion is the eigenvector proposition. The other two are proved in Chapter 101.3.2 and Chapter 101.6.2. □

Remark 108.8.2 *(The complete Weil form).* The finite-prime functional is explicit, but its explicit calculation is not an absorption into a positive trace. The condition remains $P(f * f^*) - W_\infty(f * f^*) - W_{\mathrm{fin}}(f * f^*) \geq 0$ for every compact smooth complex test. A local functional equation or an idele scaling phase does not imply this inequality.

Maps and domains

PROPOSITION 108.8.3 *(Limits of the obstructions).* The eigenvector obstruction applies whenever the deciding zero-energy vector is in the domain of an injective intertwiner. It does not exclude a densely defined map whose domain omits that vector, a noninjective map, or a comparison preserving a specified distribution rather than the generator. Each alternative requires its own domain and trace theorem.

Proof. The obstruction uses $HAv = ANv = 0$ and $Av \neq 0$. Removing either hypothesis removes that inference. No existence assertion follows from removing it. □

Remark 108.8.4 *(The arithmetic realization question).* A new construction must state its carrier and preserved operation. The distributional explicit formula remains valid independently of these failed generator transports. A general impossibility claim for other arithmetic trace constructions does not follow.

108.9 Comparison with Cohomological and Scattering Models

Proposition 108.9.1 *(Transport of a specified cohomological operator).* Suppose a cohomological realization supplies a Hilbert space H_D, a self-adjoint D, and a unitary $U : H_D \to H'$. Then UDU^{-1}, on U Dom D, has the same spectral multiplicities and trace functional as D. Any spectral determinant construction invariant under unitary conjugation has the same normalization after this transport.

Proof. Functional calculus gives $h(UDU^{-1}) = Uh(D)U^{-1}$. It identifies spectral projections and preserves traces of trace-class operators. Apply the assumed determinant prescription to the identical spectral data. □

Remark 108.9.2 *(Cohomological comparisons).* A Deninger-type cohomological construction must supply the space, operator, and comparison maps in addition to its determinant identity. The proposition does not construct those data or identify its generator with the full BC generator.

Scattering and signed traces

Proposition 108.9.3 *(Scattering does not force Weil positivity).* Complete unitary scattering does not imply positivity of a trace difference on Fourier squares. An ordinary trace-class spectral shift giving a positive trace difference on every such square must vanish.

Proof. The pair $M_\lambda \oplus 0$, $M_\lambda \oplus 1$ has scattering operator one, but trace difference $h(1) - h(0)$. For $f(u) = \phi(u) + \phi(u - \pi)$, $\int \phi = 1$, and $h = |h_f|^2$, this is -4. The general vanishing statement is Chapter 101.5.1. □

Remark 108.9.4 *(The arithmetic test identity).* Since $\mathrm{PW}^{\mathrm{TM}} = \{0\}$, it gives no nonzero class from which Weil positivity can be extended. The proposed arithmetic trace must be constructed on all of $\mathscr{A}$, retaining the polar, archimedean, and finite-prime terms. Its operators, domains, and regularization are additional data, as in Chapter 101.8.3.

Bulk observables and parameter derivatives

Proposition 108.9.5 *(A scalar partition function does not fix its generator).* Equality of scalar partition functions does not by itself identify the operator derivative in a family on a fixed Hilbert space. Even finite-dimensional unitarily conjugate families can have identical partition functions and different derivatives.

Proof. Let $D = \mathrm{diag}(0, 1)$, $K = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$, and $D(s) = e^{isK} D e^{-isK}$. For every real s and $\beta > 0$, $\mathrm{Tr}\, e^{-\beta D(s)} = 1 + e^{-\beta}$, whereas $D'(0) = i[K, D] \neq 0$. The constant family D has the same traces and derivative zero. □

Remark 108.9.6 *(The required bulk comparison).* An arithmetic Chern–Simons bulk construction must identify its state space, observable, and domain before comparing a parameter derivative with an ordinate operator. A partition identity alone supplies none of these maps. The Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ is not, by itself, a vertex algebra or a Hilbert-space generator.

Positive spectral realization

THEOREM 108.9.7 *(Positive trace implies the Weil inequality).* A self-adjoint operator with the trace identity of Chapter 108.7.4 gives Weil positivity and therefore RH. In an ordinary trace-class difference model, the same positive nonzero Weil identity is impossible.

Proof. The positive trace proposition and the Weil criterion prove the first assertion. The second is Chapter 101.8.1. □

Remark 108.9.8 *(Separate realization requirements).* A virtual character, a scattering determinant, a positive trace, and a normalized spectral determinant are different data. A comparison must specify its maps, domains, and test identities. For a regularized trace, positivity must be proved separately. The Dirac double below concerns closure of a specified operator; it does not construct those arithmetic comparisons.

108.10 Polyakov–Dirac Normal Form for the Residual

A scalar normalization does not determine an operator domain or a spectral measure. The Dirac double tests essential self-adjointness of an independently specified symmetric operator. Its determinant and arithmetic trace remain separate conditions.

Polyakov Rigidity of the Rank Residue

PROPOSITION 108.10.1 *(Polyakov rank-residue rigidity).* In the primary Heisenberg domain of Chapters 35 and 107, any spectral-flow closure compatible with

(i) the rank-2 per-prime Sugawara Heisenberg stress tensor,
(ii) the global Fock partition $Z(s) = \prod_p \prod_{n\geq 1}(1 - p^{-sn})^{-2}$, and
(iii) the archimedean Polyakov anomaly of the rank-2 free-field completion,

has determinant rank residue

$$r_\zeta = 2.$$

This scalar identity supplies no Hilbert carrier, generator-domain map, or zero-divisor determinant.

Proof. Chapter 107.6.1 proves that the unrenormalised conformal scalar $\sum_p c^{(p)}$ diverges, that the negative global modes do not act on the restricted vacuum, and that the global Fock-partition residue gives $r_\zeta = 2$. The same chapter proves the Polyakov rank comparison Chapter 107.5.3, identifying this finite-prime residue with the rank-2 archimedean conformal anomaly. These inputs fix the rank residue. They do not fix an entire exponential factor in a spectral determinant: multiplication by e^{a+bs} changes its logarithmic derivative by b, whose residue is zero. The normalization of a spectral determinant remains separate from this rank comparison. □

Remark 108.10.2 *(what Polyakov does and does not buy).* Polyakov regularisation is decisive for the determinant rank, not for RH. It supplies the finite scalar $r_\zeta = 2$ and rules out the divergent prime-zeta prescription; it does not produce the Hilbert space on which the zero ordinates are a self-adjoint spectrum.

Dirac Closure of the Remaining Operator

Definition 108.10.3 *(A specified symmetric core).* Choose a complex Hilbert space $\mathcal{H}_{\mathrm{res}}$, a dense linear subspace C_{res}, and a symmetric operator $H_{\mathrm{res}}^{\mathrm{sym}}$ with exactly that domain. Inner products are linear in the first variable. These are independently specified operator data. A multiplication chart or a residue map is additional structure, with its own domain requirements. No comparison with BC or with a zero-divisor operator is part of this definition.

Definition 108.10.4 *(Dirac double of the residual).* The *Dirac double* of the residual ordinate core is the odd symmetric operator

$$\mathscr{D}_{\mathrm{res}}^{\circ} := \begin{pmatrix} 0 & H_{\mathrm{res}}^{\mathrm{sym}} \\ H_{\mathrm{res}}^{\mathrm{sym}} & 0 \end{pmatrix} \quad \text{on} \quad C_{\mathrm{res}} \oplus C_{\mathrm{res}},$$

with grading $\Gamma = \mathrm{diag}(1, -1)$. A *Dirac closure* is a self-adjoint closure $\mathscr{D}_{\mathrm{res}} = \overline{\mathscr{D}_{\mathrm{res}}^{\circ}}$ whose spectral measure satisfies the regularised determinant identity

$$\det_{\infty}\big(s \cdot \mathrm{id} - (\tfrac{1}{2}\mathrm{id} + i H_{\mathrm{res}})\big) \;=\; \xi_{\mathbb{R}}(s), \tag{108.3}$$

where H_{res} is the off-diagonal component recovered from $\mathscr{D}_{\mathrm{res}}$ by the grading.

Lemma 108.10.5 *(Dirac double detects self-adjointness).* Let H be a densely defined symmetric operator on a Hilbert space $\mathcal{H}$ and $\mathscr{D}_H^{\circ} = \left(\begin{smallmatrix} 0 & H \\ H & 0 \end{smallmatrix}\right)$ on $\mathcal{D}(H) \oplus \mathcal{D}(H)$. Then $\mathscr{D}_H^{\circ}$ is essentially self-adjoint if and only if H is essentially self-adjoint. When this holds,

$$\overline{\mathscr{D}_H^{\circ}} \;=\; \begin{pmatrix} 0 & \overline{H} \\ \overline{H} & 0 \end{pmatrix}, \qquad \overline{\mathscr{D}_H^{\circ}}^{\,2} \;=\; \begin{pmatrix} \overline{H}^{\,2} & 0 \\ 0 & \overline{H}^{\,2} \end{pmatrix}.$$

Proof. For a symmetric H, $(\mathscr{D}_H^{\circ})^* = \left(\begin{smallmatrix} 0 & H^* \\ H^* & 0 \end{smallmatrix}\right)$ on $\mathcal{D}(H^*) \oplus \mathcal{D}(H^*)$. Hence the closure of $\mathscr{D}_H^{\circ}$ is self-adjoint exactly when the closure of H has adjoint domain equal to its own domain, i.e. exactly when H is essentially self-adjoint. The displayed square is the usual block-matrix product on $\mathrm{Dom}(\overline{H}^{\,2}) \oplus \mathrm{Dom}(\overline{H}^{\,2})$, justified after closure by the spectral theorem for the self-adjoint operator $\overline{H}$ (Reed–Simon I, Ch. VIII). □

Theorem 108.10.6 *(Dirac double of a specified operator).* For the specified $H_{\mathrm{res}}^{\mathrm{sym}}$, essential self-adjointness is equivalent to essential self-adjointness of its Dirac double. If these conditions hold, requiring the closure to have the normalized determinant (108.3) is exactly the additional determinant condition in the definition of Dirac closure. This equivalence concerns this operator and this domain.

Proof. Apply Chapter 108.10.5. The off-diagonal component of the closed double is the closure of the original symmetric operator. Substituting that component in the determinant definition proves the remaining assertion. Existence of a different Hilbert–Pólya operator supplies no core or unitary comparison with this specified one. □

Remark 108.10.7 *(Closure and determinant).* The squared graph norm $\|u\|^2 + \|H_{\mathrm{res}}^{\mathrm{sym}} u\|^2$ defines the graph completion. Essential self-adjointness asks whether the closure equals its adjoint. A determinant identity requires an admissible spectral determinant and its normalization; it is not a consequence of graph completeness.

Definition 108.10.8 *(closed Tate-polar operator quotient).* A *closed Tate-polar operator quotient* for $H_0 = H_{\mathrm{res}}^{\mathrm{sym}}$ is additional data of a Hilbert quotient

$$\pi : \mathcal{H}_{\mathrm{res}} \longrightarrow \mathcal{H}_{\mathrm{res}}^{\circ}$$

with closed finite-rank kernel P_{Tate}, an induced dense domain

$$C_{\mathrm{res}}^{\circ} := \pi(C_{\mathrm{res}}),$$

and a symmetric operator H_0° on C_{res}° satisfying

$$H_0^{\circ} \pi u = \pi H_0 u, \qquad u \in C_{\mathrm{res}}.$$

The quotient is required to be compatible with closure and adjoint domains:

$$\mathcal{D}(\overline{H_0^{\circ}}) = \pi \mathcal{D}(\overline{H_0}), \qquad \mathcal{D}((H_0^{\circ})^*) = \pi \mathcal{D}(H_0^*),$$

after completing both sides in their graph norms. It is also required to admit a separately specified unitary $U_{\mathrm{res}} : \mathcal{H}_{\mathrm{res}}^{\circ} \to L^2(\mathbb{R})$ that represents the quotient operator by multiplication on its image domain, in the sense of Chapter 108.10.15. No pre-quotient unitary is presupposed.

The existence of this quotient and compatibility data is a separate hypothesis.

Remark 108.10.9 *(post-quotient notation).* In the boundary and deficiency discussion below,

$$T_0 := H_0^{\circ} : C_{\mathrm{res}}^{\circ} \subset \mathcal{H}_{\mathrm{res}}^{\circ} \longrightarrow \mathcal{H}_{\mathrm{res}}^{\circ}$$

denotes the post-Tate residual operator supplied by Chapter 108.10.8. The pre-quotient operator $H_0 = H_{\mathrm{res}}^{\mathrm{sym}}$ is only the source operator. Thus every adjoint, deficiency kernel, boundary quotient, and multiplication-coordinate graph statement below is a statement about T_0. Without the closed Tate-polar quotient, these formulas are well-formed as conditional operator theory but not as an unconditional construction.

Boundary Form and Deficiency Kernels

The boundary quotient tests essential self-adjointness of the specified operator. Rank-residue normalization does not determine that quotient, the spectral determinant, or the arithmetic trace.

Definition 108.10.10 *(residual boundary form).* Under the post-quotient notation of Chapter 108.10.9, the adjoint-domain boundary form is the Hermitian symplectic form

$$\mathcal{B}_{\mathrm{res}}(u, v) \;:=\; \langle T_0^* u, v\rangle - \langle u, T_0^* v\rangle, \qquad u, v \in \mathcal{D}(T_0^*).$$

The *residual boundary space* is the quotient

$$Q_{\mathrm{res}} \;:=\; \mathcal{D}(T_0^*)/\mathcal{D}(\overline{T_0}),$$

with the induced form still denoted $\mathcal{B}_{\mathrm{res}}$.

PROPOSITION 108.10.11 *(Boundary quotient and essential self-adjointness).* For the specified densely defined symmetric T_0,

$$Q_{\mathrm{res}} = 0$$

is equivalent to essential self-adjointness. Vanishing of the boundary form on the original domain alone asserts only symmetry. Identifying this operator boundary space with a BV–BFV boundary space requires a separate map preserving the forms and domains.

Proof. The closure is self-adjoint exactly when $\operatorname{Dom} \overline{T}_0 = \operatorname{Dom} T_0^*$, which is the zero-quotient condition. Symmetry already makes the boundary form vanish on $\operatorname{Dom} T_0$, regardless of whether its adjoint domain is larger. Neither assertion includes a determinant or arithmetic trace identity. □

Definition 108.10.12 *(deficiency spaces of the residual).* The residual deficiency spaces are

$$\mathcal{N}_+ := \ker(T_0^* - i), \qquad \mathcal{N}_- := \ker(T_0^* + i).$$

Theorem 108.10.13 *(Dirac two-test form of the residual).* For this specified T_0, a self-adjoint closure with the stated determinant exists exactly when both conditions hold:

(i) *Deficiency vanishing:*

$$\mathcal{N}_+ = 0 = \mathcal{N}_-. \tag{108.4}$$

(ii) *Determinant identity for the closure:*

$$\det_\infty\big(s \cdot \mathrm{id} - (\tfrac{1}{2}\mathrm{id} + i\overline{T_0})\big) \;=\; \xi_{\mathbb{R}}(s). \tag{108.5}$$

Define the post-quotient double

$$\mathscr{D}^\circ_{T_0} = \begin{pmatrix} 0 & T_0 \\ T_0 & 0 \end{pmatrix} \quad \text{on } C^\circ_{\mathrm{res}} \oplus C^\circ_{\mathrm{res}}.$$

Equivalently, this Dirac double $\mathscr{D}^\circ_{T_0}$ has no deficiency states and its closed off-diagonal component has determinant $\xi_{\mathbb{R}}$.

Proof. By von Neumann's deficiency-index criterion, a densely defined symmetric operator T_0 is essentially self-adjoint if and only if $\ker(T_0^* - i) = \ker(T_0^* + i) = 0$. Thus (108.4) is exactly the essential self-adjointness part of Chapter 108.10.4. By Chapter 108.10.5, the same condition is equivalent to essential self-adjointness of the Dirac double $\mathscr{D}^\circ_{T_0}$.

The regularized determinant is an additional datum for this closure. Equation (108.5) is imposed on $\overline{T}_0$, the off-diagonal component of the closed post-quotient double. Combining the deficiency criterion with this separate determinant identity proves the stated equivalence. The pre-quotient double is a different operator. No existence theorem for another operator identifies its domain with this one. □

Remark 108.10.14 *(Scope of deficiency vanishing).* Vanishing of both deficiency kernels proves essential self-adjointness of T_0. The determinant condition remains separate. In a unitary multiplication chart, deficiency vanishing has the stronger spectral consequence proved below: the closure is continuous multiplication and cannot realize a discrete zero-eigenvalue divisor.

The Deficiency Calculation

In multiplication coordinates the deficiency kernels are the orthogonal complements of the ranges of $(M_t \pm i)$ on the residual core, with the sign convention matching the conjugate-linear second slot in the inner product. The computation applies to a specified residual multiplication chart and the closed Tate-polar operator quotient of Chapter 108.10.8; without those it is conditional operator theory. The obstruction is a graph-core question for the residual Hadamard domain, not an Euler-product calculation.

Definition 108.10.15 *(multiplication-coordinate residual chart).* Let

$$M_t\colon \mathcal{D}(M_t) \subset L^2(\mathbb{R}, dt) \to L^2(\mathbb{R}, dt), \qquad (M_t f)(t) = t f(t),$$

be the self-adjoint multiplication operator. A *multiplication-coordinate residual chart* is a unitary map, denoted U_{res} by abuse of notation,

$$U_{\mathrm{res}}\colon \mathcal{H}^{\circ}_{\mathrm{res}} \longrightarrow L^2(\mathbb{R}, dt),$$

from the residual quotient Hilbert space of Chapter 108.10.8 such that the multiplication-coordinate residual core is

$$C^{M}_{\mathrm{res}} \;:=\; U_{\mathrm{res}}(C^{\circ}_{\mathrm{res}}) \;\subset\; \mathcal{D}(M_t),$$

and

$$T_{\mathrm{o}} = H^{\circ}_{\mathrm{o}} \quad \text{is represented by} \quad M_t|_{C^{M}_{\mathrm{res}}}.$$

This chart is additional data. The virtual character theorem Chapter 108.7.2 does not supply it. Once specified, it determines the graph and spectral-type consequences below.

THEOREM 108.10.16 *(deficiency kernels are range defects).* Assume a multiplication-coordinate residual chart in the sense of Chapter 108.10.15. Then

$$U_{\mathrm{res}}\mathcal{N}_{+} \;=\; \big((M_t + i)C^{M}_{\mathrm{res}}\big)^{\perp}, \tag{108.6}$$

and

$$U_{\mathrm{res}}\mathcal{N}_{-} \;=\; \big((M_t - i)C^{M}_{\mathrm{res}}\big)^{\perp}.$$

Consequently $\mathcal{N}_{+} = 0 = \mathcal{N}_{-}$ if and only if both ranges

$$(M_t - i)C^{M}_{\mathrm{res}}, \qquad (M_t + i)C^{M}_{\mathrm{res}}$$

are dense in $L^2(\mathbb{R}, dt)$.

Proof. We prove the + identity; the − identity is identical with i replaced by $-i$. The inner product is linear in the first slot and conjugate-linear in the second. By definition, $u \in \mathcal{N}_{+}$ means $u \in \mathcal{D}(T_{\mathrm{o}}^{*})$ and $(T_{\mathrm{o}}^{*} - i)u = 0$. Equivalently, for every $f \in C^{\circ}_{\mathrm{res}}$,

$$\langle T_{\mathrm{o}} f, u\rangle \;=\; \langle f, iu\rangle.$$

Since the second slot is conjugate-linear, $\langle f, iu\rangle = -i\langle f, u\rangle$. Transport by U_{res}. Write $\tilde{u} = U_{\mathrm{res}}u$ and $\tilde{f} = U_{\mathrm{res}}f$. Since T_{o} is represented by M_t on C^{M}_{res}, the adjoint equation becomes

$$\langle M_t\tilde{f}, \tilde{u}\rangle \;=\; \langle \tilde{f}, i\tilde{u}\rangle, \qquad \tilde{f} \in C^{M}_{\mathrm{res}}.$$

Hence

$$\langle (M_t + i)\tilde{f}, \tilde{u}\rangle = 0 \qquad \text{for all } \tilde{f} \in C^{M}_{\mathrm{res}},$$

which says precisely that $\tilde{u} \in ((M_t + i)C^{M}_{\mathrm{res}})^{\perp}$. The converse is the same implication read backwards, so (108.6) follows. The density criterion follows because a subspace has zero orthogonal complement exactly when its closure is the full Hilbert space. □

Corollary 108.10.17 *(range density is graph density for M_t).* For a subspace $C \subset \mathcal{D}(M_t)$, the following are equivalent:

$$\overline{C}^{\|\cdot\|_{M_t}} = \mathcal{D}(M_t), \qquad \overline{(M_t - i)C}^{L^2} = L^2(\mathbb{R}, dt), \qquad \overline{(M_t + i)C}^{L^2} = L^2(\mathbb{R}, dt).$$

Consequently, under the residual multiplication chart hypothesis, C_{res}^M is a graph core for M_t if and only if

$$\mathcal{N}_+ = 0 = \mathcal{N}_-.$$

Proof. For $\operatorname{Im} z \neq 0$, the map

$$M_t - z \colon \mathcal{D}(M_t)_{\mathrm{graph}} \to L^2(\mathbb{R}, dt)$$

is boundedly invertible: its inverse is multiplication by $(t - z)^{-1}$, which maps L^2 into $\mathcal{D}(M_t)$ with bounded graph norm. Hence a subspace is dense in the graph norm if and only if its image under $M_t - z$ is dense in L^2. Apply this with $z = i$ and $z = -i$, then use Chapter 108.10.16. □

Lemma 108.10.18 *(rank-one graph-boundary model).* Let $\psi(t) = (1 + |t|)^{-1}$. Then $\psi \in L^2(\mathbb{R}, dt)$ but $\psi \notin \mathcal{D}(M_t)$. Define

$$C_\psi := \{ f \in \mathcal{D}(M_t) \mid \langle (M_t - i)f, \psi \rangle = 0 \}.$$

Then C_ψ is L^2-dense and graph-closed of codimension one, but it is not graph-dense. Its range defects are

$$\big((M_t - i)C_\psi\big)^\perp = \mathbb{C}\psi, \qquad \big((M_t + i)C_\psi\big)^\perp = \mathbb{C}\,\frac{t + i}{t - i}\psi.$$

Proof. The function ψ is square-integrable, while $t\psi(t)$ is not square-integrable. Since

$$M_t - i \colon \mathcal{D}(M_t)_{\mathrm{graph}} \to L^2(\mathbb{R}, dt)$$

is a bounded isomorphism, C_ψ is the inverse image of the closed hyperplane $\psi^\perp$; hence it is graph-closed of codimension one and its first range defect is $\mathbb{C}\psi$. The defining functional is not continuous for the L^2-topology on $\mathcal{D}(M_t)$, because such continuity would represent it by an L^2-vector, equivalently would put ψ in $\mathcal{D}(M_t)$. Therefore its kernel is L^2-dense.

For the second range, write

$$(M_t + i)(M_t - i)^{-1}$$

as multiplication by $(t + i)/(t - i)$, a unitary multiplier on L^2. The orthogonal complement of its image of $\psi^\perp$ is the span of $(t + i)(t - i)^{-1}\psi$. □

Lemma 108.10.19 *(point conditions are graph-invisible).* Let $\Gamma \subset \mathbb{R}$ be locally finite. Then $C_c^\infty(\mathbb{R} \setminus \Gamma)$ is graph-dense in $\mathcal{D}(M_t)$. In particular, a boundary condition that is only pointwise at the zero ordinates cannot obstruct graph density for the ordinary M_t-graph norm.

Proof. The graph norm of M_t is the L^2-norm for the measure $(1 + t^2)\,dt$. Locally finite sets have zero measure for this weight. Given $f \in \mathcal{D}(M_t)$, truncate f to a compact interval, remove intervals of arbitrarily small weighted measure around the finitely many points of Γ in that interval, and then mollify. The approximants lie in $C_c^\infty(\mathbb{R} \setminus \Gamma)$ and converge in the graph norm. □

Definition 108.10.20 *(Hadamard-supported graph functional).* Let

$$\Gamma_\xi^{\mathrm{crit}} := \{\, \gamma \in \mathbb{R} \mid \tfrac{1}{2} + i\gamma \text{ is a non-trivial zero of } \zeta \,\}$$

with multiplicities forgotten. This is the real critical-line ordinate support relevant to the Hilbert–Pólya target; it is not an assertion that the full Hadamard divisor has already been realised on $\mathbb{R}$. A continuous functional

$$\beta \colon \mathcal{D}(M_t)_{\mathrm{graph}} \longrightarrow \mathbb{C}$$

is *Hadamard-supported on the zero ordinates* if

$$\beta(\phi) = 0 \qquad \text{for every } \phi \in C_c^\infty(\mathbb{R} \setminus \Gamma_\xi^{\mathrm{crit}}).$$

This is the graph-norm formulation of the idea that the boundary condition sees only point or finite-jet Hadamard residue data at the zero ordinates.

THEOREM 108.10.21 *(no Hadamard residue functional in the ordinary graph dual).* The ordinary M_t-graph dual contains no non-zero Hadamard-supported functional. Equivalently,

$$\beta \in (\mathcal{D}(M_t)_{\mathrm{graph}})^*, \qquad \operatorname{supp}\beta \subset \Gamma_\xi^{\mathrm{crit}} \quad \Longrightarrow \quad \beta = 0$$

in the sense of Chapter 108.10.20. Thus there is no non-zero

$$\beta_{\mathrm{Had}} \colon \mathcal{D}(M_t)_{\mathrm{graph}} \to \mathbb{C}$$

whose graph-closed kernel is exactly a Hadamard-residue boundary condition supported only at the zero ordinates. The statement also rules out finite-jet residue data at those ordinates, if such data are asked to be continuous for the ordinary M_t-graph topology.

Proof. The non-trivial zeros of ζ form a discrete subset of the critical strip, and only finitely many have ordinate in a bounded interval. Hence $\Gamma_\xi^{\mathrm{crit}}$ is locally finite as a subset of $\mathbb{R}$. By Chapter 108.10.19,

$$C_c^\infty(\mathbb{R} \setminus \Gamma_\xi^{\mathrm{crit}})$$

is dense in $\mathcal{D}(M_t)$ for the graph norm. If β is continuous for the graph norm and vanishes on this dense subspace, it vanishes on all of $\mathcal{D}(M_t)$.

Equivalently, the graph norm is the L^2-norm for the weighted measure $(1 + t^2)\,dt$, so the graph dual is represented by weighted L^2-functions, or, after the isometric resolvent chart

$$M_t - i \colon \mathcal{D}(M_t)_{\mathrm{graph}} \xrightarrow{\sim} L^2(\mathbb{R}, dt),$$

by L^2-vectors. No non-zero L^2-vector is supported on the locally finite set $\Gamma_\xi^{\mathrm{crit}}$, which has Lebesgue measure zero. □

COROLLARY 108.10.22 *(Hadamard residue data is graph-invisible).* In the ordinary multiplication graph topology, β_{Had} does not exist as a non-zero graph-dual boundary functional. Therefore a boundary condition whose only data are point or finite-jet Hadamard residues at the locally finite real ordinate set $\Gamma_\xi^{\mathrm{crit}}$ is graph-invisible: it cannot by itself obstruct graph density of C_{res}^M in $\mathcal{D}(M_t)$.

Remark 108.10.23 *(surviving branches after the graph-dual no-go).* The preceding corollary is not an exhaustive boundary-state classification. It eliminates only the ordinary point-supported graph-dual path. Assuming the closed Tate-polar quotient and residual multiplication chart have been constructed, a surviving operator obstruction must take a different form. The known nonexclusive presentations are:

(i) the exact Hadamard residue or finite-jet trace lives in a stronger rigged, Paley–Wiener, de Branges, or reproducing-kernel topology $\Phi_\xi \subset \mathcal{D}(M_t)_{\mathrm{graph}}$, where point evaluation is continuous;

(ii) the ordinary graph obstruction is nonlocal, represented under the resolvent chart by an L^2-vector or closed L^2-subspace as in Chapter 108.10.18, and is therefore not point-residue data;

(iii) a physical Ward/BV–BFV argument supplies extra boundary phase space not yet identified with Q_{res}; this is a physics residual, not an operator-theoretic graph-dual boundary functional.

These are different possible constructions. No equivalence between them, or with Weil positivity, follows from the graph-dual theorem. The stronger-topology approach would require, at minimum, a continuous Hadamard trace-and-jet map $\Phi_\xi \to \ell^2(\Gamma_\xi^{\mathrm{crit}}, w)$, compatibility with the post-Tate quotient and adjoint domains, and a proof that the resulting closed condition is not a tautological insertion of the zero divisor.

Remark 108.10.24 *(Graph density fixes the closure).* In a specified unitary multiplication chart, graph density gives $\overline{T}_0$ unitarily equivalent to M_t. Its spectral measures are then absolutely continuous. Point-supported residue functionals are absent from the ordinary graph dual; nonlocal graph conditions can have nonzero deficiency, as the rank-one graph-boundary example shows. Neither outcome constructs a zero-divisor operator on this chart.

Graph Closure and Spectral Type

The ordinary multiplication closure has continuous spectrum. The diagonal zero-space construction instead uses zeros as input. The following comparison makes their different spectral types explicit.

Lemma 108.10.25 *(classical multiplication-line graph closure).* Let

$$M_t^\circ : C_c^\infty(\mathbb{R}) \subset L^2(\mathbb{R}, dt) \longrightarrow L^2(\mathbb{R}, dt), \qquad (M_t^\circ f)(t) = tf(t).$$

Then M_t° is essentially self-adjoint. Its graph-norm closure is multiplication by t on

$$\mathcal{D}(M_t) \;=\; \{\, f \in L^2(\mathbb{R}, dt) \mid tf(t) \in L^2(\mathbb{R}, dt) \,\}.$$

The spectrum is the absolutely continuous spectrum $\mathrm{Spec}(M_t) = \mathbb{R}$.

Proof. The operator M_t with the displayed maximal domain is self-adjoint by the spectral theorem for multiplication operators. The core $C_c^\infty(\mathbb{R})$ is dense in the graph norm: truncate f by compactly supported cutoffs and then mollify; both f and tf converge in L^2. Hence the closure of M_t° is M_t. Since M_t is multiplication by the coordinate on $L^2(\mathbb{R}, dt)$, its spectrum is the essential range of t, namely $\mathbb{R}$, with absolutely continuous spectral measure. □

Proposition 108.10.26 *(why the classical closure is insufficient).* The closure of Chapter 108.10.25 does not solve the spectral-flow problem. Its graph norm is complete and its operator is self-adjoint, but its spectrum is continuous $\mathbb{R}$, not a divisor with zero multiplicities of $\xi_{\mathbb{R}}$. Consequently it cannot satisfy

$$\det_\infty\big(s \cdot \mathrm{id} - (\tfrac{1}{2}\mathrm{id} + iM_t)\big) = \xi_{\mathbb{R}}(s)$$

as a zero-eigenvalue determinant.

Proof. The determinant identity in Chapter 108.5 has divisor div $\xi_{\mathbb{R}}$. The multiplication operator M_t on $L^2(\mathbb{R}, dt)$ has Lebesgue spectral measure on the line, not this determinant divisor. An eigenvector would have to be supported on a singleton, which has Lebesgue measure zero. This excludes a determinant whose zeros are precisely finite-multiplicity eigenvalues of this operator. □

PROPOSITION 108.10.27 *(formal zero-space closure is tautological).* On the formal zero Hilbert space $\mathcal{H}_\xi^{\mathrm{formal}}$ of Chapter 108.1.3, the diagonal ordinate operator has graph-norm closure. Its projected operator $\Theta_\xi^{\mathrm{proj}}$ satisfies the regularised determinant identity for $\xi_{\mathbb{R}}$ only if the original zero divisor already lies on the critical line. This proves no non-formal spectral-flow closure.

Proof. The finite-support diagonal operator on $\bigoplus_{\rho\in\mathcal{Z}}\mathbb{C}$ closes in the graph norm to the maximal diagonal multiplication operator by the real numbers $t_\rho = \mathrm{Im}(\rho)$; its closure is self-adjoint. The operator $\Theta_\xi^{\mathrm{proj}} = \frac{1}{2} + iH_{\mathrm{ord}}^{\mathrm{formal}}$ has spectral divisor $\{\frac{1}{2} + it_\rho\}$. Hadamard factorisation identifies its regularised determinant with $\xi_{\mathbb{R}}$ only when $\beta_\rho = 1/2$ for every ρ. Otherwise it is the determinant of the projected divisor, not of $\xi_{\mathbb{R}}$. The construction has therefore used the zero divisor and then discarded its real-part defect. It supplies no Bost–Connes, Meyer, Connes, Deninger, or chiral-homological source for the Hilbert space or the Weil–Connes trace; it is the formal target explicitly excluded by Chapter 108.1.4. □

THEOREM 108.10.28 *(Spectral type forced by a multiplication chart).* Let T_0 be densely defined and symmetric. Suppose a unitary $U : \mathcal{H} \to L^2(\mathbb{R}, dt)$ satisfies $UT_0U^{-1} = M_t|_C$, with $C \subset \mathrm{Dom}\, M_t$. If T_0 is essentially self-adjoint, then

$$U\overline{T}_0U^{-1} = M_t.$$

Consequently the closure has purely absolutely continuous spectrum and no eigenvalues. It cannot have the nonempty zero-eigenvalue determinant divisor div $\xi_{\mathbb{R}}$.

Proof. The closure of $M_t|_C$ is a restriction of M_t. Essential self-adjointness makes it self-adjoint. A self-adjoint operator has no proper self-adjoint extension: taking adjoints reverses the inclusion and gives the reverse inclusion. Thus the closure equals M_t. Its scalar spectral measures have densities $|g(t)|^2 dt$. An eigenvector of eigenvalue λ would be supported on the null set $\{\lambda\}$, hence is zero. □

Remark 108.10.29 *(A different spectral carrier).* Within the stipulated unitary chart, closing the symmetric operator cannot create a zero-eigenvalue divisor. A stronger topology can make residue evaluation continuous, but its Hilbert completion, operator domain, and arithmetic trace must then be constructed. The preceding theorem concerns every essentially self-adjoint restriction in the ordinary multiplication chart, not only the compact smooth core.

Comparison of the constructions. Modular theory supplies the critical generator on its GNS space. Mellin analysis diagonalizes idele norm scaling. Residue calculus gives meromorphic evaluation maps, while Birman–Krein theory relates a specified trace-class pair to its spectral shift. Meyer's virtual representation supplies a signed character. Their comparison requires explicit maps, compatible domains, and preservation of the complete normalized Weil functional.

Chapter 109

Functoriality of the Triple Identification in A and g

Chapter 104 isolated the conditional triple comparison $H^\bullet_\Delta = H^\bullet_{\mathrm{ch}} = \partial$-chiral on the primary Heisenberg domain for the baseline genus $g = 0$ and the fixed arithmetic Heisenberg H^{Ar}. The functoriality residuals of Section 104.12(5,6) remain: the three cohomology assignments must extend to functors on a category $\mathsf{ArChAlg}$ of arithmetic chiral algebras on $\overline{\mathrm{Spec}\,\mathbb{Z}}$, and the triple comparison must become a natural isomorphism of these functors, uniformly compatible with the genus-g restriction and induction maps of Chapter 102. The conditional master theorem is Theorem 109.6.1; it rests on the chain-level identification Ξ of Theorem 109.3.2, the naturality diagram Theorem 109.4.1, and the genus-stability theorem Theorem 109.5.3. The diagonal morphism $\mathsf{H}^{\mathrm{Ar}} \to \mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$ is the explicit non-conformal additivity test. The residuals are exactly the hypotheses inherited from Chapters 103 and 104.

109.1 The Category of Arithmetic Chiral Algebras

The three cohomology assignments of Chapter 104 are defined on an individual object, the arithmetic Heisenberg H^{Ar}. To state functoriality we introduce the ambient category.

Definition 109.1.1 *(arithmetic chiral algebra).* An *arithmetic chiral algebra on* $\overline{\mathrm{Spec}\,\mathbb{Z}}$ is a datum

$$\mathsf{A} \;=\; \Big(\mathsf{A}^{(\infty)},\ \{\mathsf{A}^{(p)}\}_{p\in\mathbb{P}},\ \{u^{(v)}\}_{v\in|\overline{C}|},\ \{m^{(v,w)}\}_{v<w},\ \{\partial^{\mathrm{PG}}_{v,w}\}_{v<w}\Big)$$

subject to the axioms below. Write $|\overline{C}| = \mathbb{P}\cup\{\infty\}$.

(i) *Archimedean factor.* $\mathsf{A}^{(\infty)}$ is a pointed E_1-chiral factorisation algebra on $\mathbb{C}_\infty$ in the Beilinson–Drinfeld / Costello–Gwilliam sense (Ch. 58.1.1), together with a conformal vector $T \in \mathsf{A}^{(\infty)}_2$ and a spherical unit $u^{(\infty)} \in \mathsf{A}^{(\infty)}_0$.

(ii) *Finite-prime factors.* For every prime $p \in \mathbb{P}$, $\mathsf{A}^{(p)}$ is a pointed E_0-chiral coefficient object on the Fargues–Scholze perfectoid diamond chart S_p, equipped with a Bost–Connes Adams endomorphism $\psi_p \in \mathrm{End}(\mathsf{A}^{(p)})$ and a Frobenius-semilinear orientation $\mathfrak{J}_p^{\mathrm{Ar}}$ (the finite-place substitute for the archimedean $i \in \mathbb{C}$).

(iii) *Spherical units.* The collection $\{u^{(v)}\}_{v\in|\overline{C}|}$ satisfies the Tate spherical compatibility (Section 50.1.1): $u^{(v)}$ is closed for the local bar differential d_v, is a compact central idempotent, and is the monoidal unit at almost every prime.

(iv) *Adjacent products.* For every pair of distinct places $v < w$ in the auxiliary order $2 < 3 < 5 < \cdots < \infty$, the datum $m^{(v,w)}$ is a map

$$m^{(v,w)} : \mathsf{A}^{(v)} \widehat{\otimes} \mathsf{A}^{(w)} \longrightarrow \mathsf{A}^{(vw)},$$

with $\mathsf{A}^{(vw)}$ the formal merged-block coefficient in the sense of Definition 103.5.2. The $m^{(v,w)}$ are required to be ψ_p-equivariant at every finite $v = p$ and to intertwine the archimedean L_0-action at $v = \infty$.

(v) *Residue coupling.* Specify common coefficient complexes, residue operations and degree-one operators τ_S as in Definition 58.3.1, satisfying $D_{0,S}\tau_S + \tau_S D_{0,S} + \tau_S^2 = 0$ and intertwining stage transitions. Their identification with tame-weighted chiral operations is additional arithmetic realization data.

(vi) *Tate compatibility.* The restricted tensor product $\otimes'_v \mathsf{A}^{(v)}$ in pointed E_2-monoidal stable presentable ∞-categories (Corollary 50.8.3) is well-defined, i.e. almost every $u^{(v)}$ is the monoidal unit and the Tate-pair compatibility F2.c of Section 43.3 is satisfied.

The archimedean $\mathsf{A}^{(\infty)}$ is always genuinely chiral; finite factors may be E_0 per Definition 103.5.2. Fix $g \geq 0$. Call A *abelian Heisenberg-type* if each finite $\mathsf{A}^{(p)}$ is a rank-$2g$ bosonic Fock space. Require $\mathsf{A}^{(\infty)}$ to be the rank-$2g$ archimedean Heisenberg algebra with its specified oscillator grading. The integer g is the genus of this datum. The single-mode Mellin character of Theorem 33.5.1 does not define this full Fock space or its operations.

Remark 109.1.2 *(on the merged-block target).* The formal merged-block coefficient $\mathsf{A}^{(vw)}$ is not a new arithmetic place. It is the target of the adjacent contraction map in the sense of the ordered incidence category $\mathsf{Inc}_<(V)$ of Definition 103.5.1; concretely a completed tensor product of $\mathsf{A}^{(v)}$ and $\mathsf{A}^{(w)}$ modulo a quotient relation recording that the two local operators act on the same global fibre. This convention is essential to avoid the naive reading that primes are fused into composite arithmetic objects.

Definition 109.1.3 *(morphism of arithmetic chiral algebras).* A *morphism* $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$ of arithmetic chiral algebras is a collection $\phi = \{\phi^{(v)}\}_{v \in |\overline{C}|}$ with $\phi^{(v)}\colon \mathsf{A}_1^{(v)} \to \mathsf{A}_2^{(v)}$ such that

(i) $\phi^{(\infty)}$ is an E_1-chiral factorisation map preserving the conformal vector;

(ii) at every prime p, $\phi^{(p)}$ is ψ_p-equivariant and $\mathfrak{J}_p^{\mathrm{Ar}}$-compatible: $\phi^{(p)} \circ \psi_{p,1} = \psi_{p,2} \circ \phi^{(p)}$;

(iii) the spherical units are preserved: $\phi^{(v)}(u_1^{(v)}) = u_2^{(v)}$ for every $v \in |\overline{C}|$;

(iv) the adjacent products are intertwined: $m_2^{(v,w)} \circ (\phi^{(v)} \otimes \phi^{(w)}) = \phi^{(vw)} \circ m_1^{(v,w)}$ for every $v < w$;

(v) the Parshin–Gersten boundaries are intertwined: $\phi \circ \partial_1^{\mathrm{PG}} = \partial_2^{\mathrm{PG}} \circ \phi$ at every pair of ramified places;

(vi) the restricted-tensor map $\widehat{\phi} := \otimes'_v \phi^{(v)}$ is a map in the pointed E_2-monoidal category of Corollary 50.8.3; this is automatic from (1)–(5) at almost every place by the spherical-unit preservation.

Composition is place-wise; identities are place-wise identities. The resulting category is $\mathsf{ArChAlg}$.

PROPOSITION 109.1.4 *(*$\mathsf{ArChAlg}$ *is a well-defined category).* Composition of morphisms satisfies the axioms of Definition 109.1.3: axioms (1)–(5) are place-wise, and axiom (6) follows from place-wise axioms by the almost-every-place triviality of the units. Identity morphisms are identities in every axiom. Associativity and unitality are inherited from the underlying categories of E_1-chiral factorisation algebras at ∞ and E_0-coefficient categories at finite places.

Proof. For composition: given $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$ and $\chi\colon \mathsf{A}_2 \to \mathsf{A}_3$, the collection $(\chi \circ \phi)^{(v)} := \chi^{(v)} \circ \phi^{(v)}$ preserves each axiom: axiom (1) is closed under composition of E_1-chiral maps; axiom (2) is closed because ψ_p-equivariance composes; axiom (3) uses $\chi^{(v)}(\phi^{(v)}(u_1^{(v)})) = \chi^{(v)}(u_2^{(v)}) = u_3^{(v)}$; axiom (4) similarly using the stacked naturality diagrams. Axiom (5) uses the linear action of the boundary. Associativity

and unitality are automatic at each place. Axiom (6) follows from the almost-every-place compatibility of the Tate restricted tensor (Section 43.3): the set of places at which $u^{(v)}$ fails to be a strict unit is bounded, and composition preserves this bound. □

Definition 109.1.5 *(genus stabilization).* For every $g \geq 0$, let $\mathsf{ArChAlg}_g \subset \mathsf{ArChAlg}$ be the full subcategory of abelian Heisenberg-type arithmetic chiral algebras of genus g in the sense of Definition 109.1.1. The stabilization functor $S_{g,g+1}\colon \mathsf{ArChAlg}_g \to \mathsf{ArChAlg}_{g+1}$ tensors with the rank-2 archimedean Heisenberg (Definition 102.1.1's rank-2 enhancement at each place). A projection to genus g is defined only on split objects with a specified decomposition into old and new oscillators.

Remark 109.1.6 *(why the filtration).* The filtration records stabilization by a fresh rank-2 factor at every place. It is not a reflective inclusion without a chosen splitting of oscillators.

Remark 109.1.7 *(Local structures and comparison maps).* The archimedean factor carries the specified chiral factorization structure, while the finite-place factors carry their specified coefficient structures. A morphism must preserve each local structure and the common residue couplings. Functoriality of their combined arithmetic realization requires the same compatibility maps. Background on the local structures is given by Beilinson–Drinfeld, Francis–Gaitsgory, Fargues–Scholze and Bhatt–Scholze.

109.2 The Three Functors

The cohomology assignments of Chapter 104 are defined on the single object H^{Ar}. Functoriality requires a target category. Write $\mathrm{grVect}_{\mathbb{C}}^{\mathrm{Frob}}$ for the category of finite-dimensional graded $\mathbb{C}$-vector spaces equipped with a graded-linear automorphism F (the Frobenius) and a graded-symmetric non-degenerate pairing PD (the Poincaré duality); morphisms are graded linear maps commuting with both structures.

Definition 109.2.1 *(Deninger functor $H^\bullet_\Delta$).* The *Deninger functor* is the conditional assignment

$$H^\bullet_\Delta\colon \mathsf{ArChAlg} \longrightarrow \mathrm{grVect}_{\mathbb{C}}^{\mathrm{Frob}}$$

defined on the residual domain where the Deninger Frobenius has been chosen. It sends an arithmetic chiral algebra A to the triple $(H^\bullet_\Delta(\mathsf{A}), F_{\mathsf{A}}, \mathrm{PD}_{\mathsf{A}})$ of Definition 104.3.2, with $F_{\mathsf{A}} = F_{\infty,\mathsf{A}} \otimes \bigotimes'_p \psi_{p,\mathsf{A}}$ the global Frobenius of Definition 104.5.5 and PD_{A} the Poincaré duality pairing of Theorem 104.7.1. On a morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$, the functor sends ϕ to the induced map $H^\bullet_\Delta(\phi)\colon H^\bullet_\Delta(\mathsf{A}_1) \to H^\bullet_\Delta(\mathsf{A}_2)$.

Definition 109.2.2 *(chiral-homology functor $H^\bullet_{\mathrm{ch}}$).* The *chiral-homology functor*

$$H^\bullet_{\mathrm{ch}}\colon \mathsf{ArChAlg} \longrightarrow \mathrm{grVect}_{\mathbb{C}}^{\mathrm{Frob}}$$

sends A to $H^\bullet(B^{\mathrm{Ar}}(\mathsf{A}), D_{\mathsf{A}})$ of Definition 58.3.1, with D_{A} the signed total differential determined by A. On a morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$, the induced chain map $B^{\mathrm{Ar}}(\phi)$ commutes with D_{A_1} and D_{A_2} by axioms (3), (4), (5) of Definition 109.1.3; pass to cohomology for $H^\bullet_{\mathrm{ch}}(\phi)$.

Definition 109.2.3 *(bulk-boundary functor pair $\partial \circ \mathrm{BdryACS}$).* The *bulk-boundary assignment* is the composite

$$\partial \circ \mathrm{BdryACS}\colon \mathsf{ArChAlg} \xrightarrow{\mathrm{BdryACS}} \mathsf{3DACS}_{\overline{\mathrm{Spec}\,\mathbb{Z}}} \xrightarrow{\partial} \mathrm{grVect}_{\mathbb{C}}^{\mathrm{Frob}},$$

where

- $\mathsf{3DACS}_{\overline{\mathrm{Spec}\,\mathbb{Z}}}$ is the category of conjectural 3D quantum arithmetic Chern–Simons theories on the étale 3-space $\overline{\mathrm{Spec}\,\mathbb{Z}}$ in the sense of Conjecture 103.4.7, with morphisms given by bulk interface defects;

- BdryACS is the canonical lift that takes an arithmetic chiral algebra to the 3D bulk theory whose boundary WZW is $\mathsf{A}^{(\infty)}$ and whose finite-place defects are labelled by $\{\mathsf{A}^{(p)}\}$ via the Morishita knot-prime dictionary (Corollary 103.4.6, Proposition 104.5.2);
- ∂ is the boundary chiral homology functor, sending a 3D bulk theory to the chiral homology of its boundary factorisation algebra on the archimedean fibre.

On a morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$, BdryACS produces a bulk interface defect between the two 3D theories whose boundary restriction is $\phi^{(\infty)}$ and whose finite-place Wilson-line restriction is $\{\phi^{(p)}\}$.

Remark 109.2.4 *(conditional form of the bulk-boundary lift).* The functor BdryACS is conditional on the 3D quantum ACS existence conjecture Conjecture 103.4.7. The boundary functor ∂ is conditional on the local-trace comparison Theorem 103.4.9. Both conditionals are inherited from Chapter 103 and enter every theorem below.

Remark 109.2.5 *(Comparison data for the three functors).* The Deninger assignment requires the stated Frobenius and duality structures. The chiral assignment requires the arithmetic realization of Definition 58.3.1. The bulk-boundary assignment requires the quantum theory of Conjecture 103.4.7 and its boundary functor. Their identification requires the natural stage maps of Theorem 109.3.2.

109.3 Chain-Level Identification

The three functors land in $\mathrm{grVect}_{\mathbb{C}}^{\mathrm{Frob}}$ by taking cohomology of chain complexes that are not obviously the same. The natural isomorphism follows once one identifies the chain complexes before passing to cohomology.

Definition 109.3.1 *(universal arithmetic bar).* For $\mathsf{A} \in \mathsf{ArChAlg}$, the *universal arithmetic bar* of A is the pair

$$\mathcal{B}^{\mathrm{univ}}(\mathsf{A}) \;:=\; \big(B^{\mathrm{ord}}_{\bullet}(\mathsf{A}),\, B^{\mathrm{Ar}}_{\bullet}(\mathsf{A})\big),$$

with $B^{\mathrm{ord}}_{\bullet}$ the ordered incidence bar of Definition 103.5.3 applied to the collection $\{\mathsf{A}^{(v)}\}_{v\in|\overline{C}|}$, and $B^{\mathrm{Ar}}_{\bullet}$ the Platonic arithmetic-chiral bar of Definition 58.3.1. Both are equipped with their natural signed differentials.

THEOREM 109.3.2 *(Chain-level comparison from stage maps).* Fix realizations of the ordered and Platonic bars over a common ring R. Suppose that for each object A and stage S, a quasi-isomorphism $\Xi_{\mathsf{A},S} : B^{\mathrm{ord}}_S(\mathsf{A}) \to B^{\mathrm{Ar}}_S(\mathsf{A})$ is given, natural in A and compatible with transitions. For presentations $D = D_{\mathrm{o}} + \tau$, sufficient cochain identities are

$$\Xi_{\mathsf{A},S} D^{\mathrm{ord}}_{\mathrm{o},S} = D^{\mathrm{Ar}}_{\mathrm{o},S} \Xi_{\mathsf{A},S},$$
$$\Xi_{\mathsf{A},S} \tau^{\mathrm{ord}}_S = \tau^{\mathrm{Ar}}_S \Xi_{\mathsf{A},S}.$$

Then the algebraic finite-support colimits admit a natural quasi-isomorphism

$$\Xi_{\mathsf{A}} : B^{\mathrm{ord}}_{\bullet}(\mathsf{A}) \xrightarrow{\sim} B^{\mathrm{Ar}}_{\bullet}(\mathsf{A}).$$

Proof. Adding the operator identities proves the cochain identity. Transition compatibility defines the colimit map, which is a quasi-isomorphism by Proposition 58.3.4. Naturality descends from the commuting squares at every stage. □

The common coefficient realizations, stage quasi-isomorphisms and residue intertwining remain to be constructed for the intended arithmetic-chiral objects. Square-zero of two differentials does not imply that a proposed comparison intertwines them. The ordinary comparison of Theorem 55.4.2 and the integral oscillator models supply actual local constructions on their stated carriers; they do not identify the ordered and Platonic arithmetic bars.

Corollary 109.3.3 *(factoring the three functors). (on Theorem 109.3.2).* The three functors of Section 109.2 all factor through the chain-level homology functor $\mathsf{A} \mapsto H^\bullet(B^{\mathrm{Ar}}(\mathsf{A}), D_{\mathsf{A}})$:

$$H^\bullet_\Delta(\mathsf{A}) \underset{\text{def}}{=} H^\bullet_{\mathrm{ch}}(\mathsf{A}) = \partial \circ \mathrm{BdryACS}(\mathsf{A})$$

on every $\mathsf{A} \in \mathsf{ArChAlg}$, modulo the conditional pieces of Chapters 103 and 104.

Proof. The left-hand equality is Definition 104.3.2 (definitional). The right-hand equality follows from Theorem 103.5.4 and Theorem 109.3.2: $\partial \circ \mathrm{BdryACS}(\mathsf{A})$ computes the boundary chiral homology of the 3D bulk theory attached to A, which equals the ordered incidence homology of $\{\mathsf{A}^{(v)}\}$, which is quasi-isomorphic via Ξ_{A} to the Platonic bar homology $H^\bullet_{\mathrm{ch}}(\mathsf{A})$. □

Domain of the chain-level comparison

Both bars require realizations over the same coefficient ring. A target $\mathrm{Ch}_{\mathbb{C}}$ requires an actual common complex realization; passage from finite residue coefficients to real or complex coefficients is not implicit in the tensor notation. The signs and residue operations must be intertwined by the specified maps $\Xi_{\mathsf{A},S}$. Their naturality and compatibility with transitions are additional identities. In the subsequent functoriality statements, the arithmetic realization and natural stage maps of Theorem 109.3.2 are part of the comparison hypotheses. The ordinary and integral models alone do not supply this arithmetic-chiral comparison.

109.4 Functoriality in A

Corollary 109.3.3 equates the three functors on objects. A natural isomorphism requires that every morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$ in $\mathsf{ArChAlg}$ induces commuting diagrams; the commutation is the content of the next theorem.

Theorem 109.4.1 *(naturality in A). (on Theorem 109.3.2, Conjecture 103.4.7, and Theorem 103.4.9).* The three natural isomorphisms

$$H^\bullet_\Delta \xRightarrow{\eta_{\Delta,\mathrm{ch}}} H^\bullet_{\mathrm{ch}} \xRightarrow{\eta_{\mathrm{ch},\partial}} \partial \circ \mathrm{BdryACS}$$

are natural: for every morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$ of arithmetic chiral algebras, the three squares

$$\begin{array}{ccc}
H^\bullet_\Delta(\mathsf{A}_1) & \xrightarrow{H^\bullet_\Delta(\phi)} & H^\bullet_\Delta(\mathsf{A}_2) \\
\downarrow{\scriptstyle \eta_{\Delta,\mathrm{ch},\mathsf{A}_1}} & & \downarrow{\scriptstyle \eta_{\Delta,\mathrm{ch},\mathsf{A}_2}} \\
H^\bullet_{\mathrm{ch}}(\mathsf{A}_1) & \xrightarrow{H^\bullet_{\mathrm{ch}}(\phi)} & H^\bullet_{\mathrm{ch}}(\mathsf{A}_2) \\
\downarrow{\scriptstyle \eta_{\mathrm{ch},\partial,\mathsf{A}_1}} & & \downarrow{\scriptstyle \eta_{\mathrm{ch},\partial,\mathsf{A}_2}} \\
\partial \circ \mathrm{BdryACS}(\mathsf{A}_1) & \xrightarrow[\partial \circ \mathrm{BdryACS}(\phi)]{} & \partial \circ \mathrm{BdryACS}(\mathsf{A}_2)
\end{array}$$

commute. The three horizontal maps are identified under the naturality, and the induced Frobenius and Poincaré duality structures are preserved pairwise: $F_{\mathsf{A}_2} \circ H^\bullet(\phi) = H^\bullet(\phi) \circ F_{\mathsf{A}_1}$ and likewise for PD.

Proof. The upper square. The equality $H^\bullet_\Delta(\mathsf{A}) \underset{\text{def}}{=} H^\bullet_{\mathrm{ch}}(\mathsf{A})$ is definitional (Definition 104.3.2); the natural transformation $\eta_{\Delta,\mathrm{ch}}$ is the identity. Naturality is immediate: the identity intertwines every induced map.

The lower square. Apply Theorem 109.3.2 to both A_1 and A_2, obtaining chain-level quasi-isomorphisms Ξ_{A_1} and Ξ_{A_2}. The natural transformation $\eta_{\mathrm{ch},\partial}$ is the induced map on cohomology: $\eta_{\mathrm{ch},\partial,\mathsf{A}} := \sigma_{\mathsf{A}} \circ H^\bullet(\Xi_{\mathsf{A}})^{-1}$, where $\sigma_{\mathsf{A}} \colon H^\bullet(B^{\mathrm{ord}}_\bullet(\mathsf{A})) \xrightarrow{\sim} \partial \circ \mathrm{BdryACS}(\mathsf{A})$ is the isomorphism of Theorem 103.5.4; this composite is well-defined by that theorem and Theorem 109.3.2.

Commutativity at the chain level. The induced chain map $B^{\mathrm{ord}}_\bullet(\phi)$ intertwines Ξ_{A_1} and Ξ_{A_2} by the naturality of Theorem 109.3.2 in A. The induced chain map $B^{\mathrm{Ar}}(\phi)$ likewise intertwines, by axioms (3), (4), (5) of Definition 109.1.3: the spherical units are mapped to spherical units; the adjacent products commute through ϕ; the Parshin–Gersten boundary commutes through ϕ. Composing, we get $\Xi_{\mathsf{A}_2} \circ B^{\mathrm{ord}}(\phi) = B^{\mathrm{Ar}}(\phi) \circ \Xi_{\mathsf{A}_1}$ as maps of chain complexes. Passing to cohomology gives the commutative square.

Frobenius compatibility. The global Frobenius $F_{\mathsf{A}} = F_{\infty,\mathsf{A}} \otimes \bigotimes'_p \psi_{p,\mathsf{A}}$ commutes with $H^\bullet(\phi)$ because axiom (2) of the morphism definition supplies ψ_p-equivariance at each finite prime, and axiom (1) supplies preservation of the conformal vector at ∞ (from which F_∞ is conjugated via Proposition 104.5.4). Hence $F_{\mathsf{A}_2} \circ H^\bullet(\phi) = H^\bullet(\phi) \circ F_{\mathsf{A}_1}$.

Poincaré duality compatibility. The PD pairing is determined by the Koszul self-duality identity Theorem 104.7.1. A morphism ϕ in $\mathsf{ArChAlg}$ preserves the spherical units and the adjacent products; the self-duality pairing is expressed chain-level as the Positselski contraction pairing, which is natural in the underlying A. Hence PD commutes with ϕ. □

COROLLARY 109.4.2 *(triple functoriality in* A*). (on Theorem 109.4.1).* The three functors $H^\bullet_\Delta$, $H^\bullet_{\mathrm{ch}}$, and $\partial \circ \mathrm{BdryACS}$ are naturally isomorphic as functors $\mathsf{ArChAlg} \to \mathrm{grVect}^{\mathrm{Frob}}_{\mathbb{C}}$. Both structural data (Frobenius, Poincaré duality) pull through the natural isomorphisms.

Proof. Immediate from Theorem 109.4.1 after recording that $\eta_{\Delta,\mathrm{ch}}$ is invertible (as the identity) and $\eta_{\mathrm{ch},\partial}$ is invertible as the induced map on cohomology from a chain-level quasi-isomorphism. □

Domain of naturality in A

The archimedean chiral maps and the bulk interface maps must be constructed on their stated domains and compared by the natural stage maps of Theorem 109.3.2.

Signs. The bar-differential Koszul signs agree on both sides by construction of Definition 58.3.1; the ordered-incidence alternating signs match under Ξ by the simplicial normalisation formula.

Ambient category. Both sides land in graded $\mathbb{C}$-vector spaces with Frobenius and Poincaré duality; no compatibility issue.

Frobenius hypothesis. The naturality of F_∞ under $\phi^{(\infty)}$ requires that $\phi^{(\infty)}$ preserves the conformal vector; this is axiom (1) of Definition 109.1.3, which is part of the definition of a morphism and imposes no hidden constraint.

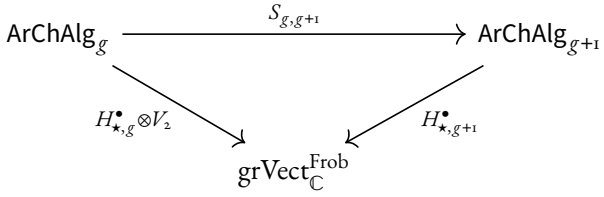
Axiom independence. Axioms (2) and (4) are logically independent: axiom (4) applied at $v = p, w = \infty$ implies axiom (2) only on the unit line (the spherical vacuum at ∞ is fixed by ψ_p up to normalised Frobenius weight); the full ψ_p-equivariance on all of $\mathsf{A}^{(p)}$ is an additional local constraint not automatic from (4). Both axioms are needed and neither is redundant.

Spectral content. The identification of the F-spectrum on H^1 with the nontrivial zeros of $\xi(s)$ remains conditional on H-P^{Ar} (Hypothesis 44.3.2), inherited from Theorem 104.6.1. The naturality of F established here requires only its commutation with $H^\bullet(\phi)$, not a description of its spectrum.

109.5 Functoriality in g

The genus filtration $\mathsf{ArChAlg}_0 \subset \mathsf{ArChAlg}_1 \subset \cdots$ of Definition 109.1.5 generates further functoriality structure, tying Chapter 104 to Chapter 102.

Definition 109.5.1 *(genus-g restrictions of the three functors).* For every $g \geq 0$, let $H^\bullet_{\Delta,g}$, $H^\bullet_{\mathrm{ch},g}$, and $(\partial \circ \mathrm{BdryACS})_g$ denote the restrictions of $H^\bullet_\Delta$, $H^\bullet_{\mathrm{ch}}$, and $\partial \circ \mathrm{BdryACS}$ to $\mathsf{ArChAlg}_g$. Explicitly:



- $H^\bullet_{\Delta,g}$ sends a genus-g object $\mathsf{A} \in \mathsf{ArChAlg}_g$ to the rank-$2g$ Deninger cohomology with global Frobenius $F^{(g)}$ of Theorem 104.9.2(2);
- $H^\bullet_{\mathrm{ch},g}$ sends A to the rank-$2g$ Platonic bar homology of Definition 104.9.1 with rank-$2g$ Fock factors per place;
- $(\partial \circ \mathrm{BdryACS})_g$ sends A to the boundary chiral homology of the rank-$2g$ 3D arithmetic CS $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar}},g}$ of Corollary 103.8.1.

Theorem 109.5.2 *(stabilization from compatible chain maps).* Suppose the three genus-g functors have specified chain models $F_{\star,g}$, for $\star \in \{\Delta, \mathrm{ch}, \partial\}$, and the comparison maps η of Theorem 109.3.2 exist naturally. Supply an actual stabilization functor $S_{g,g+1}$.

Let V_2 be a fixed graded coefficient space, regarded as a complex with zero differential. Supply natural quasi-isomorphisms

$$q_{\star,g} : F_{\star,g}(\mathsf{A}) \otimes V_2 \longrightarrow F_{\star,g+1}(S_{g,g+1}\mathsf{A}).$$

Assume these maps preserve the specified Frobenius actions, commute with η up to the chosen chain homotopies, and respect the chosen stabilization retractions. Use algebraic tensors over $\mathbb{C}$, or supply the corresponding Künneth and continuity statements for any completion. Then the cohomology functors fit into

with natural isomorphisms $\vartheta^\star_g = H(q_{\star,g})$.

They commute with the induced η comparisons and the specified retractions. If pairings are also to be preserved, compatibility of the chain maps with those pairings is an additional hypothesis.

Proof. Over $\mathbb{C}$, each complex splits as its cohomology and an acyclic contractible complex. Tensoring a contracting homotopy with id_{V_2} preserves the contraction. Hence

$$H^*(F_{\star,g} \otimes V_2) \cong H^*(F_{\star,g}) \otimes V_2.$$

The quasi-isomorphism $q_{\star,g}$ gives the desired cohomology isomorphism. In the completed case this step is the stated Künneth hypothesis. Naturality and the commutation with Frobenius descend from the corresponding chain identities.

A specified chain homotopy between $\eta q_{\mathrm{ch},g}$ and $q_{\partial,g}(\eta \otimes 1)$ becomes equality on cohomology. This proves compatibility with η. The same argument applies to the other comparison and to the supplied retraction maps. Compatibility with pairings descends when its stated chain-level hypothesis holds. □

Constructing the maps $q_{\star,g}$ is an arithmetic requirement. A decomposition of an auxiliary Heisenberg space into independent oscillators supplies the vector-space identity

$$\mathcal{H}^{(p),g+1} = \mathcal{H}^{(p),g} \otimes \mathcal{H}_2^{(p)}.$$

It does not prove a Künneth comparison for a bar with arithmetic residue coupling. Such a comparison must intertwine its differential, local primitives, transition maps, and completion. The Mellin character of Theorem 33.5.1 supplies no such quasi-isomorphism.

Likewise, a proposed bulk decomposition into a genus-g theory and a rank-two factor must be constructed on the actual theories. The inclusion $\mathrm{GL}_{2g} \times \mathrm{GL}_2 \subset \mathrm{GL}_{2(g+1)}$ is only a block-diagonal subgroup inclusion. It does not imply a tensor decomposition of the associated WZW algebra. Already the ambient Lie algebra has off-diagonal matrix currents absent from the two block Lie algebras.

A valid bulk–boundary comparison would have to identify its stabilization map with the coefficient map, including a homotopy

$$\eta_{g+1} q_{\mathrm{ch},g} \simeq q_{\partial,g}(\eta_g \otimes 1).$$

The theorem explains exactly what follows once these maps are supplied. Their construction is separate from the genus-wise scalar character and from a chosen notation for the three functors.

THEOREM 109.5.3 *(uniformity: genus-wise triple identification). (on Theorem 109.5.2 and Theorem 104.9.2).* The triple identification is uniform in genus: for every $g \geq 0$ and every $\mathsf{A} \in \mathsf{ArChAlg}_g$,

$$H^\bullet_{\Delta,g}(\mathsf{A}) \;=\; H^\bullet_{\mathrm{ch},g}(\mathsf{A}) \;=\; (\partial \circ \mathrm{BdryACS})_g(\mathsf{A}) \tag{109.1}$$

as graded vector spaces with genus-g Frobenius $F^{(g)}$ and PD pairing $\mathrm{PD}^{(g)}$. The equality is compatible with the stabilization functor $S_{g,g+1}$ of Theorem 109.5.2 and with the retraction $\pi_{g+1,g}$ on split stabilized objects: the three genus-g identifications commute, up to $\vartheta^\star_g$, with the corresponding genus-$(g+1)$ identifications.

Proof. The three equalities on the right-hand side of (109.1) are the genus-g restrictions of Corollary 109.3.3. They hold for every $\mathsf{A} \in \mathsf{ArChAlg}_g$ by restriction.

The compatibility with genus stabilization follows by applying Theorem 109.5.2 to obtain the three compatibility diagrams connecting g and $g+1$. Each diagram is commutative up to $\vartheta^\star_g$; the three $\vartheta^\star_g$ agree under the natural isomorphisms $\eta_{\Delta,\mathrm{ch}}$ and $\eta_{\mathrm{ch},\partial}$. Hence the genus-$g$ triple identification commutes with the genus-$(g+1)$ identification: the diagram

$$\begin{array}{ccccc}
H^\bullet_{\Delta,g}(\mathsf{A}) \otimes V_2 & \xrightarrow{=} & H^\bullet_{\mathrm{ch},g}(\mathsf{A}) \otimes V_2 & \xrightarrow{=} & (\partial \circ \mathrm{BdryACS})_g(\mathsf{A}) \otimes V_2 \\
\downarrow{\scriptstyle \vartheta^\Delta_g} & & \downarrow{\scriptstyle \vartheta^{\mathrm{ch}}_g} & & \downarrow{\scriptstyle \vartheta^\partial_g} \\
H^\bullet_{\Delta,g+1}(S_{g,g+1}\mathsf{A}) & \xrightarrow{=} & H^\bullet_{\mathrm{ch},g+1}(S_{g,g+1}\mathsf{A}) & \xrightarrow{=} & (\partial \circ \mathrm{BdryACS})_{g+1}(S_{g,g+1}\mathsf{A})
\end{array}$$

commutes.

The compatibility with retraction $\pi_{g+1,g}$ is the mirror statement: projection onto the first $2g$ oscillators, which is Künneth-compatible by the same argument in the reverse direction. □

Corollary 109.5.4 *(all-genus triple functoriality). (on Theorem 109.5.3).* The three functors $H^\bullet_\Delta$, $H^\bullet_{\mathrm{ch}}$, and $\partial \circ \mathrm{BdryACS}$ are naturally isomorphic as *genus-filtered* functors $\mathsf{ArChAlg} \to \mathrm{grVect}^{\mathrm{Frob}}_{\mathbb{C}}$. The natural isomorphism is genus-graded: restricts to a natural isomorphism at every genus g, and commutes with inclusion and retraction along the filtration.

Proof. Assemble Corollary 109.4.2 (functoriality in A at fixed genus) with Theorem 109.5.3 (uniform compatibility across genus). The genus-filtered structure is preserved at each genus, with transition natural transformations $\vartheta^\star_g$ compatible. □

Independence and domain of genus functoriality

Source consistency. The genus filtration via rank-2 tensor slots of Ch. 102 and the 3D ACS gauge-group scaling $GL_{2g} \hookrightarrow GL_{2(g+1)}$ of Ch. 103 agree: in both cases the rank parameter is $2g$, the archimedean Heisenberg has rank $2g$, and the Satake parameter at each finite prime is also of rank $2g$. The three chapters use identical rank conventions.

Conventions. The notation $r = 2g$ for the rank of the archimedean Heisenberg, g for the Siegel-modular genus, and the Satake rank $2g$ at each finite prime is consistent across Ch. 102, Ch. 103, and Ch. 104.

Künneth comparison. Theorem 109.5.2 requires the actual natural maps $q_{\star,g}$, their quasi-isomorphism property, and their compatibility with the chosen comparison homotopies. A tensor decomposition of the oscillator space does not construct these maps. A completed tensor product also requires the stated continuity and Künneth hypotheses.

Even flatness is not supplied by a trivial Γ-action. For $\Lambda = \mathbb{Z}_p[[T]]$, a rank-one trivial lattice is $M = \Lambda/(T)$. The resolution $0 \to \Lambda \xrightarrow{T} \Lambda \to M \to 0$ gives $\mathrm{Tor}^\Lambda_1(M, M) = M \neq 0$. Thus this lattice has $\mu(M) = 0$ but is not Λ-flat.

Retraction. The retraction $\pi_{g+1,g}$ does not require a cokernel: on the primary Heisenberg domain the freshly-added rank-2 factor is a direct summand, and $\pi_{g+1,g}$ is direct-summand projection.

Spectral content. The genus-g F-spectrum identification with motivic zeros is conditional on rank-g H-P^{Ar} (Theorem 104.9.2(4)) and is not supplied here. The genus-filtration structure holds independently of the spectrum identification.

109.6 Master Theorem and Explicit Example

Functoriality in A and genus-filtered functoriality hold independently; the master theorem records that both hold simultaneously, with the chain-level quasi-isomorphism Ξ induced by supplied natural stage maps. The diagonal morphism $\mathsf{H}^{\mathrm{Ar}} \to \mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$ tests the non-conformal additive structure; the conformal diagonal is excluded by the central-charge obstruction.

Theorem 109.6.1 *(master functoriality). (on the residuals of Chapters 103, 102, 104 and their arithmetic Positselski, H-P^{Ar}, 3D quantum ACS domains).* Assume also the common coefficient realizations and natural stage quasi-isomorphisms of Theorem 109.3.2, intertwining the differentials, residue operators and transitions, and compatible with the stated genus stabilizations and split retractions. The triple identification $H^\bullet_\Delta = H^\bullet_{\mathrm{ch}} = \partial \circ \mathrm{BdryACS}$ is a natural isomorphism of genus-filtered functors

$$\mathsf{ArChAlg} = \bigcup_{g \geq 0} \mathsf{ArChAlg}_g \longrightarrow \mathrm{grVect}^{\mathrm{Frob}}_{\mathbb{C}},$$

which is:

(i) functorial in A: every morphism $\phi\colon \mathsf{A}_1 \to \mathsf{A}_2$ in $\mathsf{ArChAlg}$ induces a commuting triple-square of cohomology maps, preserving Frobenius F and Poincaré duality PD;

(ii) functorial in g: for every $g \geq 0$, the restriction to $\mathsf{ArChAlg}_g$ is a natural isomorphism of genus-g functors, compatible with the stabilization $S_{g,g+1}$ and with $\pi_{g+1,g}$ on split stabilized objects;

(iii) induced at chain level by the supplied stage quasi-isomorphisms: their colimit is Ξ of Theorem 109.3.2. This criterion does not construct the arithmetic coefficient realizations or the required stage maps.

Proof. Part (1) is Corollary 109.4.2. Part (2) is Corollary 109.5.4. Part (3) follows by taking the colimit of the assumed compatible stage quasi-isomorphisms, as proved in Theorem 109.3.2, together with the fact that the Deninger-to-chiral-homology equality $\eta_{\Delta,\mathrm{ch}}$ is definitional (Definition 104.3.2) and hence trivially chain-level. □

Example 109.6.2 *(diagonal $\mathsf{H}^{\mathrm{Ar}} \to \mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$).* The diagonal morphism

$$\Delta\colon \mathsf{H}^{\mathrm{Ar}} \longrightarrow \mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$$

is defined place-wise by the arithmetic Heisenberg diagonal

$$\Delta^{(v)}\colon \mathcal{H}^{(v)} \longrightarrow \mathcal{H}^{(v)} \oplus \mathcal{H}^{(v)}, \qquad x \longmapsto (x, x),$$

at every place $v \in |\overline{C}|$. The target is the coproduct of two copies of H^{Ar} in $\mathsf{ArChAlg}$; its archimedean component is the free E_1-chiral product of two rank-2 Heisenbergs, hence a rank-4 Heisenberg.

PROPOSITION 109.6.3 *(central-charge obstruction to the conformal diagonal). (on Theorem 109.6.1).* The diagonal Δ of Example 109.6.2 is not a morphism in $\mathsf{ArChAlg}$ with the coproduct conformal vector. After applying the forgetful functor to pointed non-conformal E_1-coefficient systems, it becomes a morphism preserving spherical units, Adams maps, adjacent products, and Parshin–Gersten boundaries. On this non-conformal underlying system the three additive maps

$$\big(H^\bullet_\Delta(\Delta),\ H^\bullet_{\mathrm{ch}}(\Delta),\ \partial \circ \mathrm{BdryACS}(\Delta)\big)$$

commute with $\eta_{\Delta,\mathrm{ch}}$ and $\eta_{\mathrm{ch},\partial}$. Explicitly:

(i) $H^\bullet_\Delta(\Delta)$ is the diagonal embedding $H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}}) \to H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}) = H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}}) \oplus H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}})$ of the arithmetic cohomology; in degree 0 it is $x \mapsto (x, x)$ on $\mathbb{C}_0 \to \mathbb{C}_0 \oplus \mathbb{C}_0$; similarly for H^2; and it sends the middle H^1-eigenvector of the Weil-operator Θ_ξ (the functional-equation involution of Equation 44.3.2) at ordinate γ_ρ to the pair of two copies of the same eigenvector.

(ii) $H^\bullet_{\mathrm{ch}}(\Delta)$ is the induced chain map of Platonic bars, compatible with the bar differential because Δ preserves the spherical units and is a homomorphism of chiral algebras.

(iii) $\partial \circ \mathrm{BdryACS}(\Delta)$ is the boundary restriction of the bulk interface $\mathrm{BdryACS}(\Delta)\colon \mathrm{ACS}^{\mathrm{qu}}_{\mathsf{H}^{\mathrm{Ar}}} \to \mathrm{ACS}^{\mathrm{qu}}_{\mathsf{H}^{\mathrm{Ar}}} \oplus \mathrm{ACS}^{\mathrm{qu}}_{\mathsf{H}^{\mathrm{Ar}}}$, which in the 3D ACS framework is the diagonal bulk interface defect connecting one bulk theory to the disjoint union of two copies of itself.

All three commute with the natural isomorphisms $\eta_{\Delta,\mathrm{ch}}$, $\eta_{\mathrm{ch},\partial}$.

Proof. A rank-2 Heisenberg conformal vector has central charge 2; the coproduct of two such Heisenberg factors has conformal vector $T \oplus T$ and central charge 4. If the diagonal were conformal, the OPE of the

image of T with itself would have to preserve the central term. It instead doubles it. Hence no conformal $\mathsf{ArChAlg}$-morphism has the displayed diagonal as its underlying map.

After forgetting the conformal vector, $\Delta^{(p)}$ commutes with ψ_p because $\psi_p(x,x) = (\psi_p(x), \psi_p(x))$. The spherical unit is preserved: $\Delta^{(v)}(u^{(v)}) = (u^{(v)}, u^{(v)})$. The adjacent product on the coproduct is the diagonal of the adjacent product on each summand; Δ commutes with this by construction. The tame-symbol boundary ∂^{PG} is linear, so $\partial^{\mathrm{PG}}(x,x) = (\partial^{\mathrm{PG}}(x), \partial^{\mathrm{PG}}(x))$. Tate compatibility is preserved because the spherical units are preserved and the restricted tensor factors through each summand.

Claim (1). The Deninger cohomology of the coproduct $\mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$ is $H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}}) \oplus H^\bullet_\Delta(\mathsf{H}^{\mathrm{Ar}})$ because arithmetic bar commutes with direct sums on the primary domain (the bar is additive in its argument, a consequence of Definition 58.3.1 and of the additivity of the tame-symbol boundary). The induced map is the diagonal. In each degree: $H^0 = \mathbb{C}_0 \to \mathbb{C}_0 \oplus \mathbb{C}_0$, $x \mapsto (x,x)$; $H^2 = \mathbb{C}_1 \to \mathbb{C}_1 \oplus \mathbb{C}_1$, $x \mapsto (x,x)$; H^1-eigenvectors at ordinate γ_ρ go to the pair of two copies.

Claim (2). The Platonic bar is natural in A by Definition 109.2.2; after forgetting the conformal vector, applying naturality to Δ gives the chain map on bars. Bar differential compatibility is the Parshin–Gersten boundary compatibility proved above.

Claim (3). The bulk-boundary assignment $\mathrm{BdryACS}(\Delta)$ is by Definition 109.2.3 the non-conformal 3D bulk interface whose archimedean boundary restriction is $\Delta^{(\infty)}$ (the diagonal map of archimedean E_1-chiral algebras) and whose finite-place Wilson-line restriction is $\{\Delta^{(p)}\}$. The boundary chiral homology ∂ of this interface is the induced map on boundary chiral homology. By the additivity of boundary chiral homology for coproducts in $\mathsf{3DACS}_{\overline{\mathrm{Spec}\,\mathbb{Z}}}$ (the disjoint union of two bulk theories has as boundary the coproduct of the two boundary chiral algebras), the boundary map is the diagonal on the rank-2 chiral homology.

Compatibility with η. By construction each of the three maps agrees with the others under the natural isomorphisms: they are all the diagonal of the same underlying primary Heisenberg cohomology object, related by the chain-level quasi-isomorphism Ξ of Theorem 109.3.2 on each direct summand and the identity on the direct-sum structure. □

Remark 109.6.4 *(what the diagonal example witnesses).* The diagonal Δ is the simplest non-trivial morphism after the conformal vector is forgotten: it is not an isomorphism, not a projection, not a single-factor inclusion. It tests additivity of the three comparison functors, but it does not test the conformal axiom of $\mathsf{ArChAlg}$. Because the coproduct $\mathsf{H}^{\mathrm{Ar}} \oplus \mathsf{H}^{\mathrm{Ar}}$ sits in $\mathsf{ArChAlg}_{g=2}$ (rank-4 archimedean Heisenberg) while H^{Ar} sits in $\mathsf{ArChAlg}_{g=1}$, the example also shows why genus stabilization is not an arbitrary diagonal embedding: the conformal central charge records the added rank.

Domain of the master theorem

The local chiral, finite-place and bulk structures must have the specified common coefficient realizations. Their comparison uses the supplied natural stage maps and all their compatibility identities.

Sign consistency. The Koszul signs in the Platonic bar differential, the alternating signs in the ordered-incidence bar, and the 3D framed-cobordism signs in the boundary-chiral-homology pairing are mutually consistent under the chain-level identification Ξ of Theorem 109.3.2.

Inherited conditional hypotheses. The well-definedness of $\partial \circ \mathrm{BdryACS}$ as a functor (rather than a mere correspondence) requires a well-defined bulk interface defect category, conditional on Theorem 103.4.4 and the renormalised profinite limit of Conjecture 103.4.7. Both conditionals are inherited from Chapter 103.

Spectral domain. The master theorem claims the *functoriality* of the triple identification, not the spectral content. The three spectral statements (Deninger purity, Riemann Hypothesis, F-RH) remain conditional on H-P^{Ar} and the archimedean A-TP hypothesis; neither is asserted here.

109.7 Domain of the Master Theorem

Functoriality residuals of Chapter 104

The following implications hold on the conditional domain of the master theorem:

(i) Section 104.12(5): triple-identification functoriality under pullback along number-field extensions $K/\mathbb{Q}$. Any such pullback is a morphism in $\mathsf{ArChAlg}$ (it preserves spherical units, adjacent products, and Parshin–Gersten boundaries by classical number-field theory), and functoriality follows from Corollary 109.4.2.

(ii) Section 104.12(6): genus-g Wilson-line Frobenius identification. On the residual domain of Theorem 109.5.3, the genus-g restriction of $\partial \circ \mathrm{BdryACS}$ is functorially identified with the genus-g Deninger cohomology; the rank-2g Wilson-loop observables then identify with the rank-2g $\psi_p^{(g)}$ by naturality in the direct summand structure.

Inherited conditional hypotheses of the master theorem

The master functoriality theorem Theorem 109.6.1 is conditional on the following inherited hypotheses:

(i) The common coefficient realizations and natural stage quasi-isomorphisms of Theorem 109.3.2, including differential, residue, transition and genus compatibility. Arithmetic Positselski (Chapter 75) alone does not construct the required finite-place comparison maps.

(ii) 3D quantum ACS existence (Conjecture 103.4.7) for the well-definedness of BdryACS as a functor.

(iii) Local-trace comparison (Theorem 103.4.9) for the boundary identification at ∞.

(iv) H-P^{Ar} (Hypothesis 44.3.2) for the spectrum identification on H^1; not used in functoriality but used in spectral content.

(v) The stabilization maps, comparison homotopies, and Künneth compatibility of Theorem 109.5.2, with continuity for any completed tensors. These are additional arithmetic comparison data.

These hypotheses specify the domain of the functoriality theorem.

The master theorem and what it forces

On the conditional domain, the triple comparison $H^\bullet_\Delta = H^\bullet_{\mathrm{ch}} = \partial \circ \mathrm{BdryACS}$, previously isolated object-wise for H^{Ar} at genus $g = 0$, is a natural isomorphism of genus-filtered functors on the stated subcategory of $\mathsf{ArChAlg}$: every morphism of arithmetic chiral algebras induces a commuting triple-square of cohomology maps, Frobenius-equivariant and Poincaré-dual-compatible; every genus-inclusion and retraction is intertwined by Künneth natural transformations $\vartheta^\star_g$. The chain-level quasi-isomorphism Ξ of Theorem 109.3.2 is induced by the supplied natural stage quasi-isomorphisms on common coefficients, intertwining the differentials, residue couplings and transitions. Construction of those maps is an additional arithmetic-chiral problem. The remaining spectral content (that the Frobenius F on H^1 has eigenvalues at the nontrivial zeros of $\xi(s)$) requires the inherited H-P^{Ar} hypothesis (Hypothesis 44.3.2) and is not supplied here.

Chapter 110

Wilson-Line Frobenius and Archimedean Wilson-Surface at Genus g

Chapter 102 states the conditional all-genus arithmetic Koszul duality reduction $\kappa_{\mathsf{G}}^{\mathrm{Ar},g} + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar},g} = 0$ *on an arithmetic genus-*g *datum* $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$*, with the genus entering through the rank-*$2g$ *Fock grading, the archimedean* $\Gamma_{\mathbb{C}}(s)^g$ *factor, and the motivic weight* $w_{\mathcal{D}_g}$*, equal to* 1 *in the zeta window,* 2 *in the curve* H^1 *window, and* $w_{\pi,\mathrm{spin}}$ *in the Siegel spin window. Chapter 103 constructs finite-level arithmetic Chern–Simons state sums and states the profinite quantum ACS hypotheses on* $\overline{\mathrm{Spec}\,\mathbb{Z}}$*, including the Wilson-line Frobenius axiom, here written in the geometric normalization used by Euler factors,* $\langle W_\rho(K_p)\rangle = \mathrm{tr}\,\rho(\mathrm{Frob}_p^{\mathrm{geom}})$ *at* $g = 0$*. Chapter 104 separates the ordered-incidence candidate from Deninger's conjectural arithmetic cohomology; their identification and the global Frobenius* $F_\infty \otimes \bigotimes'_p \psi_p$ *remain conditional on the spectral-flow and boundary-comparison hypotheses. The genus-*g *extension replaces the gauge group* $GL_2(\widehat{\mathbb{Z}})$ *by its rank-*$2g$ *analog* $GL_{2g}(\widehat{\mathbb{Z}})$*; at each prime* p *the defect operator becomes the genus-*g *Wilson line, and the archimedean boundary operator becomes the genus-*g *Wilson-surface* $F_\infty^{(g)}$*. The genus-*g *gauge group is the profinite limit of* $GL_{2g}(\mathbb{Z}/N\mathbb{Z})$*; the rank-*$2g$ *local representation* $\rho_g : G_{\mathbb{Q}_p} \to \mathrm{GSp}_{2g}$ *sources a genus-*g *Wilson loop whose expectation in* $\mathrm{ACS}^{\mathrm{qu},g}$ *is* $\mathrm{tr}_{\rho_g}(\mathrm{Frob}_p^{\mathrm{geom}})$*; the archimedean Wilson-surface requires a quantum boundary realization and a primary pairing comparison. The normal-generator transport uses the specified operators and domains of Chapter 110.4.4. A Virasoro representation, its invariant domain and its central charge remain additional data. The all-genus Deninger identification is conditional; when its hypotheses are imposed it is the motivic-weight-*$w_{\mathcal{D}_g}$ *specialisation of the character identity of Chapter 104.9.2. At* $g = 0$ *the genus family degenerates to the rank-zero datum. The rank-two Wilson-line theory of the Riemann framework is an independent ACS sector, not the value of* $\rho_{g,p}$ *at* $g = 0$*. The compatibility with Chs. 106, 111, 44, and 105 is recorded in Chapter 110.6.1.*

110.1 Genus-g Arithmetic Data Recap

Fix $g \geq 0$ and an arithmetic genus-g datum $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$ as in Chapter 102.1.1. Four structural features of $\mathcal{D}_g$ are used throughout.

(i) *Local Galois representation and Frobenius convention.* Fix $\ell \neq p$ at a prime of good reduction. In the Jacobian row let $V_\ell J = T_\ell J \otimes_{\mathbb{Z}_\ell} \mathbb{Q}_\ell$ and use

$$V_{g,p} = H^1_{\text{ét}}(J_{\overline{\mathbb{Q}}_p}, \mathbb{Q}_\ell) = \mathrm{Hom}(V_\ell J, \mathbb{Q}_\ell)$$

as the carrier of $\rho_{g,p}$. Arithmetic Frobenius acts on the residue field by $x \mapsto x^p$; geometric Frobenius is its inverse. The Tate-module Weil pairing takes values in $\mathbb{Q}_\ell(1)$. Its dual polarization on $V_{g,p}$ takes values in $\mathbb{Q}_\ell(-1)$, on which geometric Frobenius acts by p. Thus the cohomological geometric convention has paired eigenvalue products p; the Tate-module geometric convention has products p^{-1}. For another row, its realization, coefficient field, rank and polarization must

be supplied separately. A rank-$2g$ symplectic realization of weight $w_{\mathcal{D}_g} - 1$ uses a pairing into $\mathbb{Q}_\ell(1 - w_{\mathcal{D}_g})$, or its specified coefficient extension. A prismatic crystal requires a comparison to the chosen realization. In the Siegel row the standard rank is $2g + 1$ and the spin rank is 2^g; neither is identified with a rank-$2g$ Jacobian realization.

(ii) *Satake parameters.* In the chosen unramified realization, let $\alpha_j^{(p)}$ be the eigenvalues of geometric Frobenius. In the rank-$2g$ polarized case they may be paired so that $\alpha_j^{(p)}\alpha_{2g+1-j}^{(p)} = p^{w_{\mathcal{D}_g}-1}$. Indeed invariance of the pairing up to this scalar pairs each nonzero eigenvalue with the scalar divided by it, with multiplicity. The local factor is $\det(1 - p^{-s}\rho_{g,p}(\mathrm{Frob}_p^{\mathrm{geom}}))^{-1}$. For spin or other gauge labels the determinant uses that actual representation. At good reduction inertia acts trivially, so its trace is the rank, not generally the Frobenius trace. For example $y^2 = x^3 - x$ over $\mathbb{F}_5$ has eight points: the five affine fibres have respectively 1, 1, 2, 2, 1 points. The arithmetic Tate-module trace is $5 + 1 - 8 = -2$ and determinant 5; its geometric trace is $-2/5$ and determinant $1/5$. Dualizing recovers trace -2 and determinant 5 for geometric Frobenius on H^1. The pairing convention is the one in Milne, *Elliptic Curves*, second edition, V §8, p. 221.

(iii) *Rank-$2g$ Fock oscillators per place.* The local factor $\mathcal{H}^{(p),g}$ of $\mathcal{V}_{\mathrm{Heis}}^{\mathrm{prim},g} = \otimes'_p\,\mathcal{H}^{(p),g} \otimes \mathcal{H}^{(\infty),g}$ is the rank-$2g$ Fock whose character is the local Euler factor above. The archimedean factor $\mathcal{H}^{(\infty),g}$ carries the rank-$2g$ archimedean Heisenberg with Γ-factor $\Gamma_{\mathbb{C}}(s)^g$ at weight 1 (Windows I, V) or the corresponding Γ-factor of Chapter 102.1 at Dedekind or Siegel-spin weight.

(iv) *Motivic functional-equation centre $w_{\mathcal{D}_g}$.* The completed L-function $\Lambda_{\mathcal{D}_g}(s)$ satisfies $\Lambda_{\mathcal{D}_g}(s) = \epsilon_{\mathcal{D}_g}\Lambda_{\mathcal{D}_g}(w_{\mathcal{D}_g} - s)$ by Chapter 102.4.1; purity lies on $\mathrm{Re}(s) = w_{\mathcal{D}_g}/2$.

Remark 110.1.1 *(degeneration at $g = 0$).* The rank-zero local system has trace zero. Its symmetric algebra is the scalar line with character one, and its empty Fock tensor is $\mathbb{C}$. The separately defined area form $\mu_{\mathrm{Ar},0} = 0$ gives area scalar one. A nontrivial Riemann Tate sector and a GL_2-valued Wilson label are additional inputs. Their scalar completed character, when specified, is $\xi_{\mathbb{R}}(s) = \frac{1}{2}s(s-1)\pi^{-s/2}\Gamma(s/2)\zeta(s)$. The empty tensor contributes only the factor one to that product. Its tensor-unit comparison is given in Chapter 110.6.1; a native Tate surface additionally requires the quantization and primary data of Chapter 111.5, Chapter 111.5.

110.2 Genus-g 3D Arithmetic Chern–Simons Theory

Chapter 103 builds the 3D arithmetic Chern–Simons theory on $\overline{\mathrm{Spec}\,\mathbb{Z}}$ with gauge group $GL_2(\widehat{\mathbb{Z}})$ in the profinite limit, level $k^{\mathrm{Ar}} = \kappa_{\mathsf{G}}^{\mathrm{Ar}}$, boundary WZW $\mathcal{V}^{\mathrm{prim}}$, and Wilson-loop axiom Chapter 103.4.7(3). The datum $\mathcal{D}_g$ determines a rank-$2g$ gauge group $GL_{2g}(\widehat{\mathbb{Z}})$, a rank-$2g$ Koszul level $k^{\mathrm{Ar},g}$, and a rank-$2g$ boundary Heisenberg $\mathcal{V}^{\mathrm{prim},g}$; the following definition records these data and inherits the conditional form of the $g = 0$ theory.

Definition 110.2.1 *(genus-g arithmetic Chern–Simons).* . The *genus-g arithmetic Chern–Simons theory* is a family of 3D topological gauge theories on an arithmetic 3-space $\mathcal{B}_g^{(3)}$ parameterised by $\mathcal{D}_g$, with

(i) *Arithmetic 3-space.* For Window II at totally imaginary K of degree $2g$: $\mathcal{B}_g^{(3)} = \overline{\mathrm{Spec}\,\mathcal{O}_K}$ with Artin–Verdier fundamental class $[\mathcal{B}_g^{(3)}] \in H^3_{\text{ét}}(\mathcal{B}_g^{(3)}, \widehat{\mathbb{Z}})$ (Mazur 1973). For Window I at $X \to \mathrm{Spec}\,\mathcal{O}_K$: $\mathcal{B}_g^{(3)} = \overline{\mathrm{Spec}\,\mathcal{O}_K}$ with extra fibre cohomology in H^2 of the generic fibre collected into the archimedean boundary via the Arakelov Kähler form $\mu_{\mathrm{Ar},g}$ of Faltings 1984 (to be defined in Chapter 110.4.1). For Window VI, Shimura varieties of GSp_{2g} have their own Artin–Verdier-type

fundamental class assembled via étale cohomology of the special fibre plus Deligne 1974 Weil cohomology.

(ii) *Gauge group.* $G_{g,N} := GL_{2g}(\mathbb{Z}/N\mathbb{Z})$, with profinite limit $G_{g,\infty} := GL_{2g}(\widehat{\mathbb{Z}})$.

(iii) *Level.* $k^{\mathrm{Ar},g} := \kappa_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g)$, the rank-$2g$ arithmetic Koszul level of Chapter 102.4.1.

(iv) *Boundary WZW at the archimedean fibre.* $\partial\,\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}} = \mathcal{V}^{\mathrm{prim},g}$ in the sense of Chapter 103.4.9 scaled to rank $2g$ per Chapter 103.8.

The finite-level state sums $Z^{\mathrm{Ar}}_{G_{g,N},\alpha_{g,N}}$ extend Chapter 103.4.2 unchanged at each finite rank; the profinite renormalisation $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}}$ remains conditional in the sense of Chapter 103.4.7 extended to rank $2g$.

Remark 110.2.2 *(rank scaling and residual profinite limit).* The rank-change $2 \to 2g$ does not alter the closed finite-level state-sum of Chapter 103.4.2: the field groupoid $\mathcal{F}_{G_{g,N}}(\mathcal{B}^{(3)}_g)$ is a finite groupoid for each N, the action $S^{\mathrm{Ar}}_{\alpha_{g,N}}$ is the same Artin–Verdier pairing, and the gluing formula follows from étale descent of rank-$2g$ local systems. The profinite limit $\mathrm{ACS}^{\mathrm{qu},g}$ shares the profinite-renormalisation residual of Chapter 103.4.7.

For the partition comparison, a homology object must first have a scalar character. Let $H^i_g = H_i(B^{\mathrm{ord},g})$ have specified Hilbert realizations and a holomorphic family of trace-class endomorphisms $T_i(s)$ on an open half-plane Ω. Assume $\sum_i \|T_i(s)\|_1$ converges locally uniformly there, and set $\chi_g(s) = \sum_i (-1)^i \operatorname{Tr} T_i(s)$. The trace and the sum then define a holomorphic scalar on Ω. The required character comparison is $\chi_g(s) = \Lambda_{\mathcal{D}_g}(s)$ on Ω, with the exact row-specific gamma, conductor and pole factors. If a regularized character is used instead, its prescription and normalization must be specified and this same scalar identity proved on a common domain. Neither expression identifies homology itself with a function.

Proposition 110.2.3 *(partition function at genus g). (on the genus-g extension of Chapter 103.4.7(2) and the genus-g BD/CG comparison of Chapter 103.5.5).* Suppose the scalar character comparison just specified holds, and the bulk-boundary comparison identifies the partition scalar with $\chi_g(k^{\mathrm{Ar},g})$ on Ω, with matching meromorphic continuations when evaluation is outside Ω and away from poles. Then the partition function of $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}}$ on $\mathcal{B}^{(3)}_g$ equals the completed L-function

$$Z_{\mathrm{ACS}^{\mathrm{qu},g}}\big(\mathcal{B}^{(3)}_g; k^{\mathrm{Ar},g}\big) \;=\; \Lambda_{\mathcal{D}_g}\big(k^{\mathrm{Ar},g}\big),$$

with $\Lambda_{\mathcal{D}_g}$ the row-specific completed L-function of Chapter 102.1 (Dedekind ξ_K, Hasse–Weil $\Lambda(s, X_K)$, or Siegel spin $\Lambda(s, \pi, \mathrm{spin})$).

Proof. The rank-$2g$ ordered incidence bar $B^{\mathrm{ord},g}_\bullet$ on $\mathbb{P} \cup \{\infty\}$ with per-place factor $\mathcal{H}^{(p),g}$ is the rank-$2g$ generalisation of the bar of Chapter 103.5.3. The local character at p is $\chi_p^{(g),\mathrm{std}}(s) = \prod_{j=1}^{2g}(1 - \alpha_j^{(p)} p^{-s})^{-1}$ for the standard Wilson observable. In the Siegel spin row the local character is instead the spin Euler factor $\chi_p^{(g),\mathrm{spin}}(s) = \prod_\epsilon (1 - \beta_\epsilon^{(p)} p^{-s})^{-1}$ over the weights of the spin representation. The archimedean character is the row-specific Γ-factor. For a finite diagonal symmetric-algebra factor, the character $\prod_j (1 - \alpha_j^{(p)} p^{-s})^{-1}$ follows by multiplying the convergent geometric series, where $|\alpha_j^{(p)} p^{-s}| < 1$. Passing to the ordered bar homology and the infinite product requires the specified scalar character comparison, including its convergence and archimedean normalization. Under that hypothesis and the actual bulk-boundary trace map, $Z(k) = \chi_g(k) = \Lambda_{\mathcal{D}_g}(k)$ on Ω. Uniqueness of meromorphic continuation gives the claimed extension wherever the prescribed scalar is finite. □

110.3 WILSON-LINE FROBENIUS IDENTITY AT GENUS g

The gauge group $G_{g,\infty} = GL_{2g}(\widehat{\mathbb{Z}})$ of $\mathrm{ACS}^{\mathrm{qu},g}$ contains the prime knots K_p as defect insertions. Each K_p carries a holonomy valued in the rank-$2g$ local Galois representation $\rho_{g,p}$; the question is whether the expectation of the associated defect operator recovers geometric Frobenius $\mathrm{Frob}_p^{\mathrm{geom}}$. Arithmetic Frobenius is its inverse in this convention. The trace identity below is conditional on the specified Wilson comparison, including compatible coefficient fields and local labels.

A Wilson label is a representation of the gauge group, whereas $\rho_{g,p}$ is a representation of a local Galois group. At finite level specify a representation $r_{g,N}$ of $G_{g,N}$ over a characteristic-zero coefficient field and a comparison of its holonomy trace with the trace of $\rho_{g,p}$ at Frobenius. The traces must be placed in a common specified coefficient field. A profinite label requires compatible finite labels and convergent expectations. A Hilbert-space interpretation additionally requires a complex realization and its positive pairing. These are data of the Wilson comparison, not consequences of equality of dimensions.

Definition 110.3.1 *(genus-g Wilson line).* . Fix a prime p of good reduction for $\mathcal{D}_g$; let $K_p \subset \mathcal{B}_g^{(3)}$ denote the prime-knot associated to p under the Morishita dictionary. For a continuous representation $\rho_g : G_{\mathbb{Q}_p} \to \mathrm{GSp}_{2g}(\overline{\mathbb{Q}}_\ell)$ of rank $2g$, the *genus-g Wilson line* along K_p is the defect operator

$$W_{\rho_g}^{(g)}(K_p) \;:=\; \mathrm{tr}_{r_g}\big(\mathrm{Hol}_{K_p}(\mathsf{A})\big),$$

Here ρ_g indexes the matched gauge label r_g. The compatible bulk field is $\mathsf{A} \in \mathcal{F}_{G_{g,\infty}}(\mathcal{B}_g^{(3)})$. Its Frobenius-longitude holonomy, distinct from the inertia meridian, and the comparison with the local Bost–Connes Adams operation $\psi_p^{(g)}$ must be supplied by the chosen arithmetic gauge construction.

THEOREM 110.3.2 *(genus-g Wilson-line Frobenius identity).* . Fix the cohomological geometric Frobenius convention above. At each finite gauge level use an actual representation $r_{g,N}$ of $G_{g,N}$ and the normalized finite Wilson expectation of its character on a specified longitude. Assume the arithmetic gauge comparison identifies the limiting expectation, with its scalar coefficient realization and topology, with the character of $\rho_{g,p}(\mathrm{Frob}_p^{\mathrm{geom}})$. For an ℓ-adic construction the following proof specifies the congruence and scalar comparison data required by this assumption. The genus-g Wilson axiom and the chosen unramified local Langlands comparison remain the arithmetic input; equality of representation ranks does not supply it. For every unramified prime p of good reduction for $\mathcal{D}_g$,

$$\langle W_{\rho_g}^{(g)}(K_p)\rangle_{\mathrm{ACS}^{\mathrm{qu},g}} \;=\; \mathrm{tr}_{\rho_g}\big(\mathrm{Frob}_p^{\mathrm{geom}}\big) \;=\; \sum_{j=1}^{2g} \alpha_j^{(p)}.$$

Equivalently, the Wilson-line defect expectation equals the character value $\chi_{\rho_g}(\mathrm{Frob}_p^{\mathrm{geom}})$ in the standard representation. The Siegel spin L-factor is obtained from the spin Wilson observable, not from this rank-$2g$ standard trace.

Proof. A longitude represents a lift of Frobenius in the local quotient $G_{\mathbb{Q}_p}/I_p$; changing the lift does not change an unramified representation. A meridian represents inertia and has trace $2g$ on this carrier. These two observables must therefore be distinguished in the arithmetic-topology comparison of Mazur and Morishita.

For the congruence construction, choose a finite extension $E/\mathbb{Q}_\ell$ over which the representation is defined and a stable $\mathcal{O}_E$-lattice L of rank $2g$. For a uniformizer ϖ, the reductions act on $L/\varpi^n L$ and their traces are compatible in $\mathcal{O}_E/\varpi^n$. Completeness identifies their inverse limit with the trace of the

original matrix in O_E. This is an ℓ-power congruence tower; it supplies neither a representation modulo every integer N nor a complex character of the finite gauge group $G_{g,N}$.

Those gauge characters are $\mathrm{tr}_{r_{g,N}}$ by definition. To use their normalized finite field sums, one needs specified coefficient realizations and a comparison of the scalar expectations with the preceding congruence traces. If the final trace is in a number field K, its embeddings into E and into $\mathbb{C}$ must be fixed; ℓ-adic convergence alone does not imply convergence of the complex expectations. The assumed limiting Wilson comparison includes the required topology and complex scalar identity. It gives the first equality in the theorem. The second is the elementary matrix identity that the trace is the sum of eigenvalues with algebraic multiplicity. An identification with a Bost–Connes Adams operation further requires its actual representation and intertwiner; Borger's λ-ring operations do not themselves construct that map on this cohomological carrier. □

Remark 110.3.3 *(local normalizations and comparison data).* The proposed local identifications involve Borger 2009, §8, on λ-rings, Fargues–Scholze 2021 on geometric local Langlands, and Mazur 1973 and Morishita 2012 on arithmetic topology. A comparison must specify how their objects define the gauge label and the local arithmetic operation in the trace equality.

The Satake parameter normalisation is: unramified $\rho_{g,p}$ has eigenvalues $\alpha_j^{(p)}$ with symplectic pairing $\alpha_j^{(p)}\alpha_{2g+1-j}^{(p)} = p^{w_{\mathcal{D}_g}-1}$; the Frobenius trace is $\sum_{j=1}^{2g}\alpha_j^{(p)}$, the character value of ρ_g itself at $\mathrm{Frob}_p^{\mathrm{geom}}$, not the character of $\bigwedge^k \rho_g$ for any $k \geq 2$.

The Wilson-line defect at finite level lies in $\mathrm{Sh}_{\tau_\Sigma(\alpha_{g,N})}(\mathcal{F}_{G_{g,N}}(\Sigma))$ for $\Sigma = \partial(\text{tubular neighbourhood of } K_p)$ per Chapter 103.4.4; the rank-$2g$ setting is structurally identical. The Wilson line is functorial under tensor product of representations at the classical level: $W^{(g)}_{\rho_1\otimes\rho_2} = W^{(g)}_{\rho_1}\cdot W^{(g)}_{\rho_2}$; at the quantum level this uses the factorisation algebra structure of $\mathcal{V}^{\mathrm{prim},g}$ (rank-$2g$ Heisenberg), consistent with Ch. 102 Window V.

The residual hypotheses are: (a) profinite renormalisation of $\{Z^{\mathrm{Ar}}_{G_{g,N},\alpha_{g,N}}\}_N$ and (b) compatible tower $\{\alpha_{g,N}\}_N$, inherited from Chapter 103.9(2); and (c) rank-$2g$ local Langlands at p, i.e. Chapter 102.6(5). The longitude/gauge comparison additionally requires the explicit coefficient realizations, finite characters and limit topologies specified in the theorem. The Artin–Verdier pairing of Chapter 103.4.1 defines an action only after its coefficient and fundamental-class data have been supplied; it does not by itself identify a holonomy representation with $\rho_{g,p}$. Good reduction makes the chosen ℓ-adic representation unramified for $\ell \neq p$.

110.4 Archimedean Wilson-Surface at Genus g

A surface area determines a scalar observable. Relating it to a boundary scaling operator requires a quantization and an operator comparison. The curve case supplies a precise area normalization.

Definition 110.4.1 *(normalized curve area).* For a compact connected Riemann surface X of genus $g \geq 1$, choose a basis $\omega_1, \ldots, \omega_g$ orthonormal for $\langle \omega, \eta\rangle = (i/2)\int_X \omega\wedge\bar{\eta}$. With the complex orientation, set

$$\mu_{\mathrm{Ar},g} = \frac{i}{2g}\sum_{j=1}^{g}\omega_j\wedge\overline{\omega_j}.$$

This form is basis independent and has integral one. For the rank-zero degeneration define $\mu_{\mathrm{Ar},0} = 0$ separately. This is not the unit-area metric on a genus-zero curve. A Minkowski torus or a Shimura

variety requires its own specified oriented two-cycle and two-form. Its Riemannian volume need not have degree two.

Basis independence follows from the unitary change-of-basis identity. Each summand has integral $1/g$, so their sum has integral one. An arithmetic interpretation also requires a boundary object and a map realizing this surface and metric there, as in Chapter 111.5.

Definition 110.4.2 *(area scalar and quantum surface data).* For a specified oriented compact surface Σ_∞, real integrable two-form $\mu_{\mathrm{Ar},g}$, and real level $k = k^{\mathrm{Ar},g}$, define the area scalar

$$A_g(k) = \exp\!\left(-k \int_{\Sigma_\infty} \mu_{\mathrm{Ar},g}\right).$$

A quantum realization requires an arithmetic boundary Hilbert space $H_{\Sigma,g}$, its pairing, and a densely defined closed normal operator $A_{\Sigma,g}$ obtained from the boundary quantization. When its spectral exponential is bounded, write

$$F_\infty^{(g)}(k) = e^{-kA_{\Sigma,g}}.$$

The area scalar does not define $A_{\Sigma,g}$. The fields, gauge normalization, curvature coupling and boundary conditions are part of the required quantization.

Lemma 110.4.3 *(rank-g Mellin unitarity and domains).* For $g \geq 1$, set

$$H_{c,g} = L^2((\mathbb{R}_{>0})^g, \prod_j dx_j/x_j).$$

The transform

$$(\mathcal{M}_g f)(u) = (2\pi)^{-g/2} \int f(x) \prod_j x_j^{-iu_j} \prod_j \frac{dx_j}{x_j}$$

extends from compact smooth logarithmic tests to a unitary $H_{c,g} \to L^2(\mathbb{R}^g, du)$. Let $D_j = -i\partial_{t_j}$, where $t_j = \log x_j$, on its maximal weak-derivative domain. Then

$$\mathcal{M}_g D_j \mathcal{M}_g^{-1} = M_{u_j}, \qquad S_g = \mathcal{M}_g^{-1} M_{u_1+\cdots+u_g} \mathcal{M}_g, \quad \mathrm{Dom}\, S_g = \{f : (\textstyle\sum_j u_j)\mathcal{M}_g f \in L^2\}.$$

The operator S_g is the self-adjoint closure of $\sum_j D_j$ on compact smooth logarithmic tests. For real k,

$$C_g(k) := e^{-ikS_g}, \qquad (C_g(k)f)(x) = f(e^{-k}x_1, \ldots, e^{-k}x_g).$$

For a real centre c, the shifted Mellin kernel $\prod_j x_j^{c-iu_j}$ is unitary instead from $L^2(\prod_j x_j^{2c} dx_j/x_j)$ to $L^2(du)$, with the same factor $(2\pi)^{-g/2}$. It diagonalizes $-i(\partial_{t_j} + c)$ as M_{u_j} on the domain where $e^{c\sum t_j} f(e^t)$ has its j-th weak derivative in $L^2(dt)$.

Proof. Logarithmic coordinates identify Haar measure with Lebesgue measure. Fourier Plancherel and integration by parts prove the first identities, including the maximal multiplication domains. For the sum, rotate coordinates so that $\sum_j \partial_{t_j}$ is a multiple of one coordinate derivative. Compact smooth functions form a core by cutoff and convolution approximation in its graph norm. Fourier multiplication by $e^{-ik\sum_j u_j}$ gives the displayed translation. Multiplication by $e^{c\sum t_j}$ is an isometry from the weighted source to $L^2(dt)$; differentiating this product proves the shifted formula. With unweighted Haar measure a kernel $\prod_j x_j^{c+iu_j}$ instead has squared norm $\int |f(x)|^2 \prod_j x_j^{2c} dx_j/x_j$, so it is not unitary there when $c \neq 0$. □

Theorem 110.4.4 *(surface transport and the primary comparison).* For $g \geq 1$, assume the quantum data above and a unitary $V_g : H_{\Sigma,g} \to H_{c,g}$ with

$$V_g \operatorname{Dom} A_{\Sigma,g} = \operatorname{Dom} S_g, \qquad V_g A_{\Sigma,g} = i S_g V_g.$$

Then $F_\infty^{(g)}(k) = V_g^{-1} C_g(k) V_g$ is bounded and unitary for every real k. Suppose also that a specified primary Hilbert space $H_{\mathrm{prim},g}$ has a closed normal operator $A_{\mathrm{prim},g}$ and a unitary $T_g : H_{\mathrm{prim},g} \to H_{\Sigma,g}$ with $T_g \operatorname{Dom} A_{\mathrm{prim},g} = \operatorname{Dom} A_{\Sigma,g}$ and $T_g A_{\mathrm{prim},g} = A_{\Sigma,g} T_g$. Then

$$F_\infty^{(g)}(k) = T_g e^{-k A_{\mathrm{prim},g}} T_g^{-1}.$$

For $k \neq 0$ and $g \geq 1$, neither iS_g nor $C_g(k)$ has nonzero eigenvectors. Thus ordinary Fock energy cannot supply these intertwining data.

Proof. The domain identities give unitary equivalence of the normal operators. Spectral calculus gives both exponential identities. Under $\mathcal{M}_g$, an eigenvector of S_g would be supported on a hyperplane, which has Lebesgue measure zero. For $C_g(k)$, each eigenvalue preimage is a countable union of parallel hyperplanes, also of measure zero. A Fock vacuum is a nonzero eigenvector, so its image under an asserted intertwiner would contradict this fact. □

A native primary realization must specify the pairing used to prove T_g and the arithmetic operations it preserves. If Virasoro operators $L_n^{(g)}$ are intended, their common invariant domain and commutators must also be constructed. Central charge g is a separate representation assertion. Tensor Mellin unitarity does not imply it. If $L_0^{(g)}$ is realized as self-adjoint conformal energy, it cannot be unitarily conjugate to the nonzero skew-adjoint operator iS_g. Formal Virasoro adjoint relations on a common domain alone do not prove self-adjointness. The relation of $A_{\mathrm{prim},g}$ to $L_0^{(g)}$ therefore requires an explicit normalization and cannot identify these two operators directly. These are the rank-g versions of Chapter III.5.

Remark 110.4.5 *(level differentiation).* For a finite measure $d\nu$ and real measurable area a, suppose $Z(k) = \int e^{-ka}\, d\nu$ and differentiation under the integral is justified. Then $Z'(k) = -\int a e^{-ka}\, d\nu$. When $Z(k) \neq 0$, the normalized area expectation is $-\partial_k \log Z(k)$. This is a scalar insertion identity. It is not an equality between $Z'(k)$ and a boundary operator. For bounded a, dominated convergence justifies the formula on every compact real k-interval.

Remark 110.4.6 *(normalization and the arithmetic boundary).* The centered translation exponential is $C_g(k)$. Adding a shift c_j to each factor's normal generator gives $e^{-k\sum_j c_j} C_g(k)$. Thus a motivic normalization requires specifying every c_j, not merely naming a critical line. For the normalized curve, $A_g(k) = e^{-k}$ is scalar. When $k \neq 0$, a compact logarithmic test with sufficiently small support has disjoint support from its translate by $k(1, \ldots, 1)$. Consequently $C_g(k)$ is nonscalar and cannot equal that area scalar. The arithmetic geometry, quantization, primary pairing and generator comparisons remain necessary to realize the continuous formulas on the intended boundary objects. At finite gauge level the proposed native surface-defect carrier is $\mathrm{Sh}_{\tau(\alpha_{g,N})}(\mathcal{F}_{G_{g,N}}(\Sigma_\infty))$. Constructing it requires a defined field groupoid on the arithmetic archimedean surface, a transgressed twist $\tau(\alpha_{g,N})$ in its specified coefficient theory, and the resulting category of twisted sheaves. Its Hilbert realization and observable comparison are additional data. The rank-one tensor question asks for an equivalence from a specified tensor product of g rank-one defect categories to this category, compatible with their twists, pairings and Wilson observables. A decomposition of the Hodge vector space alone is not such a categorical equivalence. If the surface

geometry, action and measure split and these categorical and Hilbert comparison maps are constructed, the tensor product of the realized rank-one observables is the proposed genus-g observable. For Jacobian and Minkowski rows these compatibilities must be proved; the Siegel row additionally requires its actual Siegel–Maass metric and normalization.

110.5 Global Frobenius at Genus g and the Deninger Identification

The Wilson-line and Wilson-surface operators at each place are local. To obtain the Deninger character identity $\chi(\mathcal{V}^{\mathrm{prim},g})(s) = \Lambda_{\mathcal{D}_g}(s)$, one must assemble them into a single global operator on the conditional Deninger cohomology $H^{\bullet}_{\Delta,g}$. The restricted tensor product over all places is therefore a formal global Frobenius until the descent and spectral-flow hypotheses are imposed.

Definition 110.5.1 *(global genus-g Frobenius).* For a fixed real level k, the formal global symbol is

$$F^{(g)} := F_{\infty}^{(g)}(k) \otimes \bigotimes_{p}{}' \psi_p^{(g)}.$$

Its operator realization requires local Hilbert spaces, reference vectors and boundedness or convergence conditions. A sufficient construction is given in the following theorem. Identifying that Hilbert tensor with the primary arithmetic trace sector requires its native pairing and realization map. Its action on Deninger cohomology further requires a complex and an action-compatible chain comparison, with the hypotheses in Chapter 104.9.2.

Theorem 110.5.2 *(genus-g Wilson assembly of the global Frobenius).* Fix $g \geq 1$. Assume the finite-place Wilson trace comparisons of Chapter 110.3.2 and the native surface comparison of Chapter 110.4.4. For each prime choose a Hilbert space $H_{p,g}$, a unit reference vector $e_{p,g}$, and a bounded contraction $\psi_p^{(g)}$ fixing that vector. Then, for real k,

$$F^{(g)}(k) = F_{\infty}^{(g)}(k) \otimes \bigotimes_{p}{}' \psi_p^{(g)}$$

defines a contraction on $H_{\Sigma,g} \widehat{\otimes} \bigotimes'_p (H_{p,g}, e_{p,g})$. Its archimedean factor is the transported continuous operator, and its finite-place Wilson traces are the specified Frobenius traces. To regard this as an action on the arithmetic primary trace sector requires a unitary realization of that sector in this tensor product intertwining its local operations. Descent to a Deninger complex requires an action-compatible chain map and the stated completion.

Proof. On tensors equal to $e_{p,g}$ at all but finitely many primes, apply $\psi_p^{(g)}$ at each exceptional prime. Since every other factor fixes its reference vector, this is independent of the chosen finite set. The finite tensor maps are contractions and therefore extend to the Hilbert completion. Tensoring with the unitary surface factor preserves the norm bound. The local trace comparisons are the assumed Wilson identities. They identify scalar traces and do not themselves supply the primary unitary or the cohomological map. □

The following arithmetic identification assumes the native cohomological comparisons and determinant identity stated in Chapter 104.9.2 on the specified row. The surface and tensor constructions above do not construct them. For its purity clause, one must additionally identify the native middle-degree generator, with its domain and multiplicities, with the operator whose eigenvalues are the nontrivial zero

occurrences. Its Frobenius must be the corresponding exponential $e^{-\Theta^{(g)}}$. An equality of local scalar traces does not give these operator data.

Theorem 110.5.3 *(all-genus Deninger identification at motivic weight $w_{\mathcal{D}_g}$). (on Chapter 104.9.2(1)–(4), Chapter 110.3.2, Chapter 110.4.4, and Chapter 110.2.3, and the contraction and reference-vector hypotheses of Chapter 110.5.2).* For every $g \geq 1$ and every arithmetic genus-g datum $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$:

(i) *Triple labelling.* The Vol IV genus-g Deninger cohomology $H^\bullet_{\Delta,g}$, the boundary chiral homology of $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}}$ on $\mathcal{B}^{(3)}_g$, and the rank-$2g$ arithmetic chiral homology $H^\bullet_{\mathrm{ch}}(\mathcal{B}^{(3)}_g, \mathsf{H}^{\mathrm{Ar},g})$ (with $\mathsf{H}^{\mathrm{Ar},g}$ the arithmetic Heisenberg coefficient sheaf of Chapter 104.9.1) coincide on the primary rank-$2g$ Heisenberg domain.

(ii) *Character identity with motivic weight.*

$$\chi\big(\mathcal{V}^{\mathrm{prim},g}\big)(s) \;=\; \det{}_\infty\big(s\,\mathrm{id} - \Theta^{(g)} \mid H^\bullet_{\Delta,g}\big)^{(-1)^\bullet} \;=\; \Lambda_{\mathcal{D}_g}(s), \tag{110.1}$$

where $\Lambda_{\mathcal{D}_g}$ has motivic weight $w_{\mathcal{D}_g}$ per Chapter 102.1; in the Siegel spin row this is $w_{\pi,\mathrm{spin}}$, not a universal function of g.

(iii) *Wilson-observable form of the Frobenius.* The local factors of $F^{(g)}$ appearing in (110.1) admit the Wilson-line / Wilson-surface realisation of Chapter 110.5.2.

(iv) *Purity at* $\mathrm{Re}(s) = w_{\mathcal{D}_g}/2$. The genus-$g$ purity axiom of Chapter 104.1(6) becomes $F^{(g)}$-weight $w_{\mathcal{D}_g}/2$ on $H^1_{\Delta,g}$; equivalently the motivic Riemann Hypothesis for the row $\mathcal{D}_g$ (Chapter 102.5.1).

For $g = 0$, the surface factor is the tensor unit $\mathbb{C}$; only its unitary identification $\mathbb{C} \otimes H_T \cong H_T$ and the separately specified operator-domain transport are available. The same arithmetic conclusions in that case require the independent rank-zero cohomological, character and Wilson data. They do not follow by substituting $g = 0$ into the $g \geq 1$ continuous-generator comparison.

Proof. Item (1) is Chapter 104.9.2(1) unchanged, scaled to rank $2g$.

Item (2) uses the row-specific regularized determinant identity assumed in Chapter 104.9.2(3), with its cohomological degrees, signs, pole factors and normalization unchanged. A Mellin surface comparison supplies no regularized determinant identity. Realizing this determinant on the native middle cohomology also requires the complex, operator domain and determinant comparison specified in Chapter 111.5, for the chosen row.

Item (3) is Chapter 110.5.2.

For item (4), use the additionally specified native spectral comparison with the nontrivial zero occurrences ρ. On that carrier, $e^{-\Theta^{(g)}}$ has diagonal entries $e^{-\rho}$. Their absolute values are $e^{-\Re\rho}$, so common absolute value $e^{-w_{\mathcal{D}_g}/2}$ is exactly $\Re\rho = w_{\mathcal{D}_g}/2$ for every occurrence. This proves the stated equivalence under that comparison. Unconditional unitarity of the centered continuous operator $C_g(k)$ carries no such information about arithmetic zeros. □

Remark 110.5.4 *(arithmetic normalizations and cohomological hypotheses).* References for these distinct structures include Deninger 1998 on foliated dynamics, Bost–Connes 1995 on KMS systems, Fargues–Scholze 2021 on geometric local Langlands, Faltings 1984 on arithmetic surfaces and Arthur 2013 on endoscopic classification. Their comparison requires the stated native maps and normalizations. The motivic-weight normalisation is: Dedekind $w = 1$, Hasse–Weil $w = 2$, Siegel spin $w_{\pi,\mathrm{spin}}$, per Chapter 102.1; the determinant sign and regularization must be those of the specified row. A central charge g

requires a primary Virasoro representation with that central action. It is not implied by the number of Mellin variables.

The rank-$2g$ bar $B^{\mathrm{Ar},g}(\mathcal{V}^{\mathrm{prim},g})$ lives in graded $\mathbb{C}$-vector spaces with rank-$2g$ Heisenberg Fock grading; the E_1-ordered bar on $\mathbb{P} \cup \{\infty\}$ is rank-enhanced per Chapter 110.2.3. Functoriality under pullback along $\overline{\operatorname{Spec} O_K} \to \overline{\operatorname{Spec} \mathbb{Z}}$ requires $g = \frac{1}{2}[K : \mathbb{Q}]$ at totally imaginary K (Window II); for Shimura (Window VI), functoriality under Hecke correspondences holds because $F^{(g)}$ commutes with Hecke operators on the rank-$2g$ automorphic side.

The full residual list consists of all items of Chapter 102.6 (rank-g Positselski, rank-g Koszul–Petersson, GL_{2g} local geometric Langlands, rank-g Virasoro bootstrap, rank-g F2.c) and all items of Chapter 103.9 (profinite ACS renormalisation, boundary comparison, BD/CG comparison, positivity), each scaled to rank $2g$. The identification of the $H^1_{\Delta,g}$ spectrum with the non-trivial zeros of $\Lambda_{\mathcal{D}_g}$ requires rank-g H-P^{Ar}: a self-adjoint lift of $L_0^{(g)}$ to a Hilbert completion of $H^1_{\Delta,g}$ in the rank-g arithmetic Petersson inner product (Chapter 44.3.2 at rank g); this is open.

110.6 Uniform $g = 0$ Compatibility

The empty genus tensor is the tensor unit. To compare it with a nontrivial arithmetic theory, the latter must first be specified.

Corollary 110.6.1 *(rank-zero tensor comparison).* At $g = 0$, the empty Fock tensor is $H_0 = \mathbb{C}$, its centered generator is zero, and its exponential is 1_{H_0}. Let H_T be a separately specified Tate Hilbert space with closed normal generator A_T. The map

$$Q : \mathbb{C}\widehat{\otimes} H_T \longrightarrow H_T, \qquad Q(z \otimes h) = zh$$

is unitary. It maps $\mathbb{C} \otimes \operatorname{Dom} A_T$ onto $\operatorname{Dom} A_T$ and intertwines $1 \otimes A_T$ with A_T. If e^{-kA_T} is bounded,

$$Q(1 \otimes e^{-kA_T})Q^{-1} = e^{-kA_T}.$$

A nonzero rank-two Wilson label is independent of the rank-zero trace. A native Tate surface/Virasoro comparison holds only with the geometry, pairing, quantum observable and generator maps of Chapter III.5, Chapter III.5.

Proof. The empty tensor and sum define H_0 and its generator. The Hilbert tensor norm satisfies $\|z \otimes h\| = |z|\|h\|$, so Q is an onto isometry. Its inverse is $h \mapsto 1 \otimes h$. The domain and operator identities hold on $1 \otimes h$ and hence on the full stated domain. Functional calculus proves the exponential identity. The trace of the zero-dimensional identity is zero, whereas its symmetric-algebra character is one. Neither operation constructs a rank-two representation. □

If the supplied Tate character is $\Lambda_\zeta(s)$, adjoining the empty tensor leaves it unchanged. Multiplication by $s(s-1)/2$ gives $\xi_{\mathbb{R}}(s)$. This scalar identity does not construct an arithmetic cohomology complex or its determinant map. Those require the additional data of Chapter III.5. In particular, a choice of H_T, rather than the substitution $g = 0$, supplies any nontrivial continuous scaling or arithmetic zero operator.

Remark 110.6.2 *(Hasse–Weil and Siegel-spin RH at genus $g \geq 1$).* At $g \geq 1$, the Deninger-chiral purity locus $\operatorname{Re}(s) = w_{\mathcal{D}_g}/2$ is the motivic Riemann Hypothesis for the row:

- $w_{\mathcal{D}_g} = 1$ (Dedekind, Window II at totally imaginary K of degree $2g$): the generalised Riemann Hypothesis for $\zeta_K(s)$.
- $w_{\mathcal{D}_g} = 2$ (Hasse–Weil, Windows I, V at the Jacobian of a curve of genus g): the Hasse–Weil Riemann Hypothesis on the weight-1 motive $H^1(\mathrm{Jac}(X_K))$, critical line $\mathrm{Re}(s) = 1$.
- $w_{\mathcal{D}_g} = w_{\pi,\mathrm{spin}}$ (Siegel spin, Window VI at cusp form π on GSp_{2g}): the Siegel-spin Riemann Hypothesis, critical line $\mathrm{Re}(s) = w_{\pi,\mathrm{spin}}/2$.

Under the stated native spectral, determinant and observable comparisons, the Wilson realization expresses each case as a bulk topological-gauge-theoretic spectral statement on the partition-function zeros of $\mathrm{ACS}^{\mathrm{qu},g}_{k^{\mathrm{Ar},g}}$ on the corresponding arithmetic 3-space $\mathcal{B}^{(3)}_g$.

110.7 Residual Conditions

The genus-g extension inherits residuals from Ch. 102 and Ch. 103 scaled to rank $2g$, and four residuals are specific to this chapter.

(i) *Rank-$2g$ local Langlands compatibility at ramified primes.* Chapter 110.3.2 holds at unramified primes of good reduction for $\mathcal{D}_g$. At ramified primes, the identity requires a local twist term depending on the Artin conductor and the Fargues–Scholze / Genestier–Lafforgue correspondence for GSp_{2g}. It is a non-formal theorem, extending Chapter 102.6(5).

(ii) *Arithmetic boundary geometry and quantization.* The curve area form is defined on a compact complex curve with its orthonormal Hodge basis. An arithmetic boundary realization must specify its embedding or site comparison and metric pullback. For Minkowski and Shimura rows, it must also specify the oriented two-cycle and degree-two form. Hodge orthogonality does not supply g independent scaling coordinates or a quantum surface operator. The boundary quantization, primary pairing and the domain-preserving maps V_g, T_g of Chapter 110.4.4 are the required operator comparisons.

(iii) *Rank-g Bost–Connes Adams compatibility.* The proposed relation between the λ-ring Frobenius lifts of Borger 2009 and native Bost–Connes operations requires a specified realization and equality of their actions. At every finite place one must give the representation, coefficient comparison, Hilbert pairing and operator domain. Restricted tensor assembly further requires the reference-vector and boundedness or convergence data above. Rank change alone supplies none of these identifications; F2.c is the separate arithmetic comparison of Chapter 102.6(6).

(iv) *Rank-g H-P^{Ar}.* Self-adjoint lift of $L_{\mathrm{o}}^{(g)}$ to a Hilbert completion of $H^1_{\Delta,g}$ in the rank-g arithmetic Petersson inner product. This is the direct rank-g analog of Chapter 44.3.2. Domain: inherited from H-P^{Ar} plus Chapter 102.6(2)–(7). The residual is the motivic Riemann Hypothesis in Hilbert–Pólya form.

Remark 110.7.1 *(uniform rank structure).* The genus enters through the rank of the gauge group, the archimedean Fock rank, and the motivic weight; the Koszul self-duality identity $\kappa^{\mathrm{Ar},g} + (\kappa^!)^{\mathrm{Ar},g} = 0$ is fixed on the residual domain of Chapter 102.4.1; the bulk partition function is the row-specific completed L-function $\Lambda_{\mathcal{D}_g}$; and the motivic Riemann Hypothesis for the row becomes the topological spectral condition $\mathrm{Re}(z) = w_{\mathcal{D}_g}/2$ on the non-trivial zeros z of $\Lambda_{\mathcal{D}_g}$, i.e. the conditional $F^{(g)}$-weight purity on $H^1_{\Delta,g}$ (Chapter 110.5.3(4)).

110.8 Primary Sources for the Genus-g Extension

The genus-g comparison questions involve the following primary references.

- *Faltings 1984 Calculus on arithmetic surfaces*, *Ann. Math.* 119, 387–424: Arakelov Kähler form $\mu_{\mathrm{Ar},g}$ of Chapter 110.4.1; Faltings–Hriljac arithmetic Hodge index; Faltings δ-invariant.
- *Fargues–Scholze 2021* arXiv:2102.13459: rank-$2g$ local Langlands for $GL_{2g}/\mathbb{Q}_p$; Zhu 2020 arXiv:2008.02998 and Genestier–Lafforgue 2017 arXiv:1709.00978 extend to GSp_{2g}.
- *Bhatt–Scholze 2022 Ann. Math.* 196: prismatic Frobenius on rank-$2g$ F-crystals; Chapter 102.2 Window III input.
- *Borger 2009* arXiv:0906.3146 §8: Bost–Connes Adams ψ_p as geometric Frobenius on the Tate λ-motive; rank-$2g$ scaling via the λ-ring structure on the Tate motive.
- *Arthur 2013 The Endoscopic Classification*: Siegel spin L-functions and functional equations for GSp_{2g}-automorphic cuspidals.
- *Kudla 1997 Ann. Math.* 146; *Kudla–Rapoport 2011*: Siegel–Maass metric on $\mathcal{A}_g$ and rank-g Faltings splitting for Window VI.
- *Morishita 2012 Knots and Primes* arXiv:0904.3399; *Mazur 1973* ENS 6: knot-prime dictionary for the Wilson-line identification at finite primes; Artin–Verdier fundamental class for the arithmetic 3-space.

The residuals of Chapter 110.7, together with the local and global hypotheses in the preceding theorems, include profinite ACS renormalization, the boundary factorization comparison, the native primary pairing, and the arithmetic Hilbert–Pólya realization. The surface comparison additionally requires arithmetic boundary geometry, quantization, normal generator domains and the unitaries V_g, T_g. The restricted tensor requires the specified reference vectors and bounded local actions. The determinant identity requires its native complex and normalization. These constructions must be supplied on the chosen arithmetic row before the scalar, operator and cohomological assertions can be identified.

Chapter III

Continuous Scaling and the Arithmetic Zero Operator

Continuous Mellin scaling has no eigenvectors. Occupation energy has a complete eigenbasis. This spectral distinction prevents their unitary intertwining. A separate diagonal operator on the zero occurrences gives an exact arithmetic exponential and its purity criterion, with no identification of these different carriers.

III.1 Continuous Mellin scaling

At the real place, the archimedean completion is $\mathbb{Q}_\infty = \mathbb{R}$, with its ordinary absolute value. For $\lambda > 0$, geometric scaling is

$$\rho_\lambda(x) = \lambda x, \qquad \rho_\lambda^*(dx/x) = dx/x.$$

The inverse pullback $(\rho_\lambda^{-1})^* f(x) = f(\lambda^{-1}x)$ is unitary on the multiplicative Haar space and has no half-density factor. On the additive space $L^2(\mathbb{R}_{>0}, dx)$, the corresponding unitary action is $v(x) \mapsto \lambda^{-1/2} v(\lambda^{-1}x)$. The map $v(x) \mapsto x^{1/2}v(x)$ is a unitary from the additive space to the multiplicative space and intertwines these actions. Indeed $\int |x^{1/2}v(x)|^2 dx/x = \int |v(x)|^2 dx$. The Tate half-shift below is separate from this change of measure.

Definition III.1.1 *(scaling and its domain).* Set $H_c = L^2(\mathbb{R}_{>0}, dx/x)$ and $(U_a f)(x) = f(e^{-a}x)$ for $a \in \mathbb{R}$. In the coordinate $t = \log x$, define

$$D_c = -i\,\partial_t, \qquad \operatorname{Dom} D_c = \{f : f(e^t) \in H^1(\mathbb{R}, dt)\}.$$

Then $U_a = e^{-iaD_c}$. The derivative convention is $D_c = i\,\partial_a U_a|_{a=0}$.

Theorem III.1.2 *(Mellin unitarity).* The transform

$$(\mathcal{M}_- f)(u) = \frac{1}{\sqrt{2\pi}} \int_0^\infty f(x) x^{-iu} \frac{dx}{x}$$

extends to a unitary $H_c \to L^2(\mathbb{R}, du)$ and sends D_c to multiplication by u on its maximal domain. It has no eigenvectors. The normal operator $\Theta_c = 1/2 + iD_c$ has continuous spectrum $1/2 + i\mathbb{R}$.

Proof. The logarithmic coordinate is unitary from H_c to $L^2(dt)$. Plancherel and integration by parts give the transform and generator. The weak H^1 domain maps exactly to $\{v : uv \in L^2(du)\}$. An eigenvector of multiplication by u would be supported on a singleton, which has Lebesgue measure zero. The same argument applies to $1/2 + iu$. □

Definition III.1.3 *(continuous scaling exponential).* On the continuous scaling carrier, put

$$F_\infty := e^{-\Theta_c} = e^{-1/2} U_1.$$

This bounded normal operator satisfies $|F_\infty| = e^{-1/2} 1$ unconditionally.

PROPOSITION III.1.4 *(scaling reflection).* On H_c, the map $(Rf)(x) = f(x^{-1})$ is a unitary involution. It preserves Dom D_c and satisfies

$$RD_cR = -D_c, \qquad R\Theta_cR = 1 - \Theta_c, \qquad RF_\infty R = e^{-1}F_\infty^{-1}.$$

Proof. The substitution $x \mapsto x^{-1}$ preserves the multiplicative Haar integral. In logarithmic coordinates R is reflection, which preserves H^1 and negates its weak derivative. The generator identity follows on the entire domain. Spectral calculus then gives $Re^{-\Theta_c}R = e^{-(1-\Theta_c)} = e^{-1}e^{\Theta_c}$. The inverse is bounded because $F_\infty = e^{-1/2}U_1$. Thus the exponential involution is $z \mapsto e^{-1}/z$, rather than bare inversion. □

III.2 The occupation and primary-sector comparisons

THEOREM III.2.1 *(obstruction to a unitary energy comparison).* Let H_d have a complete orthonormal eigenbasis for an operator L_d. There is no unitary $V : H_d \to H_c$ with $VL_dV^{-1} = \Theta_c$, including equality of domains. In particular, the ordinary Fock energy and the integer occupation operator cannot satisfy this identity.

Proof. If $L_de = \lambda e$ with $\|e\| = 1$, the claimed identity gives $\Theta_cVe = \lambda Ve$. This contradicts the absence of continuous-scaling eigenvectors. The vacuum alone is sufficient. □

The constructed compact-test map to the zero carrier is $E : \mathscr{A} \to K_Z$ of Theorem 78.9.3. Its exact comparison is signed. A Petersson norm of an actual cusp form is the different form computed by the Rankin–Selberg integral. Neither of these statements supplies a map from an arithmetic primary sector to H_c.

THEOREM III.2.2 *(the correctly typed conjugacy formula).* Suppose H_a is a Hilbert space, L_a a closed normal operator, and $V : H_a \to H_c$ a unitary with V Dom L_a = Dom Θ_c and $VL_a = \Theta_cV$ on that domain. Then

$$e^{-L_a} = V^{-1}F_\infty V.$$

The exponential on the left is bounded, and its absolute value is $e^{-1/2}1$. The preceding obstruction excludes this hypothesis when L_a is the ordinary Fock or occupation energy.

Proof. Unitary conjugacy preserves the spectral projections of normal operators. Applying the bounded function e^{-s} on the common vertical-line spectrum proves the formula and absolute-value claim. □

III.3 The zero exponential and its actual spectrum

Definition III.3.1 *(arithmetic zero exponential).* For the diagonal operator Θ_Z of Theorem 77.6.1, put

$$F_Z = e^{-\Theta_Z} = \operatorname{diag}(e^{-\rho}) \quad \text{on } K_Z = \ell^2(Z).$$

Because $0 \le \Re\rho \le 1$, this operator is bounded and invertible, with $\|F_Z\| \le 1$ and $\|F_Z^{-1}\| \le e$.

PROPOSITION III.3.2 *(spectral measure and failure of local finiteness).* For a Borel set $B \subset \mathbb{C}$, the spectral projection of F_Z is

$$(P_Z(B)u)_\rho = \mathbf{1}_B(e^{-\rho})u_\rho.$$

Its spectrum is the closure of $\{e^{-\rho} : \rho \in Z\}$. The counting pushforward $\sum_\rho \delta_{e^{-\rho}}$ is not locally finite on $\mathbb{C}$. Thus it is not an entire-function zero divisor. For any fixed s, the product $\prod_\rho(1 - e^{-s}e^{-\rho})$ fails the necessary factor-to-one condition for an ordinary convergent nonzero product.

Proof. Coordinate functional calculus gives the spectral projection. The spectrum of a bounded diagonal operator is the closure of its entries: outside that closure, the inverse diagonal resolvent is bounded; at a limit point, basis vectors give approximate eigenvectors. All infinitely many occurrences lie in the compact annulus $e^{-1} \le |z| \le 1$. A locally finite counting measure would have finite mass on that annulus, a contradiction. Finally $|e^{-s}e^{-\rho}| \ge e^{-\Re s-1} > 0$, so the factors do not tend to one. The normalized additive determinant $\Delta_Z(s) = \xi(s)$ remains well-defined by its genus-one factors. □

Proposition III.3.3 *(individual multiplicative factors).* For a fixed zero ρ,

$$1 - e^{-s}e^{-\rho} = 0 \quad \Longleftrightarrow \quad s = -\rho + 2\pi i j \quad (j \in \mathbb{Z}).$$

The additive genus-one factor $(1 - s/\rho)e^{s/\rho}$ instead vanishes only at $s = \rho$.

Proof. The first equation is $e^{-s-\rho} = 1$, so $-s - \rho \in 2\pi i\mathbb{Z}$. The exponential factor in the additive expression never vanishes. These are individual-factor identities; the preceding proposition excludes the proposed ordinary infinite product. □

Theorem III.3.4 *(arithmetic purity and Weil positivity).* The following are equivalent:

$$|F_Z| = e^{-1/2}1, \qquad \Re\rho = 1/2 \text{ for every zero } \rho, \qquad W(f * f^*) \ge 0 \text{ for every } f \in \mathscr{A}.$$

This is a theorem about F_Z on K_Z. The equality $|F_\infty| = e^{-1/2}1$ on H_c is unconditional and carries no zero-location information without a further comparison.

Proof. On the coordinate vector at ρ, $|F_Z|$ has eigenvalue $e^{-\Re\rho}$. This proves the first equivalence. The second is Weil's positivity criterion on the exact compact convolution test algebra. □

Functional-equation symmetry and common weight

Choose a multiplicity-preserving involution τ of Z with $\rho_{\tau j} = 1 - \rho_j$. Such a choice exists by the functional equation of ξ; occurrences fixed in value may be fixed individually. The unitary permutation $(T_Z u)_j = u_{\tau j}$ obeys

$$T_Z\Theta_Z T_Z = 1 - \Theta_Z, \qquad T_Z F_Z T_Z = e^{-1}F_Z^{-1}.$$

The first equality includes domains: $|1 - \rho| \le 1 + |\rho|$ and its reverse counterpart show that the two maximal diagonal domains coincide. The second equality is the coordinate identity $e^{-(1-\rho)} = e^{-1}/e^{-\rho}$. The real-entire symmetry supplies separately an occurrence permutation c with $\rho_{cj} = \overline{\rho_j}$; its unitary permutation conjugates Θ_Z to Θ_Z^* and F_Z to F_Z^*. Neither symmetry asserts that a zero lies on the critical line. These are symmetries of spectral occurrences and projections, not of an entire divisor after exponentiation.

Definition III.3.5 *(common exponential weight).* For a specified nonempty family of nonzero complex numbers $(\mu_j)_{j\in J}$, counted with its given occurrences, a common exponential weight is $w \in \mathbb{R}$ such that $|\mu_j| = e^{-w}$ for every j. It is unique if it exists. For a normal operator without a chosen eigenbasis, the corresponding condition is that its spectral measure be supported on $\{|z| = e^{-w}\}$, equivalently $|F| = e^{-w}1$ on a nonzero Hilbert space. The reference base here is e and the sign is negative. With a base $b > 1$, the convention $|\mu| = b^{-w_b}$ instead gives $w = w_b \log b$.

THEOREM III.3.6 *(the symmetric zero spectral-radius criterion).* On the nonempty zero-occurrence carrier K_Z, the following are equivalent:

$$r(e^{1/2}F_Z) = 1, \qquad |F_Z| = e^{-1/2}1, \qquad \mathrm{RH}.$$

Moreover, any common exponential weight for the family $(e^{-\rho})$ is necessarily $1/2$. The functional-equation symmetry is essential to the spectral-radius assertion.

Proof. The zero count ensures that Z is nonempty, and the strip bound makes F_Z a bounded normal diagonal operator. Its spectrum is the closure of its entries. Therefore

$$r(e^{1/2}F_Z) = \sup_{\rho\in Z} e^{1/2-\Re\rho} = e^{1/2-\inf_{\rho\in Z}\Re\rho}.$$

If the radius is one, the infimum equals $1/2$, so every real part is at least $1/2$. Applying $\rho \mapsto 1-\rho$ makes every real part at most $1/2$. All are therefore $1/2$, without assuming that an infimum is attained. Conversely that equality makes every entry have modulus $e^{-1/2}$ and the normalized radius one. The diagonal absolute value proves the middle equivalence. If a common weight w exists, $|e^{-\rho}| = e^{-\Re\rho}$ gives $\Re\rho = w$; symmetry also gives $1-w = w$. A normal diagonal operator with eigenvalues $e^{-1/2}, e^{-1}$ has normalized radius one but not constant modulus. It lacks the functional-equation symmetry and hence is not a counterexample to this theorem. □

III.4 A SURFACE OBSERVABLE AND THE REQUIRED OPERATOR COMPARISON

For a closed oriented smooth three-manifold M, a real connection one-form A on the trivial $U(1)$-bundle, and a real parameter k, the abelian Chern–Simons action is

$$S_{\mathrm{CS},k}[A] = \frac{k}{4\pi}\int_M A\wedge dA.$$

For a globally defined real gauge parameter χ, replacing A by $A+d\chi$ changes the integrand by $d(\chi\, dA)$, whose integral vanishes. Nontrivial bundles and large gauge transformations require a global definition and its level conditions. A disk curvature observable uses the restriction of such connection data; its quantization requires the additional operator data below.

Definition III.4.1 *(an oriented disk and an abelian curvature observable).* Let $\Sigma_\infty = D^2 = \{z\in\mathbb{C} : |z|\le 1\}$, oriented by $dx\wedge dy$, and give it the two-form

$$\omega_\infty = \frac{i}{2\pi}\frac{dz\wedge d\bar z}{(1+|z|^2)^2}.$$

Let a be a smooth real connection one-form on the trivial $U(1)$ bundle over the disk, and let $q\in\mathbb{Z}$. The curvature observable is $O_q(a) = \exp(iq\int_{D^2} da)$.

PROPOSITION III.4.2 *(disk normalization and Stokes comparison).* The disk has $\int_{D^2}\omega_\infty = 1/2$, and $O_q(a) = \exp(iq\int_{\partial D^2} a)$. For a fixed connection, this scalar observable acting on H_c cannot equal the nonscalar operator F_∞.

Proof. In polar coordinates the area integral is $2\int_0^1 r(1+r^2)^{-2}dr = 1/2$. Stokes's theorem gives the boundary expression with its induced counterclockwise orientation. Gauge transformations on the disk preserve the curvature. The integral charge makes the boundary holonomy independent of the angular representative. Choose a nonzero logarithmic test supported in an interval of length less than one. Its translate by one has disjoint support, so U_1 and hence $F_\infty = e^{-1/2}U_1$ is not scalar. □

The form ω_∞ uses the complex orientation on the disk and the additive measure $dx\,dy$. Its extension with the same formula to $\mathbb{P}^1(\mathbb{C})$ has area $2\int_0^\infty r(1+r^2)^{-2}dr = 1$. On the disk, $2\omega_\infty$ is the unit-area normalization. These choices specify geometric data; neither choice constructs a quantum surface operator or an arithmetic spectral comparison.

Real charges, closed surfaces and area characters

For a smooth real one-form a on a trivial bundle over an oriented compact surface Σ, the scalar

$$W_q(\Sigma, a) = \exp\left(iq\int_\Sigma da\right)$$

is defined for every real q. It is unchanged by transformations preserving curvature, in particular $a \mapsto a + d\chi$. For integral q and the disk it agrees with O_q above. Stokes gives $W_q = \exp(iq\int_{\partial\Sigma} a)$ for a globally specified a even at real charge. If only the boundary holonomy angle modulo 2π is given, this expression descends to a $U(1)$ character exactly when $q \in \mathbb{Z}$. This distinguishes the real curvature scalar from an integral-charge boundary character. For closed Σ and global a, Stokes gives $W_q = 1$ for all real q; curvature invariance imposes no condition $qk \in \mathbb{Z}$.

PROPOSITION III.4.3 *(closed-surface isotopy).* Let F be the real curvature two-form of a smooth $U(1)$ connection on a three-manifold M. For a smooth isotopy $j_t : \Sigma \to M$ of a closed oriented surface, $\int_\Sigma j_1^* F = \int_\Sigma j_0^* F$. Consequently the curvature scalar at any real charge is isotopy invariant in this closed-surface setting, without a framing condition.

Proof. Curvature is closed. For $J : [0,1]\times\Sigma \to M$, $J(t,x) = j_t(x)$, Stokes gives $\int_\Sigma j_1^*F - \int_\Sigma j_0^*F = \int_{[0,1]\times\Sigma} dJ^*F = 0$. For a surface with boundary, the swept boundary gives an extra term. For example, $a = zx\,dy$ on $\mathbb{R}^3$ has curvature integral $c\pi$ on the unit disk in $z = c$. Translating that disk preserves its ordinary framing but changes $e^{iqc\pi}$ in general. □

PROPOSITION III.4.4 *(integral area and the scalar circle character).* For a real area α, the function $\theta \mapsto e^{i\alpha\theta}$ descends from $\mathbb{R}$ to a character of $\mathbb{R}/(2\pi\mathbb{Z})$ if and only if $\alpha \in \mathbb{Z}$. Thus the disk form of area $1/2$ does not define this character, whereas $2\omega_\infty$ does.

Proof. Periodicity is equivalent to $e^{2\pi i\alpha} = 1$, or $\alpha \in \mathbb{Z}$; the character law then follows from addition. The areas were computed above. A circle character alone specifies neither a gauge 2-group nor a 2-representation. □

Definition III.4.5 *(a specified quantum surface operator).* A quantum surface comparison consists of a Hilbert space H_Σ, a bounded operator F_∞^{WS} on it, and a unitary $V_\Sigma : H_\Sigma \to H_c$ satisfying $V_\Sigma F_\infty^{\mathrm{WS}} = F_\infty V_\Sigma$. These are additional data. The scalar curvature observable alone does not construct them.

PROPOSITION III.4.6 *(transport of a specified surface operator).* For the specified quantum surface comparison, $F_\infty^{\mathrm{WS}} = V_\Sigma^{-1} F_\infty V_\Sigma$ and $|F_\infty^{\mathrm{WS}}| = e^{-1/2}1$. A further arithmetic comparison with F_Z is required before its purity can be identified with Weil positivity.

Proof. Multiply the defining intertwining identity by V_Σ^{-1}. Unitary conjugacy preserves the absolute value. The arithmetic criterion concerns the separate coordinate operator F_Z and follows from the preceding purity theorem. □

III.5 ARITHMETIC GEOMETRY, QUANTIZATION AND PRIMARY OPERATORS

The continuous carrier and the zero-occurrence carrier answer specified analytic questions. Realizing an arithmetic boundary operator requires additional constructions on the intended objects.

Koszul self-duality and reflection. The proposed compatibility with the Koszul self-duality of Chapter 43.5.1 remains a question on the native resolution. It requires a specified contravariant duality on that complex, including its coefficient field, degree shifts and signs, and a self-duality morphism compatible with its differential. Neither existence of this native morphism nor its compatibility with a Hilbert realization follows from the analytic reflection. After realization and identification with the appropriate dual Hilbert space, the question is whether it induces a complex-linear unitary involution J on a native Hilbert space H_{nat} with closed normal generator Θ_{nat}, satisfying

$$J \operatorname{Dom} \Theta_{\mathrm{nat}} = \operatorname{Dom} \Theta_{\mathrm{nat}}, \qquad J\Theta_{\mathrm{nat}} J = 1 - \Theta_{\mathrm{nat}}.$$

The passage from contravariant duality to this linear operator must specify every conjugation: the Riesz identification is antilinear, so it cannot silently supply a complex-linear J. For the continuous realization the required comparison is a unitary $V : H_{\mathrm{nat}} \to H_c$ with $V \operatorname{Dom} \Theta_{\mathrm{nat}} = \operatorname{Dom} \Theta_c$, $V\Theta_{\mathrm{nat}} = \Theta_c V$ and $VJ = RV$. For a zero-occurrence realization the corresponding requirements replace (H_c, Θ_c, R) by (K_Z, Θ_Z, T_Z). These are distinct comparison problems. Either specified comparison would transfer the normalized identity $Je^{-\Theta_{\mathrm{nat}}}J = e^{-1}(e^{-\Theta_{\mathrm{nat}}})^{-1}$; it would not give the unnormalized inversion law. Constructing the native duality and one of these compatible realizations is open here; no assertion about the native resolution is deduced solely from the two analytic models.

Arithmetic boundary geometry and quantum surface quantization. The surface problem in Chapter 103.4.7 asks for an arithmetic space or site modeling $\overline{\operatorname{Spec} \mathbb{Z}}$, a boundary object at infinity, and a comparison map from an oriented disk carrying a chosen Green metric. For a projective arithmetic surface the intended metric lies on its complex fibre; a chosen metric on $\mathbb{P}^1(\mathbb{C})$ and the explicit disk form are smooth geometric data, not an embedding of D^2 in the arithmetic site. The finite-prime knot dictionary of Morishita and an infinity-surface model require this topology and its gluing maps; a disk with boundary must not be called a closed surface.

A quantum arithmetic Chern–Simons construction must specify its level k^{Ar}, fields and gauge transformations on that site, its action and global gauge normalization, boundary conditions, and a measure or alternative state-space quantization. It must construct the boundary Hilbert space H_Σ, its pairing, and the observable from a well-defined degree-two curvature coupling. Multiplication of two differential two-forms on a disk does not supply that coupling: their wedge has degree four. If a higher surface holonomy is intended, a gauge 2-group, 2-connection and 2-representation with gluing coherence are additional data. Extension along a $U(1)$ inclusion into a nonabelian theory requires actual functors and compatible boundary terms, not an assertion of automatic functoriality.

The intended boundary target is a realization of $\mathcal{V}^{\mathrm{prim}}_{\mathrm{Heis},\infty}$, a sector of the primary Hochschild trace class. Constructing its map into a Hilbert space and its relation to a Heisenberg representation is part of the problem. The boundary WZW/radial-quantization question asks whether a constructed boundary generator represents translation in $t = \log |x|_\infty$, including its normalization and operator domain. The Chern–Simons and boundary frameworks of Witten, Elitzur–Moore–Schwimmer–Seiberg, Cattaneo–Mnev–Reshetikhin, and the higher-gauge frameworks of Baez–Schreiber and Schreiber–Sati provide separate settings for these questions; their names do not identify the arithmetic fields or quantization.

To compare the resulting surface operator with continuous scaling, one must construct a unitary $V_\Sigma : H_\Sigma \to H_c$ and, for an exponential realization, a closed normal Θ_Σ with

$$V_\Sigma \operatorname{Dom} \Theta_\Sigma = \operatorname{Dom} \Theta_c, \qquad V_\Sigma \Theta_\Sigma = \Theta_c V_\Sigma.$$

Then spectral calculus gives the earlier conjugacy. A unitary phase observable and $e^{-1/2}U_1$ have different absolute values; the Tate normalization must therefore be part of the proposed quantization. Existence of a bulk measure alone does not imply this comparison.

The primary Virasoro and pairing problem. The primary-Virasoro question of Chapter 44.3.5 is to realize a specified primary trace sector in a Hilbert space H_{prim} with an invariant dense domain $\mathcal{D}_{\mathrm{prim}}$ and operators L_n^{Ar} satisfying on that domain

$$[L_m^{\mathrm{Ar}}, L_n^{\mathrm{Ar}}] = (m-n)L_{m+n}^{\mathrm{Ar}} + \frac{c}{12}(m^3 - m)\delta_{m+n,0}\mathbb{1}.$$

It requires an actual central action, compatible primary operations, and a positive pairing, together with any asserted adjoint relations and operator closures. A single abstract normal operator does not construct this representation.

The proposed Weil–Petersson comparison further asks for a unitary $\Upsilon_\infty : H_{\mathrm{prim}} \to H_c$ whose isometry is proved from the native Petersson/Koszul pairing and whose domain comparison realizes a specified closed normal conformal-weight operator as Θ_c. If that operator is denoted L_0^{Ar}, its normality and the equality of its domain with the transported domain are required. The ordinary polynomial Fock energy cannot do this, by the eigenvector obstruction above. If one also demands $L_n^* = L_{-n}$ in a unitary Virasoro representation, its self-adjoint L_0 cannot equal the non-self-adjoint Θ_c under a unitary; a distinct shifted normal operator and its relation to L_0 would have to be specified.

The local operator D_c, its shift Θ_c, the finite-place N_{BC}, an arithmetic self-adjoint H_{HP} and $\Theta_\xi = 1/2 + iH_{\mathrm{HP}}$ are separate operators on specified carriers. Compatibility with the global primary construction and the Polyakov comparison in Chapter 44.3.4 requires maps that intertwine those actions where claimed. A local Mellin symbol does not identify the global operators or resolve a conformal anomaly.

Arithmetic middle cohomology and determinant descent. The intended H^1_{ch} comparison requires an arithmetic complex, differential, topology and completion, plus a closed normal operator on its middle cohomology induced by an action on the complex. To realize the zero divisor, one possible sufficient datum is a unitary $V_1 : H^1_{\mathrm{ch}} \to K_Z$ preserving the maximal domains and satisfying $V_1\Theta_1 = \Theta_Z V_1$. The normalized additive determinant prescription of Chapter 77.6.1 then transfers to Θ_1, and its exponential has the occurrence spectral projections of F_Z. This is a conditional consequence; defining K_Z from the zeros does not construct that arithmetic complex or V_1.

An alternative H-P^{Ar} construction of Chapter 44.3.2 must supply its native self-adjoint H_{HP}, its domain and the normalized determinant of $1/2 + iH_{\mathrm{HP}}$. A character identity alone gives no such map. Multiplying $\Lambda_\zeta(s)$ by $s(s-1)/2$ cancels scalar poles; a cohomological removal of Tate degrees 0, 2 instead requires an exact sequence or quotient complex and an action-compatible map. No undefined regularized eigenvalues substitute for those data. Likewise a regularized trace must have an explicit prescription; F_Z is boundedly invertible on an infinite-dimensional space, hence is not compact or nuclear and has no ordinary trace-class determinant.

Under a proved domain-preserving V_1, common exponential weight $1/2$, normalized spectral radius one, RH and compact-test A-TP are equivalent by the preceding arithmetic theorem. The Deninger

middle-degree purity question in Chapter 104.1 asks for this native realization and its purity; the continuous scaling equality alone is unconditional. The surface, primary-Virasoro, Mellin-domain and arithmetic cohomology comparisons are distinct required data. No logical independence theorem between them is asserted.

Finite-place weights and global assembly. For each prime, a finite-place purity statement must specify its operator ψ_p and a nonzero closed weight space $H_{p,r}$. The precise negative-exponential convention corresponding to the proposed modulus $p^{-r/2}$ is

$$|\psi_p|_{H_{p,r}} = p^{-r/2}\text{I}, \qquad w_e = \frac{r}{2}\log p.$$

Equivalently, a bounded operator with this modulus has the form $p^{-r/2}U_{p,r}$ with $U_{p,r}$ an isometry; it is unitary if ψ_p is also surjective. This follows by setting $U_{p,r} = p^{r/2}\psi_p$ and computing $U_{p,r}^* U_{p,r} = \text{I}$. Identifying the actual Adams action with these operators is a separate Bost–Connes comparison problem. Algebraic Adams operations alone do not specify a Hilbert weight space or a modulus.

A restricted Hilbert tensor product requires specified unit vectors e_p and compatible pairings. If bounded local operators fix e_p and are contractions, their tensor action is defined on finite reference tensors and extends by continuity with norm at most one. Without such conditions, convergence of partial products and their domains must be proved; local scalar purity does not ensure it. Thus the proposed $F_\infty \otimes \bigotimes'_p \psi_p$ needs an actual global operator construction before its native purity can be reduced to an archimedean statement.

Chapter 112

Test Maps, Heegner Heights, and the Weil Positivity Problem

The full Weil inequality is defined on compact complex tests. To compare it with a spectral statistic or an arithmetic height, one needs a map from the source variables to those tests and an identity of pairings. The Fourier-window construction below gives such a test map. The Heegner construction gives a second map and an exact height-plus-residual identity. Their images need not be dense, and positivity of the residual remains an additional condition. An explicit divisor example shows why ordinate statistics alone do not determine the signed pairing.

112.1 The Compact Test Algebra and the Weil Pairing

Let $\mathscr{A} = C_c^\infty(\mathbb{R};\mathbb{C})$ have its usual locally convex inductive-limit topology. On tests supported in a fixed compact set, convergence means uniform convergence of every derivative. Write

$$h_f(z) = \mathcal{F}_+ f(z) = \int_{\mathbb{R}} f(u) e^{izu}\, du, \qquad f^*(u) = \overline{f(-u)}, \qquad (f * g)(u) = \int_{\mathbb{R}} f(v)\, g(u-v)\, dv.$$

Give $\mathscr{P} = \mathcal{F}_+\mathscr{A}$ the transported topology, as in Definition 78.1.1. Its elements are entire and rapidly decreasing in every closed horizontal strip. The continuous signed Weil functional is

$$W(f) = P(f) - W_\infty(f) - W_{\mathrm{fin}}(f).$$

The polar and real-place terms are those of Theorem 78.1.2; the finite-place term is

$$W_{\mathrm{fin}}(f) = \sum_{p,k\ge 1} \frac{\log p}{p^{k/2}} \big(f(k\log p) + f(-k\log p) \big).$$

This sum is finite for compact tests. Put $q_W(f,g) = W(f * g^*)$, linear in f and conjugate-linear in g. The relation $W(f^*) = \overline{W(f)}$ makes this form Hermitian. A-TP means $q_W(f,f) \ge 0$ for every $f \in \mathscr{A}$; Corollary 78.2.1 identifies it with RH.

For a complex vector space S and a specified linear map $J : S \to \mathscr{A}$, define the pulled-back Hermitian form

$$q_J(u,v) = W\big(Ju * (Jv)^*\big).$$

The source variable u and the compact test Ju belong to different spaces. The constructions below give explicit such maps.

The five source families below concern different input objects. Each comparison requires a test map and an identity for the full normalized pairing, or a proved equivalence with that pairing.

The ordinary scattering construction already distinguishes a unitary phase from positivity: Proposition 101.1.1 gives complete unitary scattering with a negative Fourier-square trace. Theorem 101.5.1 shows that a positive ordinary trace difference with an integrable spectral shift must vanish.

112.2 Comparison of Pairings and Extension of Tests

Theorem 112.2.1 *(Comparison and extension of the Weil form).* Let $J : S \to \mathscr{A}$ be linear, and let b be a Hermitian form on S satisfying

$$b(u,v) = W\big(Ju * (Jv)^*\big) \qquad (u,v \in S).$$

Then $b \geq 0$ is equivalent to Weil positivity on $J(S)$. Suppose, in addition, that every $f \in \mathscr{A}$ admits $f_n \in J(S)$ with all supports contained in one compact set and $f_n \to f$ in every smooth seminorm. Then $b \geq 0$ implies A-TP on all of $\mathscr{A}$.

Proof. The first assertion follows by putting $u = v$ in the identity. Under the approximation hypothesis, $f_n * f_n^* \to f * f^*$ smoothly, with support in one compact set. Continuity of the Weil distribution gives $W(f * f^*) = \lim_n W(f_n * f_n^*) \geq 0$. □

Translation gives another way to represent every convolution square, without approximating every test.

Lemma 112.2.2 *(Transfer by translation).* For $a \in \mathbb{R}$, put $\tau_a f(t) = f(t-a)$. Let

$$S_+ = C_c^\infty((0,\infty);\mathbb{C})$$

Give S_+ its usual test-function topology, and let $J_+ : S_+ \to \mathscr{A}$ be extension by zero. For all $f, g \in \mathscr{A}$ and $a \in \mathbb{R}$,

$$(\tau_a f) * (\tau_a g)^* = f * g^*, \qquad q_W(\tau_a f, \tau_a g) = q_W(f,g).$$

The image $J_+(S_+)$ is not dense in $\mathscr{A}$. Nevertheless, positivity of the pulled-back form q_{J_+} is equivalent to A-TP.

Proof. Every element of S_+ has support compactly contained in $(0,\infty)$, so its extension by zero is smooth. The involution and convolution satisfy

$$(\tau_a g)^* = \tau_{-a}(g^*), \qquad (\tau_a f) * (\tau_{-a} g^*) = f * g^*.$$

The second identity follows by substituting $w = v - a$ in the convolution integral. Applying W proves the pairing identity.

Evaluation at -1 is a continuous nonzero functional on $\mathscr{A}$ which vanishes on $J_+(S_+)$, so this image is not dense. For any $f \in \mathscr{A}$, compactness of its support allows a sufficiently large a such that $\operatorname{supp}(\tau_a f) \subset (0, \infty)$. Thus positivity on $J_+(S_+)$ gives

$$q_W(f, f) = q_W(\tau_a f, \tau_a f) \geq 0.$$

The converse follows by restriction. □

This argument uses equality of convolution squares, not density of the source image. Translation does not shorten a support interval, so it does not place every compact test in the fixed Fourier window. Neither this lemma nor the approximation theorem proves positivity on its source image.

Source family	Comparison required for the Weil form
Arthur–Selberg	A map from truncation tests to $\mathscr{A}$ and an identity retaining the polar, finite-prime and archimedean terms.
Geometric Langlands	An arithmetic spectral realization, a map to $\mathscr{A}$, and a pairing comparison with q_W.
Iwasawa–Kato	A map from finite-prime arithmetic data to compact complex tests and a comparison with the full Weil form.
Arithmetic quantum chaos	A comparison of multivariable correlation statistics with the one-variable Weil pairing; ordinates alone forget real parts of zeros.
Arakelov–Faltings–Hriljac	A test map, a normalized degree-zero height pairing, and a residual form whose sum is the pulled-back Weil form.

Definition 112.2.3 *(The full positivity condition).* Write $\mathsf{R}_{\text{A-TP}}$ for $W(f * f^*) \geq 0$ for every $f \in \mathscr{A}$, with the polar, finite-prime and archimedean terms all present. The digamma contribution is one summand of this condition.

Remark 112.2.4 *(Comparison with the full functional).* A comparison must retain the full normalized functional, or prove an explicit equivalence with it. The continuity argument above extends positivity under its common-compact approximation hypothesis. Lemma 112.2.2 gives a different extension mechanism, even from a nondense image. The theorem supplies no test map or pairing identity for an unnamed source.

112.3 Fourier Windows and Height Comparisons

Compact Fourier windows and co-Poisson constraints

For an integer degree $m \geq 1$, the corresponding window is $(-1/m, 1/m)$. We first use the degree-one window $(-1, 1)$. Put $\mathscr{A}_1^{\mathrm{ev}} = \{f \in C_c^\infty((-1,1); \mathbb{C}) : f(-t) = f(t)\}$. Specify a family $\mathcal{B} \subset \mathscr{D}'(\mathbb{R})$ of distributions representing the desired co-Poisson constraints. Using the translations τ_a defined above, set

$$\mathscr{A}_{1,\mathcal{B}} = \{f \in \mathscr{A}_1^{\mathrm{ev}} : B(\tau_a f) = 0 \text{ for every } B \in \mathcal{B},\ a \in \mathbb{R}\}.$$

No nonzero element is required by this definition. The associated entire source class and its test map are

$$\mathrm{PW}^{\mathrm{CP}}(\mathcal{B}) = \mathcal{F}_+ \mathscr{A}_{1,\mathcal{B}}, \qquad (J_{\mathrm{CP}} h)(u) = \frac{1}{2\pi} \int_{\mathbb{R}} h(t) e^{-itu}\, dt.$$

Give $C_c^\infty((-1,1))$ its usual test-function inductive-limit topology, and $\mathscr{A}_{1,\mathcal{B}}$ its subspace topology. Give the entire source class the topology transported from this subspace. Fourier inversion makes J_{CP} a continuous linear bijection onto that compact-test space. A particular co-Poisson construction must specify the distributions $\mathcal{B}$; the following result holds for every such specified family.

THEOREM 112.3.1 *(The window pairing and the correlation test).* For $h, k \in \mathrm{PW}^{\mathrm{CP}}(\mathcal{B})$,

$$q_{J_{\mathrm{CP}}}(h,k) = \sum_{\rho} h(z_\rho)\overline{k(\bar{z}_\rho)}, \qquad z_\rho = -i(\rho - \tfrac{1}{2}).$$

The sum converges absolutely. Under RH this form is positive semidefinite. It is also positive semidefinite when its source space is zero, without any zero-location hypothesis.

For $f \in \mathscr{A}_1^{\mathrm{ev}}$, the function

$$(\mathcal{R}f)(x_1,x_2) = h_f\big(2\pi(x_1 - x_2)\big)$$

is a symmetric, translation-invariant pair-correlation test, rapidly decreasing on $x_1 + x_2 = 0$. With Fourier kernel $e^{-2\pi i(x_1\xi_1 + x_2\xi_2)}$, its Fourier distribution is

$$f(\xi_1)\delta(\xi_1 + \xi_2),$$

supported in $|\xi_1| + |\xi_2| < 2$.

Proof. Apply the explicit formula to $J_{\mathrm{CP}}h * (J_{\mathrm{CP}}k)^*$. Its Fourier transform is $h(z)\overline{k(\bar{z})}$. Rapid decay in the critical strip and the zero-count estimate give absolute convergence. Under RH each z_ρ is real, so the diagonal value is $\sum_\rho |h(z_\rho)|^2$. On the zero space the only value is zero.

Evenness of f gives symmetry of $\mathcal{R}f$; its formula gives translation invariance. Fourier decay proves the required decrease on the difference line. Finally

$$\mathcal{R}f(x_1,x_2) = \int_{\mathbb{R}} f(u)e^{2\pi i(x_1u - x_2u)}\,du,$$

which proves the Fourier-distribution and support assertions. □

Rudnick–Sarnak, *Zeros of principal L-functions and random matrix theory*, §1, TF1–TF3 and Theorems 1.1–1.2, pp. 3–5, use Fourier support $\sum_j |\xi_j| < 2/m$ for a cuspidal GL_m input, with $m \le 3$ or their coefficient hypothesis (1.7). For the pair test above, support in $(-1/m, 1/m)$ gives precisely that bound. The window $(-1,1)$ is the degree-one case. Their smoothed theorem permits complex zero parameters; their real-spacing formulation adds RH. These correlation sums are different functionals from $q_{J_{\mathrm{CP}}}$; the test construction above identifies no equality between them.

Remark 112.3.2 *(Restricted tests and the full cone).* The image of J_{CP} lies in tests supported in $[-1,1]$ and is not dense in $\mathscr{A}$: evaluation at any point outside that interval vanishes on the image but not on all compact tests. A nonzero annihilator and an extension beyond this window are separate requirements. Different parameters do not prove two test images disjoint. The literal entire-Mellin class in Theorem 101.6.2 is zero.

Example 112.3.3 *(The annihilator depends on its defining distributions).* If $\mathcal{B} = \{\delta_0\}$, then $\delta_0(\tau_a f) = f(-a)$ for every a, so $\mathscr{A}_{1,\mathcal{B}} = 0$. If instead $\mathcal{B}$ consists of the distribution $f \mapsto \int f$, choose a nonzero even bump $b \in C_c^\infty((-1,1))$ and set $f = b''$. Then f is even, $\int \tau_a f = 0$ for every a, and $f \neq 0$: otherwise b would be affine and compactly supported, hence zero. These are explicit annihilator examples, not a construction of an arithmetic co-Poisson family.

Heegner Heights and Compact-Test Gram Matrices

Let $F = \sum_{n\ge 1} a_n(F)e^{2\pi inz}$ be a normalized weight-2 newform on $\Gamma_0(N)$ with trivial character. Let $D < 0$ be an odd fundamental discriminant prime to N, set $K = \mathbb{Q}(\sqrt{D})$, and assume $\chi_D(p) = +1$ for every $p \mid N$. These primes split in K. Let H be the Hilbert class field, $\mathcal{G} = \mathrm{Gal}(H/K)$, $h_K = |\mathcal{G}|$, and $u_K = |\mathcal{O}_K^\times|/2$. Choose a classical Heegner point $x \in X_0(N)(H)$ and put $c = [(x) - (\infty)] \in J_0(N)(H)$.

Set $V = J_0(N)(H) \otimes_{\mathbb{Z}} \mathbb{C}$, and let Θ be a symmetric theta-divisor class on $J_0(N)$. The global H-height for 2Θ gives the Hermitian pairing $\langle\ ,\ \rangle_H$ on V, linear in the first variable. Explicitly, if B_H is its real symmetric pairing, then $\langle a + ib, c + id\rangle_H = B_H(a,c) + B_H(b,d) + iB_H(b,c) - iB_H(a,d)$. It is positive definite on this finite-dimensional vector space; torsion has disappeared in the tensor product.

For $(n,N) = 1$, the good Hecke operators T_n commute and are self-adjoint for this pairing. Their correspondences are defined over $\mathbb{Q}$ and are self-dual, so height functoriality gives $\langle T_n v, w\rangle_H = \langle v, T_n w\rangle_H$; they also commute with $\mathcal{G}$. Simultaneous diagonalization defines the orthogonal projection e_F onto the particular complex eigenspace

$$V_F = \{v \in V : T_n v = a_n(F)v \text{ for all } (n,N) = 1\}.$$

This is the eigenspace for F, not the sum of its Galois conjugates; it may be zero. For a character $\chi : \mathcal{G} \to \mathbb{C}^\times$, put

$$c_{\chi,F} = e_F \sum_{\sigma\in\mathcal{G}} \chi(\sigma)^{-1}\sigma c.$$

These are the unaveraged character components. The factor h_K^{-1} is not inserted.

For an ideal class $\mathfrak{a}$ of K, let $r_{\mathfrak{a}}(n)$ count integral ideals of norm n in that class. Identify characters of the class group with characters of $\mathcal{G}$ by the Artin map. The Rankin series in the following formula is

$$L_{\mathfrak{a}}(F,s) = \left(\sum_{\substack{n\ge 1\\(n,DN)=1}} \chi_D(n)n^{1-2s}\right)\sum_{n\ge 1} a_n(F)r_{\mathfrak{a}}(n)n^{-s},$$
$$L(F,\chi,s) = \sum_{\mathfrak{a}} \chi(\mathfrak{a})L_{\mathfrak{a}}(F,s),$$

initially in a right half-plane and then by analytic continuation. Gross–Zagier, *Heegner points and derivatives of L-series*, I§§2–6, especially (4.3), (5.1), (5.3)–(5.4) and Theorem (6.3), pp. 227–230, give the self-dual correspondences and the normalization

$$\|c_{\chi,F}\|_H^2 = C_{F,K}L'(F,\chi,1), \qquad C_{F,K} = \frac{h_K u_K^2\sqrt{|D|}}{8\pi^2(F,F)}, \qquad (F,F) = \int_{\Gamma_0(N)\backslash\mathfrak{H}} |F(z)|^2\,dx\,dy. \tag{112.1}$$

This is a Rankin derivative centered at $s = 1$, not a formula for $L'(F,1)$ alone. Changing the ground-field height, averaging the character component or changing the polarization changes the constant.

Lemma 112.3.4 *(Character Gram matrix).* For $r \ge 1$ and characters $\chi_1,\dots,\chi_r$ of $\mathcal{G}$, let $G_{ij} = \langle c_{\chi_i,F}, c_{\chi_j,F}\rangle_H$ and define $D_{F,K}u = \sum_j u_j c_{\chi_j,F}$ on $\mathbb{C}^r$. Distinct characters give orthogonal vectors. Repeated characters give

$$G_{ij} = \begin{cases} C_{F,K}L'(F,\chi_i,1), & \chi_i = \chi_j,\\ 0, & \chi_i \ne \chi_j, \end{cases}$$

and consequently

$$\|D_{F,K}u\|_H^2 = C_{F,K}\sum_{\chi}\left|\sum_{j:\chi_j=\chi} u_j\right|^2 L'(F,\chi,1).$$

The sum runs over the distinct characters selected.

Proof. The global height is invariant under $\mathcal{G}$, since its places are permuted by this group. The projection e_F commutes with that action, and reindexing the character sum gives $\tau c_{\chi,F} = \chi(\tau)c_{\chi,F}$. Thus invariance and the first-linear convention imply

$$G_{ij} = \chi_i(\tau)\overline{\chi_j(\tau)}G_{ij} \qquad (\tau \in \mathcal{G}).$$

For distinct characters one can choose τ with the scalar different from 1, so $G_{ij} = 0$. For equal characters the two vectors coincide; Equation (112.1) gives their squared norm. Expand the squared norm of $D_{F,K}u$ and group equal characters. □

Choose a nonzero $\phi \in C_c^\infty((-1/4,1/4);\mathbb{C})$ and put $\phi_j(t) = \phi(t-j)$ for $1 \le j \le r$. Their supports are disjoint. With $S = \mathbb{C}^r$, define

$$J_\Phi u = \sum_{j=1}^{r} u_j\phi_j \in \mathscr{A}, \qquad D_{F,K}u = \sum_{j=1}^{r} u_j c_{\chi_j,F} \in V.$$

The map J_Φ is continuous and injective: restriction to the support of each nonzero ϕ_j recovers u_j. Define $\mathrm{PW}_F^{\mathrm{Heeg}}(K,\Phi) = \mathcal{F}_+J_\Phi(S)$ with the topology transported from S. Its compact-test map is Fourier inversion followed by inclusion in $\mathscr{A}$. The dictionary Φ is additional data, not determined by (F,K).

Define Hermitian matrices

$$M_{ij} = W(\phi_i * \phi_j^*), \qquad R_{ij} = M_{ij} - G_{ij}.$$

Each entry of M is given by the polar term, gamma integral and finite prime sum of the full explicit formula. For a matrix A, write $A[u,v] = \sum_{i,j} u_i\overline{v_j}A_{ij}$, and $A \succeq 0$ if $A[u,u] \ge 0$ for all u.

Theorem 112.3.5 *(Height comparison on a specified test image).* The matrix G is positive semidefinite, and

$$W(J_\Phi u * (J_\Phi v)^*) = \langle D_{F,K}u, D_{F,K}v\rangle_H + R[u,v].$$

Weil positivity on $J_\Phi(S)$ is equivalent to $R + G \succeq 0$, or $R \succeq -G$. The stronger condition $R \succeq 0$ is sufficient. If $D_{F,K}u = 0$, positivity in that direction is exactly $R[u,u] \ge 0$.

Proof. The height pairing gives $G[u,u] = \|D_{F,K}u\|_H^2 \ge 0$. Linearity of J_Φ, sesquilinearity of q_W and the definition $M = G + R$ prove the identity. Its diagonal gives the positivity assertions. □

Example 112.3.6 *(Repeated characters and test normalization).* For $r = 2$ and $\chi_1 = \chi_2$, the vector $u = (1,-1)$ satisfies $D_{F,K}u = 0$, whereas $J_\Phi u = \phi_1 - \phi_2 \neq 0$. The height contributes zero in this direction, leaving precisely $R[u,u] = W((\phi_1-\phi_2)*(\phi_1-\phi_2)^*)$ to control. For $r = 1$, suppose $\|c_{\chi,F}\|_H^2 = g > 0$. Replacing ϕ_1 by $\varepsilon\phi_1$ changes M_{11} to $\varepsilon^2 M_{11}$ for real $\varepsilon > 0$, while $G_{11} = g$ is unchanged. Thus $R_{11} = \varepsilon^2 M_{11} - g < 0$ for sufficiently small ε. The stronger sufficient condition $R \succeq 0$ is sensitive to the chosen dictionary and is not a consequence of height positivity.

An arithmetic-intersection interpretation requires further data: a regular proper arithmetic model of $X_0(N)$ over $\mathcal{O}_H$, degree-zero representatives, vertical corrections orthogonal to the fibre components, and archimedean Green metrics. Let $\widehat{V}_{\mathbb{R}}$ be the chosen real space of corrected degree-zero arithmetic divisor classes, and put $\widehat{V}_{\mathbb{C}} = \widehat{V}_{\mathbb{R}} \otimes_{\mathbb{R}} \mathbb{C}$. Let $I_{\mathbb{R}}$ be its real symmetric admissible intersection pairing and $I_{\mathbb{C}}$ its complex-bilinear extension. The pairing needed here is the Hermitian extension

$$I_H(A, B) = I_{\mathbb{C}}(A, \overline{B}),$$

where conjugation acts on the complex coefficients of arithmetic classes. Specify a complex-linear lift $\widehat{D} : S \to \widehat{V}_{\mathbb{C}}$ whose degree-zero divisor class is $D_{F,K}$, and a normalization $\kappa > 0$ for which one proves

$$-\kappa I_H(\widehat{D}(u), \widehat{D}(v)) = \langle D_{F,K}u, D_{F,K}v\rangle_H.$$

The model, metrics, lifts and numerical normalization are comparison data; the displayed equality is required, not inferred from the notation. It is this Hermitian form, rather than the complex-bilinear intersection form, that can match q_W.

Faltings–Hriljac arithmetic Hodge theory and a proposed Petersson– Arakelov comparison of Jorgenson–Kramer (2003) must be applied with these specific conventions. A geometrically defined Bott–Chern and vertical correction form R^{geom} gives the proposed Weil comparison only after proving $R^{\mathrm{geom}}[u, v] = R[u, v]$ on S. That identity and $R^{\mathrm{geom}} \succeq 0$ imply positivity on $J_\Phi(S)$ by the theorem. The definition $R = M - G$ proves neither this geometric identification nor its sign.

Remark 112.3.7 *(Comparison with other test images).* The Heegner construction uses degree-zero classes and a specified test dictionary. The domain-restricted Koszul–Petersson comparison of Theorem 47.9.1 in Chapter 47 has different input data. A proposed Rankin–Selberg central-value comparison through Υ_F at $L(1/2, F \otimes \bar{F})$ must exhibit the relevant cusp form, establish its required modularity and normalization, define its compact-test map, and prove the pairing identity on its stated domain. The images of the test maps must then be compared before drawing a conclusion about their intersection. Different inputs prove neither disjointness nor density. The finite-dimensional image $J_\Phi(S)$ is not dense in $\mathscr{A}$: a finite-dimensional subspace of a Hausdorff locally convex space is closed, and $\mathscr{A}$ is infinite-dimensional, as disjointly supported bumps show.

112.4 Arithmetic Comparisons and Ordinate Statistics

The Iwasawa–Kato Comparison Question

Remark 112.4.1 *(Finite-prime data and the full Weil pairing).* The Iwasawa comparison question concerns the following proposed inputs: Mazur–Wiles value formulas; Kato Euler systems and Bloch–Kato–Beilinson height pairings; a proposed archimedean counterpart of Ferrero–Washington; Perrin–Riou and Bloch–Kato exponentials; a proposed $p \to \infty$ Connes–Marcolli comparison; Kato reciprocity maps $\exp^*/\log$; Kolyvagin and Coates–Wiles height constructions; Colmez–Fontaine p-adic representations; Fukaya–Kato noncommutative methods and Skinner–Urban; and a proposed Dirichlet p-adic transport. The named reference family comprises Mazur–Wiles (1984), Kato (2004, *Astérisque* 295), Perrin–Riou (1995), Fukaya–Kato (2006), Colmez, Bloch–Kato (1990), Kolyvagin (1988), Coates–Wiles (1977), Ferrero–Washington (1979), Connes–Marcolli and Skinner–Urban.

For each such route, the missing comparison is a specified map to $\mathscr{A}$ and an identity with q_W, or an explicit equivalence, including the polar and archimedean terms. The existence, coefficients and domain of that map must be part of the assertion. No completeness of this list, exclusion of all Iwasawa methods,

or positive pairing comparison is assumed here. Functional-equation symmetry alone does not provide a sign for q_W; the abstract divisor example below already separates these properties. The conditional arithmetic complementarity statement in Theorem 43.5.1 retains its arithmetic evaluation, central-defect, and detection hypotheses. It supplies no test map in this chapter.

Remark 112.4.2 *(An archimedean Iwasawa comparison).* Deninger's cohomological analogies (ICM 1998; *Motives and algebraic cycles*, 2002) motivate asking for an archimedean analogue of an Iwasawa main-conjecture construction. To obtain a formulation of A-TP by this route, one must construct its carrier, operators and pairing and prove equivalence with the full normalized Weil condition. No such construction or RH-equivalence follows merely from the analogy.

Ordinate statistics and the divisor pairing

Theorem 112.4.3 *(Ordinate data do not determine the divisor form).* There are conjugation- and reflection-invariant divisors in $0 < \Re s < 1$ with identical ordinate multisets whose forms

$$Q_{\mathcal{D}}(f) = \sum_{\rho \in \mathcal{D}} h_f(z_\rho)\overline{h_f(\bar{z}_\rho)}, \qquad f \in \mathscr{A},$$

have different positivity properties. Their ordinate statistics are identical, including every statistic formed from finite tuples of ordinates.

Proof. Let $\Gamma \subset \mathbb{R}$ be a locally finite symmetric multiset with polynomial counting growth, and let $0 < a < 1/2$. Compare the multisets

$$\mathcal{D}_0 = \{1/2 + i\gamma : \gamma \in \Gamma\} \sqcup \{1/2, 1/2\}, \qquad \mathcal{D}_a = \{1/2 + i\gamma : \gamma \in \Gamma\} \sqcup \{1/2 - a, 1/2 + a\}.$$

Both have ordinate multiset $\Gamma \sqcup \{0, 0\}$ and the stated symmetries. The first form is a sum of absolute squares. Choose an even nonnegative nonzero $\phi \in C_c^\infty(\mathbb{R})$ and put

$$f_L(u) = \phi(u - L) - \phi(u + L), \qquad c = h_\phi(ia) = h_\phi(-ia) > 0.$$

For real t, $|h_{f_L}(t)| \le 2|h_\phi(t)|$. The number $C = \sum_{\gamma \in \Gamma} |h_\phi(\gamma)|^2$ is finite by rapid decay and polynomial counting growth. At the two nonreal spectral parameters,

$$h_{f_L}(ia) = -2c\sinh(aL), \qquad h_{f_L}(-ia) = 2c\sinh(aL).$$

Consequently

$$Q_{\mathcal{D}_a}(f_L) \le 4C - 8c^2\sinh^2(aL) < 0$$

for sufficiently large L. All sums converge absolutely. Changing the real parts has left every ordinate statistic unchanged. □

Remark 112.4.4 *(Scope of the statistical comparison).* The countermodel is a statement about abstract divisors and the information retained by ordinate statistics. It is not a zeta divisor and satisfies no stipulated prime explicit formula; it proves no logical independence assertion about RH for the fixed Riemann zeta function. The dynamical implication in Theorem 105.8.2 additionally assumes a zero-divisor realization, semiclassical dynamics, and the appropriate BGS universality statement. RH alone supplies none of those dynamical hypotheses.

112.5 Extension to the Full Weil Cone

The next proposition extends positivity by common-compact approximation. Positivity on separate images does not itself control cross terms on their linear span. Translation supplies a separate extension when every convolution square has a representative in the given image.

Proposition 112.5.1 *(Extension by approximation of compact tests).* Suppose a family of specified test maps $J_\alpha : S_\alpha \to \mathscr{A}$ has positive pulled-back Weil forms. Then q_W is positive on the union of their images. If every compact test is a smooth limit of tests from that union with all supports in a common compact set, A-TP follows. For the Heegner map, the exact positivity condition is $R + G \succeq 0$.

Proof. The comparison identities give positivity on each image. The continuity argument in Theorem 112.2.1 gives the extension. The Heegner condition is the Gram-matrix identity. □

112.6 Relation to Scattering and Arithmetic Realizations

Chapter 101 constructs specified self-adjoint scattering pairs and proves obstructions to positivity of their ordinary trace differences. Its literal entire-Mellin class is zero. Neither a scattering phase nor an inequality for a single summand supplies the full identity with $P - W_\infty - W_{\mathrm{fin}}$.

A-TP remains equivalent to RH on the full compact-test algebra. Under their respective sign hypotheses, the specified comparisons establish positivity on their stated images. Passing to all compact tests requires a further argument, such as approximation or the translation identity. The abstract divisor countermodel concerns the information lost by taking ordinates; it does not remove the arithmetic hypotheses of a zeta realization. A dynamical route to GUE statistics retains the separate assumptions of Theorem 105.8.2.

The arithmetic-gravity comparisons in Chapters 103–105 retain their separate state-space, chiral-homology, spectral-flow and semiclassical hypotheses. A proposed prismatic interpretation at the archimedean place also requires its own carrier and comparison; it is not constructed by the Fourier or height maps here.

112.7 The Remaining Comparison Requirements

(i) The comparison theorem transfers positivity through a specified map and pairing identity. Common-compact approximation gives one extension to all tests. Translation gives another, without requiring a dense image.

(ii) The Fourier-window map identifies an actual restricted test space. The Heegner map identifies a finite test image and the residual matrix $R = M - G$. Their parameterizations do not establish disjointness or density of their images.

(iii) Ordinate statistics are unchanged in the two explicit divisor models, although one divisor form has a negative square. This statement does not assert an arithmetic counterexample to RH or a theorem that RH implies GUE statistics.

(iv) The full residual is $W(f * f^*) \succeq 0$ for every $f \in \mathscr{A}$.

A comparison with A-TP must preserve the full normalized functional, or prove an explicit equivalence with it, together with an argument transferring positivity to all compact tests.

Chapter 113

Paskunas Wild Block Ext^1-Class Match at $p \in \{2, 3\}$

The intended wild-prime class comparison can be factored through Galois extension data or through a specified pseudo-character tangent space. Either factorization requires actual maps in the chosen coefficient category. A finite quiver model does not supply these arithmetic maps, and equal dimensions do not identify classes.

113.1 The Two Class-Comparison Routes

The conditional composition of Theorem 87.2.9 has the form

$$\mathrm{Ext}^1_{\mathfrak{B}} \xrightarrow{\sim} D_{\bar\rho_{\mathfrak{B}}} \xrightarrow{\sim} \mathbb{T}^1_{\mathcal{X}}|_{x_{\tau_{\mathfrak{B}}}}.$$

Here $D_{\bar\rho_{\mathfrak{B}}}$ is the fixed-determinant tangent $Z^1_{\mathrm{cts}}(G_{\mathbb{Q}_p}, \mathrm{ad}^0\,\bar\rho_{\mathfrak{B}})/d(\mathrm{ad}\,\bar\rho_{\mathfrak{B}})$, as computed in Lemma 87.2.4. Its determinant-one conjugation variant is used only when that equivalence relation is chosen. Its first arrow is the additional block-to-Galois hypothesis stated there; the spectral tangent comparison is a separate input. The pseudo-character route considered here likewise needs an actual block-to-pseudo-character map and a spectral map, with any required duals made explicit. Agreement of the routes requires a comparison of their maps, not simply a common dimension.

113.2 Block Centraliser Pseudo-Character Tangent

Pseudo-Character Tangent Space at Wild Primes

Lemma 113.2.1 *(relative first-order tangent).* Let k be a perfect field of characteristic p, and let $(R, \mathfrak{m}, k)$ be a complete Noetherian local $W(k)$-algebra. The relative tangent space consists of continuous local $W(k)$-algebra maps $R \to k[\epsilon]/(\epsilon^2)$ reducing to the residue map. It is

$$T_{R/W(k)} = \mathrm{Hom}_k\big(\mathfrak{m}/(\mathfrak{m}^2 + pR), k\big).$$

Identifying this space with a specified pseudo-character deformation tangent requires a pro-representing isomorphism $R \simeq R_{\mathrm{ps}}$.

Proof. Such a map has the form $r \mapsto \bar r + \epsilon d(r)$, where d is a $W(k)$-linear derivation with values in the residue module. On $\mathfrak{m}$, the derivation kills $\mathfrak{m}^2$ and pR. Conversely, reduce modulo p. The resulting local k-algebra splits as $k \oplus \mathfrak{m}/pR$ as a vector space. A functional on $\mathfrak{m}/(\mathfrak{m}^2 + pR)$, extended by zero on k, satisfies the Leibniz rule. These constructions are inverse. □

Remark 113.2.2 *(the pseudo-character comparison).* Pro-representability alone supplies neither a block-ring isomorphism nor a map from block extensions to a deformation tangent. At small primes one must specify the deformation object, whether a trace or a pseudorepresentation, its coefficients and its determinant condition. These choices precede any comparison with an arithmetic block.

Absolute Extensions and Relative Tangents

PROPOSITION 113.2.3 *(self-extensions of the residue field).* For a commutative Noetherian local ring $(R, \mathfrak{m}, k)$,

$$\mathrm{Ext}^1_R(k, k) \simeq \mathrm{Hom}_k(\mathfrak{m}/\mathfrak{m}^2, k).$$

Every simple R-module is isomorphic to k. Thus this formula has no grading by pairs of distinct simple R-modules.

Proof. Apply $\mathrm{Hom}_R(-, k)$ to $0 \to \mathfrak{m} \to R \to k \to 0$. The restriction $\mathrm{Hom}_R(R, k) \to \mathrm{Hom}_R(\mathfrak{m}, k)$ is zero, and $\mathrm{Ext}^1_R(R, k) = 0$. Exactness identifies the extension space with $\mathrm{Hom}_R(\mathfrak{m}, k)$. Since $\mathfrak{m}k = 0$, these homomorphisms factor precisely through $\mathfrak{m}/\mathfrak{m}^2$. Every simple module is a quotient by a maximal ideal, and a local ring has only the maximal ideal $\mathfrak{m}$. □

Example 113.2.4 *(regularity and the coefficient base).* For $R = k[[t]]$, the resolution

$$0 \longrightarrow R \xrightarrow{t} R \longrightarrow k \longrightarrow 0$$

gives $\mathrm{Ext}^1_R(k, k) = k$, although R is regular. For $R = W(k)$, multiplication by p gives the same resolution and absolute extension space k. Its tangent relative to $W(k)$ is zero. Absolute residue-field extensions therefore do not determine the relative deformation tangent without a comparison.

PROPOSITION 113.2.5 *(duality for a specified deformation tangent).* Let L_x be a complex of k-vector spaces, with $H^0(L_x)$ finite-dimensional. Suppose the specified pseudo-character tangent T_{ps} is identified with $H^0(R\,\mathrm{Hom}_k(L_x, k))$. Then $H^0(L_x) \simeq T_{\mathrm{ps}}^\vee$.

Proof. Linear duality over a field is exact, so $H^0(R\,\mathrm{Hom}_k(L_x, k)) = \mathrm{Hom}_k(H^0(L_x), k)$. Finite-dimensional biduality proves the assertion. □

The degree-one cotangent target of the arithmetic comparison requires an additional shift and a comparison of complexes. In particular, the required isomorphism

$$\mathbb{L}^1_{\chi^{\mathrm{EG,wild},p,\chi}_{GL_2}\big|_{x_{\tau_{\mathfrak{B}}}}} \xrightarrow{\sim} T_{\mathrm{ps}}^\vee$$

is an additional hypothesis, not a consequence of degree-zero duality.

113.3 WILD-PRIME CLASS-MATCH THEOREM

THEOREM 113.3.1 *(wild block* Ext^1*-class match, pseudo-character derivation). Conditional statement.* Let $p \in \{2, 3\}$, χ a central character, and $\mathfrak{B}$ a non-semisimple Paškūnas block. Assume the wild-EG datum, actual natural isomorphisms of the block extension space and the spectral cotangent fibre with the same dual pseudo-character tangent, and preservation of the chosen arithmetic classes. Then there is a canonical k-linear class-level isomorphism

$$\mathrm{c}^{\mathrm{class,B}}_{p,\mathfrak{B}} : \mathrm{Ext}^1_{\mathfrak{B}}(S, S') \xrightarrow{\sim} \mathbb{L}^1_{\chi^{\mathrm{EG,wild},p,\chi}_{GL_2}\big|_{x_{\tau_{\mathfrak{B}}}}}$$

natural in $\mathfrak{B}$. If the arithmetic classes in Questions 54.4.8 and 54.4.9 have been constructed, the class-preserving factor maps carry them to the specified cotangent directions. In characteristic two, trivial and sign characters cannot label two distinct objects. At three, a radical-square-zero model has a nonzero

adjacent Yoneda product; compatibility in higher degrees must retain it. Agreement with the map of Theorem 87.2.9 requires a specified tangent-to-cotangent identification, or maps to a common target, followed by a comparison on each labelled line.

Proof. Compose the assumed block-to-dual-pseudo-character isomorphism with the inverse of the assumed spectral-to-dual-pseudo-character isomorphism. The composite is an isomorphism and is natural because both factors are natural. Their stipulated compatibility transports the selected classes. A comparison with the other factorization is additional data; it does not follow from the existence of these maps. □

Corollary 113.3.2 *(comparison on labelled lines).* Suppose both class-comparison routes are constructed and carry each specified source line isomorphically onto the same specified target line. Their restrictions to that line differ by a nonzero scalar. For several lines these scalars may differ; there need not be one scalar for the whole vector space.

Proof. Compose one line isomorphism with the inverse of the other. Every automorphism of a one-dimensional vector space is multiplication by a nonzero scalar. This statement applies to each labelled line separately and assumes that neither map mixes those lines. □

113.4 Derivation Comparison

The pseudo-character comparison must specify its coefficient ring, block objects, deformation condition and tangent/cotangent duality. The finite-algebra examples of Chapter 54 do not establish these data in an arithmetic category. In particular, the two local comparison questions contain no trace-pairing map that could be imported as a class-level arithmetic isomorphism.

113.5 Wild Class Boundary

The two proposed routes remain conditional on their actual factor maps and class compatibility. Once supplied, composition proves a natural class isomorphism; agreement between the routes additionally requires a commuting comparison, or specified linewise normalizations. Neither a block-centraliser dimension nor a pro-representable deformation functor alone supplies those identifications. Any higher-degree arithmetic realization must also account for the Yoneda products and global tensor terms computed in Section 54.4.

Chapter 114

Ramanujan for Maass Forms: Sharpening 7/64 and a Sub-RH Conditional

114.1 Domain and Target

Fix the target. For $\mathrm{GL}_2/\mathbb{Q}$ with trivial central character, a Maass cuspidal Hecke eigenform ϕ at level 1 has local Satake parameters $(\alpha_p(\phi), \beta_p(\phi))$ with $\alpha_p\beta_p = 1$ and $\theta_p(\phi) := \max(\log|\alpha_p|, \log|\beta_p|)/\log p \geq 0$. The Ramanujan conjecture asserts $\theta_p(\phi) = 0$ for all p and all cuspidal ϕ. The current best unconditional bound is Kim–Sarnak 2003 Appendix 2 to *J. Amer. Math. Soc.* 16, $\sup_p \theta_p(\phi) \leq 7/64 = 0.109375$, established via the symmetric-fourth-power lift $\mathrm{sym}^4\phi$ on $\mathrm{GL}_5/\mathbb{Q}$ of Kim 2003 *J. Amer. Math. Soc.* 16 combined with a Luo–Rudnick–Sarnak 1995 *Geom. Funct. Anal.* 5 L-function convexity argument.

Target. Compare the attempted sub-7/64 unconditional construction through higher symmetric-power functoriality (Newton–Thorne 2021 *Publ. Math. IHES* 134; Clozel–Harris–Taylor 2008 *Publ. Math. IHES* 108 as prerequisite automorphy-of-lifts). The unconditional output remains Kim–Sarnak 7/64; the sharper bound is conditional on Maass symmetric-power functoriality, and full Ramanujan is conditional on an explicit automorphic Ramanujan input.

Domain restriction. The chapter treats level 1 Maass forms on $\mathrm{SL}_2(\mathbb{Z})\backslash\mathbb{H}$ with trivial nebentypus; extension to arbitrary level and nebentypus follows the same argument and is not used later. All stated local Satake bounds are uniform in the archimedean parameter of ϕ, in the sense of Iwaniec 2002 §14.4.

114.2 Construction A: Kim–Shahidi Symmetric-Cube and the 1/9 Baseline

The Symmetric-Cube Lift

Theorem 114.2.1 *(Kim–Shahidi: $\theta \leq 1/9$).* For the level-one Maass form ϕ fixed above, $\sup_p \theta_p(\phi) \leq 1/9$.

Proof. Write π for the unitary cuspidal automorphic representation attached to ϕ. Kim–Shahidi, *Functorial products for* $\mathrm{GL}_2 \times \mathrm{GL}_3$ *and the symmetric cube for* GL_2, Ann. Math. 155 (2002), Theorem 6.1, constructs $\mathrm{Sym}^3\pi$ on GL_4. This lift is cuspidal outside the dihedral and tetrahedral cases. If it is cuspidal, Kim–Shahidi, *Cuspidality of symmetric powers with applications*, Duke Math. J. 112 (2002), Proposition 4.8, gives

$$|\alpha_p|, |\beta_p| < p^{1/9}$$

at every unramified prime. All finite primes are unramified in the level-one domain. Taking logarithms gives the stated bound. The dihedral and tetrahedral cases are tempered, so their exponents are zero. In the dihedral case this follows from unitary automorphic induction of a character. In the tetrahedral case it follows from the unitary Weil parameter described in Proposition 3.3.8 of the same Duke paper.

Proposition 4.8 is the analytic input for this argument. Its proof uses the symmetric-ninth L-function in Proposition 4.7 and Shahidi's local estimate (1988, Lemma 5.8). These analytic properties do not assert cuspidal automorphy of $\mathrm{Sym}^9\pi$. □

General and Refined Symmetric-Power Bounds

For a unitary cuspidal representation Π of $\mathrm{GL}_n/\mathbb{Q}$, the Luo–Rudnick–Sarnak estimate bounds its unramified Satake exponents by $1/2 - 1/(n^2+1)$. Jacquet–Shalika's local generic-unitary estimate instead gives exponents strictly below $1/2$. The symmetric-power eigenvalues of a two-dimensional Satake parameter are

$$\alpha_p^m,\ \alpha_p^{m-1}\beta_p,\ \ldots,\ \beta_p^m.$$

Since $\alpha_p\beta_p = 1$, their largest absolute logarithmic exponent is $m\theta_p(\phi)$. When $\mathrm{Sym}^3\,\pi$ is cuspidal, the general estimate gives

$$\theta_p(\phi) \le \frac{1/2 - 1/17}{3} = \frac{5}{34}.$$

When $\mathrm{Sym}^4\,\pi$ is cuspidal, it gives

$$\theta_p(\phi) \le \frac{1/2 - 1/26}{4} = \frac{3}{26}.$$

The latter upper bound is weaker than $1/9$, since $3/26 - 1/9 = 1/234 > 0$. The $1/9$ and $7/64$ estimates therefore require the more specific analytic inputs, beyond this general rank bound.

114.3 Construction B: Kim's Symmetric Fourth and the 7/64 Bound

THEOREM 114.3.1 *(Kim–Sarnak: $\theta \le 7/64$).* For the level-one Maass form ϕ fixed above, $\sup_p \theta_p(\phi) \le 7/64 = 0.109375$.

Proof. Kim's symmetric-fourth transfer constructs $\Pi = \mathrm{Sym}^4\,\pi$ on GL_5. It is cuspidal outside the dihedral, tetrahedral, and octahedral cases by Kim–Shahidi, Duke Math. J. 112 (2002), Theorem 3.3.7. In the cuspidal case, the Kim–Sarnak refinement in Appendix 2 to Kim, J. Amer. Math. Soc. 16 (2003), gives

$$\max_j \left|\log_p |\alpha_j(\Pi_p)|\right| \le \frac{1}{2} - \frac{1}{1 + 5\cdot 6/2} = \frac{7}{16}.$$

This is the degree-five case of the refined estimate recorded in Sarnak, *Notes on the generalized Ramanujan conjectures*, equations (21)–(24), pp. 666–667. Its symmetric-square L-function argument has a smaller analytic conductor than the general Rankin–Selberg argument. The extremal symmetric-fourth Satake eigenvalue has exponent $4\theta_p(\phi)$. Division by four gives $7/64$. The three exceptional types are tempered, and hence satisfy the same estimate with exponent zero.

The exterior-square construction involved in the transfer has rank six. Let $V = \mathbb{C}^2$ be the standard algebraic representation of $\mathrm{GL}_2(\mathbb{C})$. Then

$$\Lambda^2\,\mathrm{Sym}^3 V \cong (\mathrm{Sym}^4 V \otimes \det V) \oplus (\det V)^3.$$

For diagonal eigenvalues a, b, the six weights on the left are a^5b, a^4b^2, a^3b^3, a^3b^3, a^2b^4, ab^5. These are exactly the five weights of $\mathrm{Sym}^4 V \otimes \det V$ and the weight of $(\det V)^3$. Complete reducibility over $\mathbb{C}$ gives the displayed representation identity. With trivial central character, this is the identity of unramified Satake representations underlying $\Lambda^2(\mathrm{Sym}^3\,\pi) = \mathrm{Sym}^4\,\pi \boxplus \mathbf{1}$. The global transfer is the separate automorphy theorem used above. The exterior square of $\mathrm{Sym}^2 V$ has rank three and is a different representation. □

Remark 114.3.2 *(analytic estimates for the symmetric fourth).* An analytic refinement through $L(s, \mathrm{sym}^4 \phi)$ must specify the varying parameters and an estimate that implies a stronger local Satake bound. For a fixed unitary cuspidal representation Π of $\mathrm{GL}_5/\mathbb{Q}$, Nelson's *Bounds for standard L-functions*, Theorem 1.1, gives

$$|L(\Pi, 1/2 + it)| \ll_{\Pi,\delta} (1 + |t|)^{5(1-\delta)/4}, \qquad 0 < \delta < 1/4050.$$

Here L is the finite standard L-function, with archimedean factors excluded. This applies when $\Pi = \mathrm{sym}^4 \phi$ is cuspidal. Its implicit constant may depend on ϕ. An improvement of $7/64$ by this route therefore requires additional uniformity and a proved implication from the analytic estimate to the local exponents. Cancellation beyond the estimate is another possible input. Construction C instead assumes cuspidal automorphy of a higher Maass symmetric power.

114.4 Construction C: Newton–Thorne Symmetric-Power Functoriality and the Sharpening

The Newton–Thorne Theorem

Theorem 114.4.1 *(Newton–Thorne 2021: unconditional holomorphic* sym^n *functoriality).* (Newton–Thorne 2021 *Publ. Math. IHES* 134, Main Theorem; extended in Newton–Thorne 2023 *Publ. Math. IHES* 137 to the non-CM case with full generality). Let ϕ be a holomorphic cuspidal Hecke newform of weight $k \geq 2$ on $\mathrm{SL}_2(\mathbb{Z})$ that is non-CM. Then for every $n \geq 1$, the symmetric-nth-power lift $\mathrm{sym}^n \phi$ exists as a cuspidal automorphic representation of $\mathrm{GL}_{n+1}/\mathbb{Q}$.

Proof. Newton–Thorne 2021 (holomorphic, $k \geq 2$). The argument proceeds by automorphy-lifting through Galois deformation rings of the ℓ-adic representation associated to ϕ, combined with $R = T$ theorems in the tame Taylor–Wiles patching framework (Taylor–Wiles 1995 *Ann. Math.* 141, extended by Clozel–Harris–Taylor 2008 *Publ. Math. IHES* 108 to the GL_n setting). □

Remark 114.4.2 *(Newton–Thorne does not cover Maass directly).* The Newton–Thorne theorem is stated for *holomorphic* cuspidal newforms, where the attached ℓ-adic Galois representation (Deligne 1971 *Sém. Bourbaki* 355 for $k \geq 2$; Deligne–Serre 1974 *Ann. Sci. ENS.* 7 for $k = 1$) is the input to the automorphy-lifting theorem. Maass cusp forms lie outside the hypothesis of Newton–Thorne 2021: the automorphy-lifting theorem requires an ℓ-adic Galois representation of algebraic Hodge weight ≥ 1, and the conjectural Langlands-attached representation of a Maass form has weight 0 in the Hodge sense. The holomorphic companion construction gives a diagnostic Rankin–Selberg convolution $L(s, \phi \times \mathrm{sym}^n F)$, but it does not transfer temperedness of $\mathrm{sym}^n F$ into a sub-$7/64$ bound for $\theta_p(\phi)$.

The Auxiliary Holomorphic Form and the Transfer

The attempted sharpening of $7/64$ through a holomorphic companion is only a test of source separation. It supplies no division of the Maass Satake exponent by n. A genuine sharper bound requires the symmetric power of the Maass form itself.

Definition 114.4.3 *(Maass–holomorphic Rankin–Selberg pairing).* . Let ϕ be a Maass cusp form of $\mathrm{GL}_2/\mathbb{Q}$ and F a holomorphic cuspidal newform of weight $k \geq 2$. The *Maass–holomorphic Rankin–Selberg L-function* is

$$L(s, \phi \times F) := \prod_p L_p(s, \phi \times F) = \prod_p \prod_{i,j=1,2} \left(1 - \alpha_{p,i}(\phi)\alpha_{p,j}(F) p^{-s}\right)^{-1},$$

with $\alpha_{p,i}(\phi) \in \{\alpha_p(\phi), \beta_p(\phi)\}$ and analogously for F. The completed L-function $\Lambda(s, \phi \times F)$ satisfies the Jacquet–Piatetski-Shapiro–Shalika 1983 functional equation.

PROPOSITION 114.4.4 *(RS convolution for a Maass form with a tempered companion).* Let ϕ be a Maass cusp form and F a holomorphic cuspidal newform of weight $k \geq 2$, non-CM. Fix $n \geq 4$. The symmetric-nth-power lift $\mathrm{sym}^n F$ (Newton–Thorne 2021) is a cuspidal tempered automorphic representation of $\mathrm{GL}_{n+1}/\mathbb{Q}$. The Rankin–Selberg L-function $L(s, \phi \times \mathrm{sym}^n F)$, as a $\mathrm{GL}_2 \times \mathrm{GL}_{n+1}$ L-function, admits a functional equation, meromorphic continuation to $\mathbb{C}$, and satisfies: $L(s, \phi \times \mathrm{sym}^n F) \neq 0$ for $\mathrm{Re}(s) \geq 1$ (Jacquet–Shalika 1981).

Proof. Newton–Thorne 2021 (Theorem 114.4.1) gives $\mathrm{sym}^n F$ as a cuspidal $\mathrm{GL}_{n+1}/\mathbb{Q}$ representation. Deligne 1974 (Weil conjectures) gives temperedness. Jacquet–Piatetski-Shapiro–Shalika (JPSS) 1983 *Amer. J. Math.* 105 establishes the Rankin–Selberg L-function theory for $\mathrm{GL}_2 \times \mathrm{GL}_{n+1}$, including the functional equation and meromorphic continuation. Jacquet–Shalika 1981 non-vanishing on $\mathrm{Re}(s) = 1$ applies to the cuspidal GL_{n+1}-factor $\mathrm{sym}^n F$. □

The Sharpened Bound: Construction C Main Theorem

Remark 114.4.5 *(why the companion trick is conditional).* Jacquet–Shalika bounds the two automorphic factors separately. It does not divide the GL_{10} exponent of $\mathrm{sym}^9 F$ by nine to bound the Maass form ϕ. A sharper Maass bound therefore requires functoriality for $\mathrm{sym}^9 \phi$ itself.

THEOREM 114.4.6 *(sharpened Ramanujan bound: conditional on Maass symmetric-power functoriality). (conditional on the Maass symmetric-ninth-power conjecture: that* $\mathrm{sym}^9 \phi$ *exists as a cuspidal automorphic representation of* $\mathrm{GL}_{10}/\mathbb{Q}$ *for the Maass form* ϕ *itself).* Let ϕ be a cuspidal Maass Hecke eigenform of $\mathrm{GL}_2/\mathbb{Q}$. Assuming $\mathrm{sym}^9 \phi$ is cuspidal on $\mathrm{GL}_{10}/\mathbb{Q}$, the Jacquet–Shalika 1981 bound applied to the GL_{10} form $\mathrm{sym}^9 \phi$ gives

$$\sup_p \theta_p(\phi) \;\leq\; \frac{1/2 - 1/(10^2+1)}{9} \;=\; \frac{1/2 - 1/101}{9} \;\approx\; 0.05446,$$

strictly below Kim–Sarnak's $7/64 \approx 0.1094$.

Proof. Conditional on $\mathrm{sym}^9 \phi$ cuspidal automorphic on $\mathrm{GL}_{10}/\mathbb{Q}$ (the Maass symmetric-ninth-power conjecture), the Jacquet–Shalika 1981 *Amer. J. Math.* 103 non-vanishing of $L(s, \mathrm{sym}^9 \phi \otimes (\mathrm{sym}^9 \phi)^\vee)$ on $\mathrm{Re}(s) = 1$ forces the Satake parameters of $\mathrm{sym}^9 \phi$ on GL_{10} to satisfy $\theta_p(\mathrm{sym}^9 \phi) \leq 1/2 - 1/101$. The extremal Satake parameter of $\mathrm{sym}^9 \phi$ at p is $p^{9\theta_p(\phi)}$, so $9\theta_p(\phi) \leq 1/2 - 1/101$, giving the stated bound. □

Remark 114.4.7 *(form of Maass symmetric-power functoriality).* Newton–Thorne 2021 establishes $\mathrm{sym}^n \phi$ cuspidal on $\mathrm{GL}_{n+1}/\mathbb{Q}$ for *holomorphic* newforms ϕ. The analogous statement for Maass forms is the content of the Langlands global functoriality conjecture for $\mathrm{GL}_2 \to \mathrm{GL}_{n+1}$ at non-algebraic archimedean type; it is open for all $n \geq 5$. The holomorphic companion trick – forming $L(s, \phi \times \mathrm{sym}^n F)$ for a holomorphic form F – does not produce a bound on $\theta_p(\phi)$ sharper than the direct GL_2 Jacquet–Shalika bound $\theta_p(\phi) \leq 2/5$: the Rankin–Selberg non-vanishing constrains the GL_{10} factor $\mathrm{sym}^n F$, not the GL_2 factor ϕ. The bound $(1/2 - 1/101)/9$ in Theorem 114.4.6 is the correct conditional bound on the Maass symmetric-power conjecture, not an unconditional sharpening.

Remark 114.4.8 *(local pairing errors require comparison estimates).* A Satake exponent bound $\theta_p \le \vartheta$ does not by itself give a norm estimate between independently defined pairings. An estimate of the form

$$\left|\langle v_p, w_p\rangle_p^{\mathrm{Pet}} - \langle v_p, \sigma_p(w_p)\rangle_p^{\mathrm{Koszul}}\right| \le C_p p^{-(1/2-\vartheta)}$$

requires bounds for the actual arithmetic comparison maps, their normalizations and the chosen local vectors. The exponent $\vartheta = 7/64$, or the conditional symmetric-power improvement, controls Satake parameters only. Moreover the indicated prime majorants are not summable without additional decay.

114.5 Construction D: Arthur Endoscopic Classification on Classical Groups

The automorphic Ramanujan conjecture for a Maass form ϕ of $\mathrm{GL}_2/\mathbb{Q}$ is detected by the tensor square $\phi \boxtimes \phi^\vee$. This is a GL_4-object, usually isobaric rather than cuspidal. Arthur's classification gives packet normalisation for the classical-group transfers; it does not prove the Ramanujan conjecture. The missing input is exactly temperedness of the relevant GL_4 isobaric representation.

Arthur's Endoscopic Classification

Theorem 114.5.1 *(Arthur 2013: endoscopic classification for classical groups).* (Arthur 2013 *Colloq. Publ.* 61, *The Endoscopic Classification of Representations*, Thm. 1.5.2). For quasi-split classical groups over a number field, the discrete automorphic spectrum is organised by global Arthur parameters. The associated standard transfer to general linear groups is automorphic, isobaric, and compatible with the local Langlands parameters at unramified places. Temperedness is present precisely for tempered Arthur parameters; it is not a formal consequence of the classification.

Proof. Arthur 2013 *The Endoscopic Classification* Thm. 1.5.2 and §4.3 give the parametrisation and the standard transfer. The stabilisation input is the Langlands–Shelstad–Ngô–Waldspurger endoscopic trace formula. Mœglin–Waldspurger controls the local discrete-series packets. None of these statements replaces the generalised Ramanujan conjecture. □

Remark 114.5.2 *(stabilisation is not Ramanujan).* For $F = \mathbb{Q}$ the required stabilisation rests on the fundamental lemma and the endoscopic transfer identities. This is a theorem of the trace formula. It identifies packets and transfers. It does not bound Satake parameters.

The Ramakrishnan Functorial Chain

Proposition 114.5.3 *(Ramakrishnan 2000:* $\mathrm{GL}_2 \boxtimes \mathrm{GL}_2 \to \mathrm{GL}_4$*).* (Ramakrishnan 2000 *Ann. Math.* 152 *Modularity of the Rankin–Selberg L-series, and multiplicity one for* SL_2, Thm. M). Let ϕ_1, ϕ_2 be cuspidal automorphic representations of $\mathrm{GL}_2/\mathbb{Q}$. Then their Langlands tensor product $\phi_1 \boxtimes \phi_2$ is an automorphic representation of $\mathrm{GL}_4/\mathbb{Q}$; it is cuspidal unless ϕ_1 and ϕ_2 are twists of a common dihedral form.

Proof. Ramakrishnan 2000 Thm. M. The proof constructs the tensor product via the converse theorem of Cogdell–Piatetski-Shapiro 1999 *Publ. Math. IHES* 88, using Bump–Friedberg 1990 *Duke Math. J.* 59 for the Rankin–Selberg L-function. □

The Automorphic Conditional

Hypothesis 114.5.4 *(Arthur–Ramakrishnan–GRC hypothesis,* AR-GRC*).* Assume:

(AR1) Arthur's endoscopic classification Theorem 114.5.1 is available for the relevant classical groups, with standard transfer compatible with unramified local parameters.

(AR2) The Ramakrishnan tensor product Proposition 114.5.3 is used for cuspidal automorphic representations attached to Maass forms. For $\phi_2 = \phi_1^\vee$ the product is interpreted isobarically.

(AR3) The isobaric representation $\phi \boxtimes \phi^\vee$ satisfies the generalised Ramanujan conjecture at every finite place.

THEOREM 114.5.5 *(AR-GRC implies full Ramanujan for Maass forms). (conditional on Hypothesis 114.5.4).* Under (AR1)+(AR2)+(AR3), every cuspidal Maass Hecke eigenform ϕ of $\mathrm{GL}_2/\mathbb{Q}$ satisfies the Ramanujan bound $\sup_p \theta_p(\phi) = 0$, i.e. is tempered at every finite prime.

Proof. At an unramified finite prime write the unitary Satake parameters of ϕ as α_p, β_p, with $|\alpha_p\beta_p| = 1$. The local parameter of $\phi \boxtimes \phi^\vee$ has eigenvalues

$$1, \quad 1, \quad \alpha_p/\beta_p, \quad \beta_p/\alpha_p.$$

By (AR3) these have modulus 1. Hence $|\alpha_p| = |\beta_p|$, and the central-character normalisation gives $|\alpha_p| = |\beta_p| = 1$. Thus ϕ_p is tempered. The ramified finite primes are controlled by the same boundedness condition on the Weil–Deligne parameter. Arthur's classification is used only to keep the transfer normalisation fixed. □

PROPOSITION 114.5.6 *(AR-GRC is separate from classical RH in this argument).* Hypothesis AR-GRC (Hypothesis 114.5.4) is an automorphic input separate from the classical Riemann hypothesis here. The proof below uses neither RH nor any zero-placement statement for $\zeta(s)$. AR-GRC is supplied by GRC for the relevant GL_4 isobaric tensor square together with the stated transfer inputs.

Proof. GRC for the GL_4 isobaric tensor square gives bounded local parameters. The proof of Theorem 114.5.5 then reads off the GL_2 Satake radii. No statement about zeros of $\zeta(s)$ enters this implication. Conversely, the argument makes no deduction from RH to AR-GRC. □

Remark 114.5.7 *(the automorphic residual).* Theorem 114.5.5 places the Maass-sector temperedness requirement of Theorem 76.6.1 on AR-GRC, while leaving its arithmetic pairing maps as separate hypotheses, which is the generalised Ramanujan conjecture for the GL_4 isobaric tensor square, together with the stated transfer normalisations. GRC for this object is open; it is an automorphic temperedness statement, not a consequence of classical RH. The Vol IV P3 identity on the Maass sector holds without further hypothesis conditional on GRC for GL_4.

114.6 CONSTRUCTION E: SYNTHESIS

THEOREM 114.6.1 *(Maass-sector P3 identity: local controls and exact conditional form).* For the displayed local pairing bounds assume the corresponding norm estimates in Remark 114.4.8. For exact global equality assume the arithmetic placement and pairing hypotheses of Hypothesis 67.1.1, the stated Maass temperedness domain, and the adelic extension. *(local pairing bounds require comparison-norm estimates; conditional on the Maass symmetric-ninth-power conjecture for the sharper local control; conditional on GRC for* $\mathrm{GL}_4/\mathbb{Q}$ *for the exact equality).* Here $\mathcal{V}^{\mathrm{prim}}$ denotes the primitive automorphic

Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2, as defined in Chapter 76, and $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}} \subset \mathcal{V}^{\mathrm{prim}}$ its Maass cuspidal sector. For local vectors v_p, w_p in the p-component and global vectors $v, w \in \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}}$, the available statements are: The first inequality assumes the local norm estimate; the second also assumes the Maass symmetric-ninth-power input. The final identity assumes the comparison maps and GRC for $\mathrm{GL}_4/\mathbb{Q}$.

$$\begin{aligned} \left|\langle v_p, w_p\rangle_p^{\mathrm{Pet}} - \langle v_p, \sigma_p^{\mathrm{BC}}(w_p)\rangle_p^{\mathrm{Koszul}}\right| &\le C_p p^{-25/64}, \\ \left|\langle v_p, w_p\rangle_p^{\mathrm{Pet}} - \langle v_p, \sigma_p^{\mathrm{BC}}(w_p)\rangle_p^{\mathrm{Koszul}}\right| &\le C_p p^{-(1/2-(1/2-1/101)/9)}, \\ \langle v, w\rangle^{\mathrm{Pet}} &= \langle v, \sigma^{\mathrm{BC}}(w)\rangle^{\mathrm{Koszul}}. \end{aligned}$$

The first two lines do not assemble to an adelic correction term without extra summability; the exact global identity is the third line.

Proof. The local bounds are exactly the assumed comparison-norm estimates with the indicated Satake exponents. The exponents alone do not prove those estimates. Exact-equality form (114.6.1): Theorem 114.5.5 gives temperedness of ϕ under AR-GRC; Theorem 76.1.1 then applies, with its arithmetic placement, pairing and adelic hypotheses, to $\mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,Maass}} \subset \mathcal{V}^{\mathrm{prim}}_{\mathrm{cusp,temp}}$. AR-GRC is GRC for the relevant GL_4 isobaric tensor square by Proposition 114.5.6. □

Construction	Bound	Form	Source
Construction A (sym^3)	$1/9 \approx 0.1111$	Unconditional	Kim–Shahidi 2002, Theorem 114.2.1

Construction C ($\mathrm{sym}^9\phi$)	$(1/2 - 1/101)/9 \approx 0.0545$	Conditional on Maass sym^9	JS 1981 + Maass sym-power conj., Theorem 114.4.6
Construction D (AR-GRC)	0 (full)	Conditional on $\mathrm{GRC}_{\mathrm{GL}_4}$	Arthur 2013 + Ramakrishnan 2000, Theorem 114.5.5

114.7 Satake Bounds and Their Hypotheses

The local exponent $\theta_p \ge 0$ uses Satake parameters normalized by $\alpha_p\beta_p = 1$. Kim's symmetric-fourth transfer and the Kim–Sarnak estimate give the unconditional bound $\theta_p \le 7/64$. The Rankin–Selberg theory of Jacquet–Piatetski-Shapiro–Shalika (1983) and the Euler-product theory of Jacquet–Shalika (1981) supply the associated L-functions and edge non-vanishing. Non-vanishing on $\mathrm{Re}(s) = 1$ is distinct from an estimate on $\mathrm{Re}(s) = 1/2$. The proposed analytic refinement through $L(s, \mathrm{sym}^4\,\phi)$ requires a specified aspect, analytic conductor, saving, and uniformity in the Maass form ϕ. It also requires an argument converting that estimate into a bound below $7/64$ for the local Satake exponents. These additional data are not specified by the edge non-vanishing theorem.

For Construction C, assume that $\mathrm{sym}^9\,\phi$ is cuspidal automorphic on $\mathrm{GL}_{10}/\mathbb{Q}$. Under this Maass symmetric-power hypothesis, Theorem 114.4.6 gives

$$\theta_p \le \frac{1/2 - 1/101}{9} \approx 0.0545.$$

Newton–Thorne functoriality applies to the holomorphic companion F of algebraic weight at least two. It does not supply the symmetric-ninth-power hypothesis for ϕ. The separation of the lowest-weight component uses the tensor decomposition in Construction C.

Construction D uses the automorphic isobaric tensor square on $\mathrm{GL}_4/\mathbb{Q}$. Ramakrishnan's tensor product is interpreted isobarically in the contragredient case. Assuming the generalized Ramanujan conjecture for this tensor square, Theorem 114.5.5 gives $\theta_p = 0$. Arthur transfer supplies the packet normalization. Its endoscopic inputs are Arthur (2013), Langlands–Shelstad (1987), Ngô (2010), Waldspurger (2008), and Chaudouard–Laumon (2012). The tensor-product and automorphy inputs are Ramakrishnan (2000) and Cogdell–Piatetski-Shapiro (1999). The dihedral case uses Deligne–Serre and Labesse–Langlands (1979). Thus the $7/64$ estimate, the conditional symmetric-ninth estimate, and the conditional temperedness conclusion use different hypotheses.

114.8 Residual Ramanujan Input

GRC for $\mathrm{GL}_4/\mathbb{Q}$. The generalised Ramanujan conjecture for the relevant isobaric $\mathrm{GL}_4/\mathbb{Q}$ tensor square is open; the Construction D closure is conditional on it. The current best unconditional bound is from Kim–Shahidi 2002 extensions to higher-rank groups: $\theta_{\mathrm{GL}_4} \le 5/14 \approx 0.357$.

Maass symmetric-power functoriality (Construction C conditional). Construction C's sharpened bound $(1/2 - 1/((n+1)^2+1))/n$ is conditional on the Maass symmetric-nth-power conjecture: the existence of $\mathrm{sym}^n \phi$ as a cuspidal automorphic representation of $\mathrm{GL}_{n+1}/\mathbb{Q}$ for the Maass form ϕ itself. This is the Langlands global functoriality conjecture for $\mathrm{GL}_2 \to \mathrm{GL}_{n+1}$ at non-algebraic archimedean type; it is open for all $n \ge 5$. Newton–Thorne 2021/2023 covers only holomorphic forms (ℓ-adic algebraic weight). The bound $\theta^{(n)} = (1/2 - 1/((n+1)^2+1))/n \to 0$ as $n \to \infty$ at rate $\sim 1/(2n)$; closing to $\theta = 0$ via this mechanism would require a proof of the Maass symmetric-power conjecture for all n, which would imply the Ramanujan conjecture by the Jacquet–Shalika bound. It is stronger than the numerical estimate alone.

The dihedral edge case. Dihedral Maass forms lift from Hecke characters of quadratic fields and are tempered by class field theory (Labesse–Langlands 1979, Deligne–Serre 1974); Construction D applies without the AR2 hypothesis.

Sources for the bounds and the tensor-square comparison. Kim–Shahidi (2002), Kim (2003), and Kim–Sarnak (2003) supply the unconditional symmetric-power transfers and bounds. Construction D uses Arthur (2013), Langlands–Shelstad (1987), Ngô (2010), Waldspurger (2008), Chaudouard–Laumon (2012), Ramakrishnan (2000), Cogdell–Piatetski-Shapiro (1999), and Labesse–Langlands (1979) for its endoscopic and tensor-product comparisons. These two lists are disjoint. Both arguments also use

Jacquet–Piatetski-Shapiro–Shalika (1983) and Jacquet–Shalika (1981) for the structural theory of L-functions and non-vanishing on $\mathrm{Re}(s) = 1$. These shared inputs have distinct roles from the numerical bounds. Construction C additionally assumes cuspidal automorphy of the Maass symmetric ninth power.

Chapter 115

Quantum Arithmetic Chern–Simons: Bulk Extension and Residual Obstruction

Chapter 103 states Chapter 103.4.7, the profinite $GL_2(\widehat{\mathbb{Z}})$ quantum arithmetic Chern–Simons theory on $\overline{\mathrm{Spec}\,\mathbb{Z}}$, as three linked bulk-boundary axioms. Every formal consequence depends on its resolution: Ch. 106's continuous Wilson-Frobenius identity at $\varprojlim^{\mathrm{ren}}_N$, Ch. 111's specified unitary conjugacy between F_∞^{WS} and F_∞, the partition formula $Z_{\mathrm{ACS}^{\mathrm{qu}}} = \xi$ of Chapter 103.5.7, and the triangle of Chapter 104.4.2. The bulk measure is examined through five constructions: (i) state-sum renormalisation along the congruence tower; (ii) Reshetikhin–Turaev theory for a modular trace lift of the boundary trace class; (iii) Costello–Gwilliam factorization algebras on the étale site of $\overline{\mathrm{Spec}\,\mathbb{Z}}$; (iv) Lurie cobordism hypothesis on an étale arithmetic cobordism category; (v) Scholze six-functor on a conjectural arithmetic diamond. For a specified finite field groupoid and action, its weighted sum is defined. Coherent tower measures and an open-site factorization structure require their own maps and descent. The archimedean Hilbert realization, modular trace lift and arithmetic diamond add further comparison data.

115.1 Setup and Axiomatic Target

Definition 115.1.1 *(arithmetic space and boundary data).* Write $M = \overline{\mathrm{Spec}\,\mathbb{Z}}$ for the intended arithmetic compactification. An ACS realization must specify a site $\mathscr{X}$ for M, a boundary object $\mathscr{B}_\infty$, and a boundary morphism $j : \mathscr{B}_\infty \to \mathscr{X}$. It must state a dualizing coefficient object $\mathcal{L}$, its cohomological degree and a trace map for pairing the action with an arithmetic fundamental class. At infinity it must also specify a smooth oriented surface Σ_∞, a comparison to $\mathscr{B}_\infty$, and a metric whose curvature pulls back to a specified real two-form ω_∞. The smooth disk in Chapter 111.4.1 supplies one local metric model with area $1/2$. Its existence does not construct the arithmetic boundary morphism or its metric pullback. For that disk, boundary integrals use its counterclockwise orientation; a closed surface requires a separately specified surface.

Definition 115.1.2 *(congruence tower and gauge tower).* . The *gauge tower* is the inverse system of finite groups

$$\mathcal{T} := \left\{ G_N := GL_2(\mathbb{Z}/N\mathbb{Z}), \qquad N \in \mathbb{Z}_{\geq 1} \right\}$$

ordered by divisibility $M \mid N$ giving reductions $G_N \twoheadrightarrow G_M$, with

$$\varprojlim_{N \in \mathcal{T}} G_N \;=\; GL_2(\widehat{\mathbb{Z}}).$$

A *level datum* is a compatible system $\alpha_\bullet = \{\alpha_N \in H^3(BG_N, \mathbb{C}^\times)\}_N$ whose inverse-limit class is the arithmetic level $k^{\mathrm{Ar}} = \kappa_{\mathsf{G}}^{\mathrm{Ar}}$ of Ch. 103.

Remark 115.1.3 *(the three axioms recalled).* Chapter 103.4.7 asks for a renormalised profinite limit

$$\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}} := \varprojlim_{N}^{\mathrm{ren}} Z^{\mathrm{Ar}}_{G_N,\alpha_N}$$

satisfying: **(WZW)** $\mathrm{HH}_0(\partial\,\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}) \simeq \mathcal{V}^{\mathrm{prim}}$ on the archimedean boundary, where $\mathcal{V}^{\mathrm{prim}}$ is the Hochschild trace class of the identity on the global arithmetic Iwahori–Hecke category of GL_2 (Ch. 103); **(Z)** $Z_{\mathrm{ACS}^{\mathrm{qu}}}(\overline{\mathrm{Spec}\,\mathbb{Z}}; k^{\mathrm{Ar}}) = \xi(k^{\mathrm{Ar}})$, where ξ is the completed Riemann zeta function (Chapter 103.5.7); **(W)** $\langle W_\rho(K_p)\rangle = \mathrm{tr}\,\rho(\mathrm{Frob}_p)$, where $W_\rho(K_p)$ is the Wilson-loop observable at the prime knot $K_p \subset \overline{\mathrm{Spec}\,\mathbb{Z}}$ in representation ρ (Ch. 106).

115.2 Construction I: Tower Renormalisation via Kan Extension

The most direct construction is the one inherited from the finite-level state-sum construction of Chapter 103.4.2. For specified finite field groupoids and compatible action phases, each $Z^{\mathrm{Ar}}_{G_N,\alpha_N}$ is the corresponding finite sum. The obstruction is the existence of a profinite functor compatible with (WZW), (Z), (W).

Finite-level Kan tower

Lemma 115.2.1 *(finite reduction and lifting mass).* Let $\pi : G_N \twoheadrightarrow G_M$ be a surjection of finite groups. It induces pullback of level classes and extension of structure group on field groupoids. Suppose the chosen arithmetic space M' has finite field groupoids, with compatible phases $\alpha_N = \pi^*\alpha_M$. For a G_M field b, write $\mathcal{L}_b$ for the homotopy fibre of its lifting groupoid, including the isomorphism to b. If all these fibres have the same finite cardinality $m_{N,M}(M')$, then

$$Z^{\mathrm{Ar}}_{G_N,\alpha_N}(M') = m_{N,M}(M')\,Z^{\mathrm{Ar}}_{G_M,\alpha_M}(M').$$

For a central abelian kernel K, if a lift exists and the lifting fibre is the groupoid of K-torsors, its cardinality is $|H^1(M',K)|/|H^0(M',K)|$, when these groups are finite.

Proof. Finite-groupoid integration weights each isomorphism class by the reciprocal order of its automorphism group. Fubini over homotopy fibres gives the sum over b of its phase times $|\mathcal{L}_b|/|\mathrm{Aut}\,b|$. Constant fibre mass gives the displayed identity. For the stated torsor groupoid, the isomorphism classes form $H^1(M',K)$ and each automorphism group is $H^0(M',K)$. Their cardinality ratio proves the second assertion. A nonempty lifting fibre is a hypothesis: centrality does not remove an obstruction to lifting a G_M field. □

Remark 115.2.2 *(the measure in a reduction tower).* For $K \cong (\mathbb{F}_\ell)^d$ with trivial action, the torsor mass above is $|K|^{b_1-b_0}$, where $b_i = \dim_{\mathbb{F}_\ell} H^i(M',\mathbb{F}_\ell)$. For example, over a point the lifting fibre is BK, of mass $1/|K|$, although $b_1 = 0$. Thus central-abelian reduction alone does not give the factor $|K|^{b_1}$. The profinite construction must determine the actual lifting obstructions, stabilizers, phases and normalization at every transition.

Definition 115.2.3 *(a chosen tower normalization).* For a specified finite Euler characteristic $\chi(M')$, define

$$\widetilde{Z}_N(M') = |G_N|^{-\chi(M')}\,Z_N(M').$$

This scalar definition does not assert transition compatibility. The cohomology theory, coefficients and any compact-support or boundary conditions used to define χ are part of the datum.

Proposition 115.2.4 *(the normalized transition factor).* Under the constant-mass hypothesis of the lemma, with $K = \ker \pi$,

$$\widetilde{Z}_N(M') = |K|^{-\chi(M')} m_{N,M}(M') \widetilde{Z}_M(M').$$

Thus the equality of normalized scalar values follows when $|K|^{-\chi} m_{N,M} = 1$. This scalar condition is additional to the coherent transition maps required for state spaces and bordism assignments.

Proof. Use $|G_N| = |K||G_M|$ in the defining normalization and the preceding mass identity. No division by a possibly zero partition value is needed. □

For a connected torsor model with $b_1 = 0$ and $\chi = 0$, the factor is $|K|^{-1}$, not one. A different arithmetic measure or a renormalization yielding compatible values must therefore be specified. Nonabelian congruence kernels additionally require their full lifting fibres. The arithmetic cohomology and duality needed to compute these quantities are separate inputs; no numerical value of $\chi(\overline{\mathrm{Spec}\,\mathbb{Z}})$ is needed here.

Theorem 115.2.5 *(a coherent inverse tower defines a pro-object).* Suppose a cofiltered small category indexes actual state-sum functors and coherent transition natural transformations in a specified target category. This inverse diagram defines a pro-object in that functor category. It does not by itself define a represented Hilbert limit or a topological arithmetic field theory.

Proof. An object of the pro-category is precisely such a cofiltered diagram. An ordinary limit or a right Kan extension in a chosen target requires that target to admit the relevant limits. Representation by a Hilbert space is a further assertion, not part of the pro-object definition. □

Remark 115.2.6 *(tower and descent requirements).* The arithmetic construction must supply the lifting measures and coherent transition maps just specified. A topological state functor further requires a represented limit and compatible gluing. Its boundary trace must be identified with the designated primary trace realization. Neither an inverse diagram nor the name of a Kan extension constructs these data.

Sources and Hypotheses for Construction I

Kim's arithmetic action and its nonabelian extensions motivate the finite field groupoids. Dijkgraaf–Witten and Freed–Quinn give finite-groupoid integration models. The lifting-mass computation above states the transition datum needed in the arithmetic tower. A condensed or Tate realization additionally requires its topology, transition maps and pairing. The finite sum and the represented Hilbert limit are distinct constructions.

Theorem 115.2.7 *(Construction I conditional closure). (on a choice of condensed topology on the Kan-limit and its descent to a concrete topological state-functor).* Under the profinite-Hilbert descent hypothesis and a coherent tower as specified above, the represented limit of Chapter 115.2.5 defines $\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}$ satisfying the reduction-coherence portion of Chapter 103.4.7. The three axioms (WZW), (Z), (W) reduce to: (WZW) restriction of the Kan-limit boundary functor at Σ_∞ identifies with $\mathcal{V}^{\mathrm{prim}}$; (Z) evaluation of the Kan-limit on the closed class $[M]$ reproduces $\xi(k^{\mathrm{Ar}})$; (W) evaluation on prime-knot insertions reproduces Frobenius traces. Each of (WZW), (Z), (W) becomes a *comparison statement* at the Kan-limit, not a new existence statement.

Proof. The assumed coherent tower defines the pro-object of Chapter 115.2.5. Under a chosen condensed topology descending the pro-vector-space structure to a Hilbert-space functor, (WZW), (Z), (W) become comparison claims at the limit. Each is in principle checkable by comparing the limit with the right-hand sides of the three axioms using the finite-level comparisons of Chs. 106 and 103. The existence of the descent is hypothetical. □

115.3 Construction II: Reshetikhin–Turaev from an Arithmetic Boundary Category

The Reshetikhin–Turaev construction (Turaev 1994 *Quantum Invariants of Knots and 3-Manifolds*, de Gruyter; Reshetikhin–Turaev 1991 *Invent. Math.* 103, 547–597) constructs topological invariants and the associated bordism functor from a modular tensor category (MTC), with the required framing or anomaly data. An arithmetic bordism interpretation requires an additional comparison functor. In the arithmetic problem the input cannot be the category of modules over $\mathcal{V}^{\mathrm{prim}}$, because $\mathcal{V}^{\mathrm{prim}}$ is a Hochschild trace class, not a vertex algebra. The possible Reshetikhin–Turaev input is instead a modular tensor category whose Hochschild trace and regularised character have $\mathcal{V}^{\mathrm{prim}}$ as their boundary shadow.

The arithmetic MTC candidate

Definition 115.3.1 *(arithmetic modular tensor category candidate).* . The *arithmetic modular tensor category candidate* is

$$\mathcal{MTC}^{\mathrm{Ar}}_{k^{\mathrm{Ar}}} \;:=\; \mathcal{B}^{\mathrm{Ar}}_{k^{\mathrm{Ar}}},$$

a finite semisimple ribbon category equipped with a trace comparison

$$\mathrm{HH}_0\big(\mathcal{B}^{\mathrm{Ar}}_{k^{\mathrm{Ar}}}\big) \simeq \mathcal{V}^{\mathrm{prim}}$$

and with Frobenius-labelled simple objects at the finite places. This definition is a lifting problem from a Hochschild trace class to a boundary category; it is not a module category over $\mathcal{V}^{\mathrm{prim}}$.

Remark 115.3.2 *(the modular trace lift is conditional).* Modularity of $\mathcal{MTC}^{\mathrm{Ar}}_{k^{\mathrm{Ar}}}$ requires a non-degenerate braiding, a spherical trace, and compatibility of the categorical trace with the Iwahori–Hecke Hochschild trace. The completed-zeta character and finite-prime Fock characters are trace statements. They do not construct a braided category whose trace is $\mathcal{V}^{\mathrm{prim}}$.

Reshetikhin–Turaev state-sum

Theorem 115.3.3 *(transport of a specified Reshetikhin–Turaev theory).* Suppose the modular category and anomaly data define an RT functor Z_{RT} on its topological bordism category B_{RT}. Suppose an arithmetic bordism category B_{Ar} and a symmetric monoidal comparison $C : \mathsf{B}_{\mathrm{Ar}} \to \mathsf{B}_{\mathrm{RT}}$ are constructed. Then $Z^{\mathrm{Ar}}_{\mathrm{RT}} = Z_{\mathrm{RT}} \circ C$ is a symmetric monoidal arithmetic assignment. It has the intended primary boundary trace and Frobenius Wilson values if its boundary trace maps and label comparisons identify those values.

Proof. Composition preserves the functorial and monoidal identities. The last assertion is the stated equality of the trace and observable maps under that composition. The ordinary RT construction does not supply C or those arithmetic equalities. □

The trace of a boundary category, the state space of a surface and a scalar closed-bordism invariant have different types. Their proposed arithmetic comparison must specify the maps between these objects.

Remark 115.3.4 *(closure of (WZW) and (W) modulo modularity).* Under the RT and arithmetic bordism data just specified, and the trace comparison of Chapter 115.3.1, Chapter 115.3.3 gives the categorical form of (WZW). The Wilson-line/Frobenius identity is the Reshetikhin–Turaev quantum-trace formula only after the finite-place label comparison is supplied. The remaining axiom (Z) is not automatic: the partition function of an RT TQFT is the *Reshetikhin–Turaev invariant*, which is a finite complex number, not an entire function of the level. Matching it with $\xi(k^{\mathrm{Ar}})$ requires a separate analytic input.

Partition Identification via the Regularised Boundary Character

Proposition 115.3.5 *(conditional arithmetic partition identification).* Assume the preceding RT transport data. Suppose the closed arithmetic object has a specified decomposition whose state-space endomorphism has trace $\chi_{\mathrm{reg}}(k^{\mathrm{Ar}})$, and its RT evaluation is that trace. If the arithmetic character comparison identifies $\chi_{\mathrm{reg}}(k) = \xi(k)$, then its partition value is $\xi(k^{\mathrm{Ar}})$.

Proof. Compose the assumed evaluation-to-trace and trace-to-character identities. A topological Heegaard formula applies only after the corresponding arithmetic bordism and decomposition maps have been given. □

The existence of this decomposition, regularized trace prescription and analytic level family is part of the partition comparison problem. Modularity of a finite category alone supplies none of these data.

Sources and Hypotheses for Construction II

Reshetikhin–Turaev theory supplies a 3D TQFT from a modular tensor category. Huang–Lepowsky theory is the complex-analytic model in which a VOA produces such a category. In the arithmetic case the input is not a module category over $\mathcal{V}^{\mathrm{prim}}$, but a modular trace lift $\mathrm{HH}_0(\mathcal{MTC}^{\mathrm{Ar}}_{k^{\mathrm{Ar}}}) \simeq \mathcal{V}^{\mathrm{prim}}$, together with non-degenerate braiding, spherical trace, finite-place Frobenius labels, and the regularised character comparison.

Theorem 115.3.6 *(Construction II conditional implication). (on a modular trace lift, finite-place Frobenius labels, and the regularised-character comparison, together with the arithmetic bordism transport data).* Under these hypotheses, the Reshetikhin–Turaev functor of Chapter 115.3.3 gives the boundary trace condition, the Wilson-line trace condition, and the scalar partition identity of Chapter 103.4.7. Modularity alone does not imply the zeta partition identity.

Proof. (WZW) is the MTC-boundary identification of Chapter 115.3.1. (W) is the RT quantum-trace formula evaluated at the Frobenius conjugacy class via Morishita. (Z) is Chapter 115.3.5. The hypotheses are exactly the modular trace lift, the finite-place label comparison, and the regularised-character comparison. □

115.4 Construction III: Costello–Gwilliam Factorization on $(\operatorname{Spec}\mathbb{Z})_{\text{ét}}$

The Costello–Gwilliam formalism (Costello–Gwilliam 2017 *Factorization Algebras in Quantum Field Theory I*, Cambridge Univ. Press; vol. II 2021) builds perturbative QFTs as factorization algebras on a site. The étale site of Spec $\mathbb{Z}$ is a natural substitute for the usual differential-geometric site in the arithmetic setting.

Étale factorization algebra

Definition 115.4.1 *(an arithmetic factorization candidate).* Let $X = \operatorname{Spec} \mathbb{Z}$. Specify a category of arithmetic regions with disjoint embeddings and a chosen factorization coverage. A prefactorization candidate assigns a complex $\mathcal{F}(U)$ to each region and maps $\bigotimes_i \mathcal{F}(U_i) \to \mathcal{F}(V)$ for specified disjoint embeddings $U_i \to V$, with the required unit, symmetry and composition coherences. A factorization object must also satisfy descent for the chosen coverage. An arithmetic construction must state this coverage and its relation to the etale site. Ordinary descent of local systems does not replace this specification.

Definition 115.4.2 *(finite field functions and their action functional).* For each specified finite field groupoid $\mathcal{F}_{G_N}(U)$, let $\mathcal{V}_N(U)$ be the complex functions on its isomorphism classes. Given an isomorphism-invariant phase $a_N(b)$, define

$$\mathcal{I}_{N,U}(v) = \sum_{[b] \in \pi_0 \mathcal{F}_{G_N}(U)} \frac{a_N(b) v(b)}{|\operatorname{Aut} b|}, \qquad Z_N(U) = \mathcal{I}_{N,U}(1).$$

When the arithmetic action is defined, $a_N(b)$ is its exponential. This requires the action's coefficient object, boundary conditions and trace pairing from Chapter 115.1.1.

Proposition 115.4.3 *(finite products and weighted integration).* Suppose disjoint unions of specified arithmetic regions give products of their finite field groupoids, and their phases multiply. Then

$$\mathcal{V}_N(U \sqcup V) \cong \mathcal{V}_N(U) \otimes \mathcal{V}_N(V), \qquad \mathcal{I}_{N,U \sqcup V} = \mathcal{I}_{N,U} \otimes \mathcal{I}_{N,V}.$$

In particular $Z_N(U \sqcup V) = Z_N(U) Z_N(V)$. The vector space $\mathcal{V}_N(U)$ has dimension $|\pi_0 \mathcal{F}_{G_N}(U)|$; its scalar integral is not that vector space.

Proof. Delta functions on isomorphism classes give a basis. The product classes are pairs, and their automorphism orders multiply. The tensor basis gives the first isomorphism; finite Fubini gives the identity of integration functionals and the partition values. □

Remark 115.4.4 *(the open-site factorization problem).* The disjoint-product calculation is a part of the proposed Costello–Gwilliam construction on the arithmetic site. A factorization algebra additionally needs covariant structure maps for disjoint embeddings, their coherences, and the appropriate factorization descent condition. Descent of field groupoids does not by itself prove these assertions after passing to functions or weighted pushforwards. The action pairing on an open arithmetic region also requires its own compact-support or relative duality. Constructing these data on $X = \operatorname{Spec} \mathbb{Z}$ is a separate problem from the archimedean extension. The finite-product identity neither localizes every obstruction at infinity nor gives an unconditional factorization algebra.

Archimedean extension

Proposition 115.4.5 *(data for an archimedean operator extension).* Suppose a specified arithmetic factorization object has an extension to the boundary geometry of Chapter 115.1.1. A Hilbert realization of its primary boundary sector requires a complex vector space E_∞ extracted in a specified degree and completion from that trace sector, a Hermitian positive semidefinite pairing q_∞, linear in its first variable, and a complex-linear realization map

$$I_\infty : E_\infty \to H_B, \qquad \langle I_\infty v, I_\infty w \rangle = q_\infty(v, w), \qquad \overline{I_\infty E_\infty} = H_B.$$

It identifies H_B with the Hilbert completion of $E_\infty/\{v : q_\infty(v,v) = 0\}$. Boundary operations must preserve this nullspace to descend. Their asserted closed generators require domains and closures in H_B; a quantum surface comparison further requires the data of Chapter III.5.

Proof. Cauchy–Schwarz for a positive semidefinite Hermitian form makes its nullspace orthogonal to every vector. The displayed identity therefore induces an isometry on the quotient, which extends to its completion. The dense-range assumption makes this extension onto. If an operation does not preserve the nullspace, equivalent representatives have inequivalent images, so it cannot descend. The construction specifies neither an unbounded operator domain nor an exponential until the corresponding operator data are supplied. □

Remark 115.4.6 *(native boundary realization).* A finite field groupoid supplies finite-place state data. The passage to an arithmetic boundary Hilbert space additionally uses the geometry, native pairing and realization map above. A Hilbert completion alone does not supply the factorization gluing maps or a quantum observable. The desired boundary is a realization of a primary Hochschild trace sector, not a vertex algebra specified by that trace class. A proposed identification with an ordinary Fock representation must state the operations it preserves. Its occupation energy has eigenvectors and cannot be intertwined unitarily with continuous Mellin scaling, by Chapter III.2.1. Consequently Hilbert descent, native pairing, boundary extension and surface transport are separate required comparisons.

Sources and Hypotheses for Construction III

Costello–Gwilliam provides the factorization-algebra framework. Finite field groupoids and a specified Kim action give the functions and finite integration above. To use them as a factorization object one must construct its structure maps and descent, including the arithmetic support conditions. Its boundary realization then requires Chapter 115.4.5.

Theorem 115.4.7 *(conditional factorization and tower assignment).* Suppose the finite field-function assignments have been equipped with factorization structure and descent, and their scalar integration maps agree with the specified arithmetic action and Wilson insertions. Suppose also that coherent reduction maps define an inverse diagram of these factorization objects. Then this diagram is a pro-object in the stated factorization category, and its levelwise scalar and Wilson values are the assumed arithmetic ones. A represented limit and passage of global sections to that limit require additional continuity and descent theorems.

Proof. The supplied coherent diagram defines its pro-object. The integration identities hold at each level by hypothesis. No exchange of an inverse limit with global sections is used in this conclusion. □

115.5 Construction IV: Cobordism Hypothesis

Lurie's cobordism hypothesis (Lurie 2008 arXiv:0905.0465, Thm. 2.4.6) classifies extended n-dimensional TQFTs as fully dualizable objects in a symmetric monoidal (∞, n)-category. For $n = 3$ and a target $\mathcal{C} = \mathrm{ArithTC}$ the arithmetic tensor category, a quantum ACS is specified by a fully dualizable object of $\mathcal{C}$.

Fully dualizable object candidate

Definition 115.5.1 *(arithmetic target $(\infty,3)$-category).* . The *arithmetic target* is the symmetric monoidal $(\infty, 3)$-category ArithTC of arithmetic braided tensor categories: objects are braided tensor categories

equipped with a trace functor to arithmetic Hochschild trace classes; 1-morphisms are bimodule categories compatible with trace; 2-morphisms are bimodule functors; 3-morphisms are natural transformations; with symmetric monoidal structure from the Tate restricted tensor of Ch. 50.

Proposition 115.5.2 *(duality data for a specified arithmetic target).* Suppose the proposed target ArithTC is constructed as a symmetric monoidal $(\infty, 3)$-category, with its trace-compatible composition and coherences. An object is fully dualizable when it has a dual with evaluation and coevaluation and the required adjoints through the three morphism levels, satisfying their coherence identities. Supplying these data for the modular trace candidate is an additional arithmetic requirement.

The result of Douglas–Schommer-Pries–Snyder concerns fusion categories of nonzero global dimension in their tensor-category Morita setting. It does not construct the proposed arithmetic target or prove that a trace-compatible lift preserves the requisite dualities. This comparison must specify a monoidal functor and transport the actual evaluation, coevaluation and adjunction data.

Theorem 115.5.3 *(the framed cobordism output on specified data).* Given such a target and a fully dualizable object A in it, the framed cobordism hypothesis gives a symmetric monoidal functor $Z_A : \mathrm{Bord}_3^{\mathrm{fr}} \to \mathrm{ArithTC}$ with $Z_A(pt) = A$, classified by this fully dualizable datum. An arithmetic assignment follows if a compatible arithmetic bordism category and comparison functor into $\mathrm{Bord}_3^{\mathrm{fr}}$ are supplied. An oriented version requires the corresponding homotopy fixed-point structure.

Proof. Apply the framed cobordism hypothesis to the stated fully dualizable object, then compose with the assumed arithmetic comparison functor. The oriented extension uses its extra tangential structure. Equality with a particular RT theory further requires agreement of their extended data in a common target; it does not follow merely because both theories use a modular category. □

Remark 115.5.4 *(arithmetic cobordism category).* The cobordism hypothesis applies to a cobordism category of smooth manifolds. Its arithmetic counterpart requires an *arithmetic cobordism category* whose objects are arithmetic 2-surfaces and morphisms are arithmetic 3-spaces. Construction of such a category is Chapter 103.9 (item 1 of the residual list in Ch. 103): finite arithmetic cobordism functoriality. This is the Construction IV analogue of Construction III's archimedean extension obstruction.

Sources and Hypotheses for Construction IV

The cobordism-hypothesis presentation uses Lurie's theorem and the Douglas–Schommer-Pries–Snyder dualizability theorem in its specified tensor-category setting. It also uses the Reshetikhin–Turaev state sum on the resulting modular tensor category. The required inputs are an arithmetic cobordism category, the modular trace lift, finite-place label compatibility, and the regularised-character comparison.

Theorem 115.5.5 *(Construction IV conditional closure). (on the arithmetic cobordism category, modular trace lift, finite-place label comparison, and regularised-character comparison, the fully dualizable target data and the arithmetic bordism comparison above).* Given these hypotheses, the cobordism hypothesis produces a unique extended 3D TQFT $Z^{\mathrm{Ar}}_{\mathrm{coh}}$ whose trace, Wilson, and scalar partition data satisfy the axioms of Chapter 103.4.7.

Proof. Apply Chapter 115.5.3 and the specified arithmetic comparison. The assumed trace, Wilson and regularized character maps give the three scalar and boundary clauses. Identification with an RT theory requires the extended-data comparison stated in that theorem. □

115.6 Construction V: Six-Functor Formalism on an Arithmetic Diamond

Scholze's six-functor formalism (Scholze 2020–2022 *Lectures on Condensed Mathematics*, Bonn; Scholze 2022 *Six-Functor Formalisms* lecture notes) applies to diamonds and to a broad class of stacks. A quantum field theory on a space is given by a "theory" in the sense of six-functor formalism: an association of ∞-categories with the six operations $\otimes$, Hom, $f^*, f_*, f_!, f^!$. For 3D CS on a diamond, Scholze et al. have outlined the six-functor formalism as the natural home (Fargues–Scholze 2021 arXiv:2102.13459).

Diamond of $\overline{\mathrm{Spec}\,\mathbb{Z}}$

Conjecture 115.6.1 *(arithmetic diamond).* . There exists a diamond $\overline{\mathrm{Spec}\,\mathbb{Z}}^{\diamond}$ in the sense of Scholze 2020 *Etale Cohomology of Diamonds* (arXiv:1709.07343, §11) which is a globalisation of the Fargues–Fontaine curves at each prime, with an archimedean completion at $\{\infty\}$ given by a continuous version of Σ_∞. The diamond carries a six-functor formalism with values in condensed $\mathbb{Z}_\ell$-sheaves.

Remark 115.6.2 *(form of the arithmetic diamond).* Chapter 115.6.1 is a conjecture with no known construction in the cited literature. The closest object is the Clausen–Scholze analytic $\mathbb{Z}$-spectrum (Clausen–Scholze 2020 *Condensed Mathematics* lecture notes), which builds the condensed structure on the arithmetic side but does not supply the diamond-plus-archimedean-completion we would need.

Six-functor ACS

Proposition 115.6.3 *(a specified six-functor trace expression).* Suppose the proposed arithmetic space $X^\diamond$ has a specified six-functor theory $C(-)$ and structure map $f : X^\diamond \to pt$ for which $f^!$ and $f_!$ are defined. Choose an object $B \in C(pt)$; relating it to a boundary category or its Hochschild trace requires a specified realization functor. Then $\mathcal{T} = f^! B$ and $f_!\mathcal{T} \in C(pt)$ are defined. If $f_!\mathcal{T}$ is dualizable, its identity has a trace in $\mathrm{End}_{C(pt)}(1)$. A scalar value requires a specified map from this endomorphism ring to the scalar coefficient field.

Proof. Apply the two assumed functors in order. Dualizability supplies evaluation and coevaluation, whose trace composite is the stated endomorphism of the unit. Applying the chosen scalar map gives its scalar trace. Without dualizability or a separate regularized trace prescription this final operation is not defined. □

Identifying this trace with $\xi(k^{\mathrm{Ar}})$ requires the local-global trace comparison, including the archimedean factor and pole normalization. The arithmetic diamond, boundary object, coefficient realization and this trace identity are separate inputs. Local geometric Langlands does not supply them by formal application of $f^!$.

Remark 115.6.4 *(geometric and trace inputs for Construction V).* Write $B_{k^{\mathrm{Ar}}} \in C(pt)$ for the specified coefficient realization of the boundary datum $\mathscr{B}_{k^{\mathrm{Ar}}}$. Construction V places Chapter 103.4.7 inside the arithmetic diamond, a coefficient and boundary trace object, the requisite traceability data, and the local-global trace formula. The diamond is Chapter 115.6.1; the trace object lifts $\mathcal{V}^{\mathrm{prim}}$; the trace formula supplies the completed Euler product.

Sources and Hypotheses for Construction V

The six-functor presentation uses Scholze diamonds, Clausen–Scholze condensed sheaves, and the Fargues–Scholze spectral category at finite places. Its inputs are the arithmetic diamond, a boundary trace object $\mathscr{B}_{k^{\mathrm{Ar}}}$, the local-global trace formula, and finite-place Frobenius compatibility. Proper pushforward and shriek pullback then give the trace expression $\mathrm{Tr}(f_! f^! B_{k^{\mathrm{Ar}}})$.

Theorem 115.6.5 *(Construction V conditional closure). (on the arithmetic diamond, boundary and coefficient realization, traceability, local-global trace formula, and finite-place Frobenius compatibility).* Under these hypotheses, the six-functor ACS $\mathcal{T}_{k^{\mathrm{Ar}}} = f^! B_{k^{\mathrm{Ar}}}$ satisfies (WZW), (Z), (W) of Chapter 103.4.7.

Proof. (WZW) is the trace comparison $\mathrm{HH}_0(\mathscr{B}_{k^{\mathrm{Ar}}}) \simeq \mathcal{V}^{\mathrm{prim}}$. (Z) is the local-global trace formula for $\mathrm{Tr}(f_! f^! B_{k^{\mathrm{Ar}}})$. (W) is the finite-place spectral-Hecke compatibility producing the Frobenius trace on local Galois representations. □

115.7 Construction Comparison and Isolation of the Residual

Theorem 115.7.1 *(construction comparison).* . The five constructions to Chapter 103.4.7 decompose as follows.

- Given finite field groupoids and phases, their integrals and disjoint-product identities are defined. Construction I requires lifting measures and coherent transitions. Construction III further requires actual factorization maps and descent on the open site.
- Conditional on a modular trace lift, finite-place Frobenius labels, and the regularised-character comparison: Constructions II and IV, with their stated arithmetic bordism and duality data, give Reshetikhin–Turaev and cobordism-hypothesis realizations of the same boundary, Wilson, and scalar data.
- Conditional on the arithmetic diamond, boundary trace object, local-global trace formula, and finite-place Frobenius compatibility: Construction V, with the specified coefficient and traceability data, gives the six-functor form of the same axioms on $\overline{\mathrm{Spec}\,\mathbb{Z}}^{\diamond}$.

Proof. Chapter 115.2.5, Chapter 115.4.3, Chapter 115.3.6, Chapter 115.5.5, Chapter 115.6.5 respectively. □

The Common Archimedean Term

Theorem 115.7.2 *(comparison of two boundary Hilbert realizations).* Write $H_c = L^2(\mathbb{R}_{>0}, dx/x)$ and $\Theta_c = 1/2 + iD_c$, with D_c and its domain as in Chapter 111.1.1. Let (E_∞, q_∞) be a specified positive semidefinite primary trace realization as in Chapter 115.4.5. Suppose a descended state space H_B and a primary Hilbert space H_{prim} have complex-linear dense-range maps I_B, I_{prim} from E_∞, both preserving q_∞. Then there is a unique unitary $T : H_B \to H_{\mathrm{prim}}$ with $T I_B = I_{\mathrm{prim}}$. Suppose closed normal generators Θ_B, Θ_{prim} have cores $I_B\mathcal{D}$, $I_{\mathrm{prim}}\mathcal{D}$, for a specified $\mathcal{D} \subset E_\infty$, and their actions agree under T on these cores. Then

$$T\,\mathrm{Dom}\,\Theta_B = \mathrm{Dom}\,\Theta_{\mathrm{prim}}, \qquad T\Theta_B = \Theta_{\mathrm{prim}} T.$$

If a further unitary $V_{\mathrm{prim}} : H_{\mathrm{prim}} \to H_c$ intertwines Θ_{prim} with the continuous generator Θ_c, including domains, then $V_\Sigma = V_{\mathrm{prim}} T$ gives the surface comparison in Chapter 115.9.2.

Proof. The formula $I_B v \mapsto I_{\mathrm{prim}} v$ is well defined: both kernels are the nullspace of q_∞. It is an isometry on dense subspaces and extends uniquely to an onto unitary. The graph of each generator is the closure of its graph on the stated core. Applying $T \oplus T$ to these graphs proves domain equality and intertwining. Composition with V_{prim} proves the last assertion. □

Remark 115.7.3 *(boundary comparisons for the different constructions).* The inverse-limit, factorization and six-functor constructions each ask for a native boundary realization. They can be identified through the preceding theorem when they realize the same trace space, pairing and operator cores. Establishing

such identifications requires actual maps from their respective boundary objects. A topology on a pro-vector space does not define those maps. Likewise a modular trace lift requires its own trace-to-boundary realization before it supplies this Hilbert comparison. No implication between the modular lift, the arithmetic diamond and the Hilbert descent follows from their common intended trace class.

Relation to the Hilbert–Pólya/Connes–Deninger obstruction

Remark 115.7.4 *(Hilbert descent and arithmetic spectral realization).* Hilbert descent asks for a limit state space and its native pairing. The arithmetic Hilbert–Pólya realization further specifies an arithmetic middle-cohomology carrier, a self-adjoint operator H_{HP}, and the determinant and trace normalization of $\Theta_\xi = \frac{1}{2} + iH_{\mathrm{HP}}$. These data are not clauses of Hilbert descent. In particular, the zero-occurrence generator cannot be realized as the restriction of continuous Θ_c to an invariant Hilbert subspace by an injective generator intertwiner: each occurrence has a nonzero eigenvector, whereas Θ_c has none. An arithmetic cohomology comparison instead uses its own carrier, as in Chapter 111.5.

The purity condition depends on the operator and its carrier. For continuous scaling, set

$$H_c = L^2(\mathbb{R}_{>0}, dx/x), \qquad (U_a f)(x) = f(e^{-a}x), \qquad a \in \mathbb{R}.$$

In the logarithmic coordinate $t = \log x$, the self-adjoint generator is

$$D_c = -i\,\partial_t, \qquad \mathrm{Dom}\, D_c = \{f \in H_c : f(e^t) \in H^1(\mathbb{R}, dt)\}.$$

Thus $U_a = e^{-iaD_c}$, $\Theta_c = \frac{1}{2} + iD_c$ has the same domain, and $F_\infty = e^{-\Theta_c} = e^{-1/2}U_1$. Transport to a descended Hilbert space H_B requires a specified unitary $V : H_B \to H_c$. For a generator Θ_B, the required comparison is

$$V\,\mathrm{Dom}\,\Theta_B = \mathrm{Dom}\,\Theta_c, \qquad V\Theta_B = \Theta_c V \quad \text{on } \mathrm{Dom}\,\Theta_B.$$

It then gives $e^{-\Theta_B} = V^{-1}F_\infty V$.

The arithmetic operator instead uses the multiset Z of nontrivial zeta zeros, with one coordinate for each occurrence. On $K_Z = \ell^2(Z)$, set

$$(\Theta_Z v)_\rho = \rho v_\rho, \qquad \mathrm{Dom}\,\Theta_Z = \left\{ v \in \ell^2(Z) : \sum_{\rho \in Z} |\rho v_\rho|^2 < \infty \right\}.$$

Its bounded exponential is $(F_Z v)_\rho = e^{-\rho} v_\rho$. These operators distinguish continuous purity from arithmetic purity.

Theorem 115.7.5 *(Clausen–Scholze condensed-Hilbert descent plus A-TP ⇒ RH). (on the archimedean condensed-Hilbert descent of Chapter 115.8.3 and the A-TP archimedean positivity of Ch. 78.2.3).* Under both the Clausen–Scholze condensed-Hilbert descent and A-TP, the Riemann Hypothesis holds.

Proof. For $f \in C_c^\infty(\mathbb{R})$, with $f^*(t) = \overline{f(-t)}$, A-TP states

$$W_\infty(f * f^*) \le P(f * f^*) - W_{\mathrm{fin}}(f * f^*).$$

The signed explicit formula therefore gives $W(f * f^*) \ge 0$ for every such f. By Weil's criterion, all nontrivial zeros satisfy $\Re\rho = 1/2$, which is RH. On the coordinate vector at ρ, the absolute value $|F_Z|$

has eigenvalue $e^{-\Re\rho}$. Hence the same conclusion is precisely $|F_Z| = e^{-1/2}1_{K_Z}$, the arithmetic purity of Chapter 111.3.4. Conversely this equality forces $\Re\rho = 1/2$ at every occurrence, and Weil's criterion recovers A-TP.

On H_c, unitarity gives $F_\infty^* F_\infty = e^{-1}1_{H_c}$ without A-TP. The specified unitary V transports this identity to H_B by functional calculus, including the stated generator domains. Thus descent provides the continuous Hilbert realization when its comparison data exist. A-TP alone supplies the zero-placement implication used above. □

Remark 115.7.6 *(the archimedean Hilbert descent does not imply RH alone).* Resolving the archimedean Hilbert descent alone does not resolve RH: it constructs $\mathrm{ACS}^{\mathrm{qu}}_{k^{\mathrm{Ar}}}$ only on the descended Hilbert-trace clauses (WZW), (Z), and (W); it does not supply the full cobordism functor or the full Weil inequality A-TP. The continuous scaling exponential is already pure. Under both descent and A-TP, RH follows through the separate arithmetic operator F_Z. The archimedean Hilbert descent is the bulk-construction obstruction; A-TP is the separate positivity obstruction. After the descent, the remaining bulk gluing assertions stay separate; the RH-equivalent condition in this construction is A-TP.

115.8 Refinement: The Condensed-Hilbert Bulk

Condensed-Hilbert setup

Definition 115.8.1 *(condensed Hilbert pro-system).* Specify finite-level boundary Hilbert spaces $\mathcal{H}^{(\infty)}_{G_N,\alpha_N}$ and coherent bounded linear transition maps, including their normalization. Their associated condensed complex vector spaces form an inverse diagram, denoted $\mathcal{H}^{(\infty)}_\bullet$. Here $\mathrm{Cond}_{\mathrm{Hilb}}(\mathbb{C})$ denotes the chosen category of condensed realizations of complex Hilbert spaces with bounded linear maps. A limit in condensed vector spaces need not be represented by a Hilbert space. Such representability, its norm and its compatibility with the native pairing are the additional descent requirements below. A scalar normalization of partition values does not by itself define transition maps on these state spaces.

Definition 115.8.2 *(target archimedean Hilbert realization).* Specify a primary trace space E_∞, its Hermitian positive semidefinite form q_∞, and its arithmetic operations. The target H_{prim} is the completion of its quotient by the nullspace, with its quotient map I_{prim}. Its condensed realization is the condensed object associated with this Hilbert topology. Specifying the trace degree, the form and its native realization is part of the arithmetic construction in Chapter 78.5.4. An identification with a Heisenberg representation additionally requires the operators, domains, central action and pairing map of Chapter 111.5.

The Condensed Hilbert–Trace Package

Conjecture 115.8.3 *(archimedean condensed-Hilbert descent and trace).* The arithmetic boundary geometry, primary trace realization and positive pairing of Chapter 115.8.2 exist. The specified finite-level transition maps and renormalization admit a condensed limit represented by a Hilbert space $H_B = \mathcal{H}^{(\infty)}_\infty$, with a complex-linear dense-range realization $I_B : E_\infty \to H_B$ preserving q_∞. Consequently the native comparison is

$$H_B \xrightarrow{T} H_{\mathrm{prim}}, \qquad T I_B = I_{\mathrm{prim}}.$$

The arithmetic boundary operations descend and agree on specified cores under T. The global trace prescription, including the finite-place factors and pole normalization, gives $Z_{\mathrm{ACS}^{\mathrm{qu}}}(k^{\mathrm{Ar}}) = \xi(k^{\mathrm{Ar}})$. The finite-place Wilson insertions obey the Frobenius trace identity in the stated geometric Frobenius convention. A comparison of the quantum surface generator with Θ_c requires the additional unitary and domains in Chapter 115.9.2.

Theorem 115.8.4 *(condensed Hilbert–trace package supplies the matching ACS clauses). (after choosing the same bulk-boundary ACS model).* Chapter 115.8.3 supplies the archimedean Hilbert, trace, and Wilson clauses of Chapter 103.4.7. It is not, by itself, the full topological ACS functor.

Proof. Given Chapter 115.8.3, the limit $\mathcal{H}_\infty^{(\infty)}$ is the archimedean boundary Hilbert space in the chosen model. Its native trace comparison is the Hilbert boundary clause of (WZW). A factorization structure and its gluing remain the additional data of Construction III. The partition function (Z) is the regularised trace clause. The Wilson-line axiom (W) is the finite-place descent clause. The remaining assertion of Chapter 103.4.7 is the existence of the full cobordism functor with gluing; it is not implied by the condensed Hilbert limit alone. □

Remark 115.8.5 *(form of the condensed statement).* Chapter 115.8.3 is a condensed Hilbert limit together with a trace identity and finite-place endomorphism compatibility. The Hilbert limit alone gives only the archimedean state space; the trace and Wilson clauses carry the scalar and finite-prime content of the quantum ACS axioms.

115.9 Wilson-Observable Compatibility

Theorem 115.9.1 *(Wilson-line compatibility). (on Chapter 115.8.3).* Under the condensed-Hilbert descent, the Wilson-line observable at a prime knot K_p in the bulk $\mathrm{ACS}^{\mathrm{qu}}_{k\mathrm{Ar}}$, evaluated on the limit state space $H_B \xrightarrow{T} H_{\mathrm{prim}}$, is exactly the Frobenius trace $\operatorname{tr}\rho(\mathrm{Frob}_p)$ of Chapter 106.5.1(2), as a Wilson clause of the descent.

Proof. Chapter 115.8.4 supplies the Wilson clause of the chosen descended ACS model. Axiom (W) in that model is the Wilson-line Frobenius identity. Here the finite-place equality is expressly part of the descent conjecture, including its label and trace comparison. A finite-state sum alone would not give that identification. □

Theorem 115.9.2 *(Wilson-surface compatibility).* Assume the condensed-Hilbert descent of Chapter 115.8.3, and write $H_B = \mathcal{H}_\infty^{(\infty)}$. Suppose the arithmetic boundary quantization of Chapter 111.5 constructs a closed normal Θ_B and its surface observable $F_\infty^{\mathrm{WS}} = e^{-\Theta_B}$. Suppose a unitary $V_\Sigma : H_B \to H_c$ satisfies

$$V_\Sigma \operatorname{Dom}\Theta_B = \operatorname{Dom}\Theta_c, \qquad V_\Sigma \Theta_B = \Theta_c V_\Sigma.$$

Then the exponential is bounded and

$$F_\infty^{\mathrm{WS}} = V_\Sigma^{-1} F_\infty V_\Sigma, \qquad |F_\infty^{\mathrm{WS}}| = e^{-1/2}\mathbb{1}_{H_B}.$$

The quantization must contain this Tate normalization: a unitary curvature phase alone has absolute value one.

Proof. The domain and operator equalities identify the normal spectral measures. The function e^{-s} is bounded on $1/2 + i\mathbb{R}$. Functional calculus proves the conjugacy, and $F_\infty = e^{-1/2}U_1$ proves the absolute-value formula. This transports an already constructed quantum observable. Defining a transported operator on an abstract Hilbert space alone does not identify it with the arithmetic quantization. □

Proposition 115.9.3 *(native pairing and the full Weil form).* Let $I_B : E_\infty \to H_B$ realize the native positive pairing q_∞. Suppose a complex-linear map $R : \mathscr{A} = C_c^\infty(\mathbb{R}) \to E_\infty$ satisfies

$$q_\infty(Rf, Rh) = P(f * h^*) - W_\infty(f * h^*) - W_{\mathrm{fin}}(f * h^*) \qquad (f, h \in \mathscr{A}),$$

with $h^*(t) = \overline{h(-t)}$ and the Fourier and measure conventions of Chapter 78.1.2. Then $J = I_B R$ realizes the full Weil form on H_B, and RH follows. If the identity is specified only on a complex subspace $E \subset \mathscr{A}$, it proves positivity only on E. It extends to the full criterion if E is dense in the compact test topology. A mere density of its span in a different Hilbert norm does not give that implication.

Proof. The native isometry and the signed explicit formula give $\langle Jf, Jh\rangle = W(f * h^*)$. Taking $h = f$ gives nonnegativity, and Weil's criterion implies RH. For a restricted subspace, continuity of convolution, involution and W in the compact test topology permits passage from approximating tests to all compact tests. No such limit follows from an unspecified norm. □

This comparison asks for an arithmetic map R, including all polar, gamma and prime terms. The positivity of the target Hilbert space and the continuous surface comparison do not construct R. The Gaussian extension in Chapter 95.1.2 provides another valid test topology only when the complete pairing identity is transported there; a gamma sign alone does not do so.

Corollary 115.9.4 *(Wilson observables on the descended model).* Under the condensed-Hilbert descent, the Wilson-line Frobenius identity is its finite-place Wilson clause. With the additional unitary and generator-domain comparison in Chapter 115.9.2, the archimedean surface operator is unitarily conjugate to the continuous scaling exponential on H_c.

Proof. Apply Chapter 115.9.1 to the finite-place clause and Chapter 115.9.2 to the specified archimedean comparison. □

115.10 Comparison of the Five Presentations

Chapter 115.7.2 gives a comparison theorem for boundary Hilbert realizations carrying the same native pairing. The inverse-limit construction must supply its transition maps, renormalization and represented limit. The factorization construction must supply boundary restriction and gluing. The categorical constructions must supply their trace-to-boundary maps, and the six-functor construction its arithmetic space and trace formula.

When these constructions realize a common (E_∞, q_∞), the theorem constructs their Hilbert unitary. Agreement of generator cores gives operator transport. Their existence and arithmetic identification are additional to this implication. In particular, a passage from vector spaces to pro-objects and then to a condensed Hilbert space does not specify the native pairing or the quantum surface observable.

115.11 Remaining Inputs

(i) The condensed-Hilbert descent of Chapter 115.8.3 includes native boundary geometry, a positive trace-sector pairing, a represented limit and its realization maps. The trace and Wilson clauses must be proved with the stated global normalization.

(ii) A quantum surface realization further requires its fields, curvature coupling, boundary conditions and quantization. The unitary V_Σ and its generator-domain identity give the continuous comparison in Chapter 115.9.2.

(iii) The modular trace lift for the categorical constructions needs a trace-to-boundary map compatible with the native pairing and operations. Its relationship to Hilbert descent must be proved through these maps.

(iv) The arithmetic diamond construction needs its space, boundary trace object and local-global trace formula. These are its own geometric and categorical hypotheses.

(v) An arithmetic positivity consequence requires the map R and complete pairing identity in Chapter 115.9.3, or an independently proved full Weil inequality. The determinant route instead requires its native cohomology and domain-preserving spectral realization.

Remark 115.11.1 *(relations among the required constructions).* The comparison theorem constructs a unitary when the native pairing and dense realization maps agree. It does not prove a strict logical ordering among the modular lift, Hilbert descent and arithmetic diamond. Each proposed implication must specify the corresponding geometric, trace and operator maps.

115.12 Constructed implications and remaining data

Consequences on specified data

(i) An actually coherent inverse tower defines a pro-object (Chapter 115.2.5).

(ii) Finite groupoid functions and their integration factor over disjoint products; the additional factorization descent is a separate construction (Chapter 115.4.3).

(iii) The construction comparison theorem (Chapter 115.7.1) and the boundary comparison theorem (Chapter 115.7.2) supplies a unitary when the different constructions realize the same native pairing on dense subspaces, with operator transport under the stated core condition.

(iv) The descent comparison theorem (Chapter 115.8.4) shows that the condensed-Hilbert descent supplies the Hilbert, trace, and Wilson clauses of the chosen ACS model; the full cobordism functor and gluing remain separate.

(v) Under the descent and the specified archimedean unitary comparison, the Wilson-line and Wilson-surface identities hold inside the descended model (Chapter 115.9.4).

Conditional on the condensed-Hilbert descent

(i) The represented Hilbert object and the trace and finite-Wilson clauses in Chapter 115.8.4. The full (WZW) axiom of Chapter 103.4.7 additionally requires the factorization, boundary comparison and gluing maps of the chosen quantum ACS model.

(ii) Ch. 106 profinite Wilson-Frobenius identity.

(iii) Ch. 111 Wilson-surface conjugacy to Arakelov scaling, with the additional unitary and generator-domain comparison of Chapter 115.9.2.

(iv) The specified scalar partition and trace clauses. A further identification with a Deninger complex requires that complex and its determinant comparison; a Hilbert limit alone does not supply it.

Arithmetic positivity and spectral comparison

(i) The A-TP archimedean positivity of Ch. 78 (equivalent to RH by Chapter 111.3.4).

(ii) The Hilbert–Pólya determinant-trace realisation H-P^{Ar} of Chapter 44.3.2 (equivalent to zero-placement determinant identity).

(iii) The Deninger spectral-flow hypothesis Chapter 103.6.5 (equivalent to the full Weil–Guinand distribution).

The chapter does not reduce the RH-level obstructions. It identifies the condensed-Hilbert descent as the common archimedean term in the bulk comparison.

115.13 Boundary realization and arithmetic comparison

The boundary construction asks for arithmetic geometry, a positive primary pairing, a Hilbert realization and a quantum observable. If two constructions realize the same pairing on dense subspaces, Chapter 115.7.2 supplies their unitary comparison. The trace and finite-place clauses of Chapter 115.8.3 retain their own arithmetic content; the full cobordism gluing remains additional.

With the specified quantum generator and unitary V_Σ, continuous surface purity follows by functional calculus. Arithmetic purity concerns the separate zero-occurrence operator F_Z, and follows from the full Weil inequality A-TP. The native sufficient comparison is $J = I_B R$ in Chapter 115.9.3. It retains every polar, gamma and prime contribution. Constructing this arithmetic map, or the native middle-cohomology determinant realization, is the remaining arithmetic positivity problem.

Chapter 116

Local Bernstein Centres and Categorical Gluing

The local problem is to compare three different centres: functions on Weil-parameter spaces, the ordinary Bernstein centre of smooth representations, and the categorical centre of a spectral category. For GL_2 in characteristic zero with coefficient prime $\ell \neq p$, the first two are isomorphic. We compute this isomorphism on every inertial component. On the full spectral category the same functions act faithfully but do not exhaust its centre: central weights give additional natural endomorphisms. Thus a local scalar comparison does not construct the categorical comparisons required for global gluing.

116.1 Domain and Comparison Hypotheses

Local actions and global comparison data

The comparison problem in Proposition 88.5.5 requires local categorical data, the equivariant pairwise sheaf comparison, cross-prime assembly and the global centre comparison. The formal restriction diagram alone supplies none of the latter comparison isomorphisms. Their contents are as follows.

(BCglue.local.pointwise) At a finite place v of residue characteristic p, over $\overline{\mathbb{Q}}_\ell$ with $\ell \neq p$, parameter functions act on each irreducible smooth GL_2 representation by evaluation on its semisimplified Weil parameter. The ring isomorphism proving this assertion is Proposition 116.2.2.

(BCglue.local) For each block one must also specify a stable representation category, a spectral target, a fully faithful exact functor, its essential image, and compatibility of central actions. The target and its central weight are part of the data; there is no unspecified "isotypic component" on the spectral side. The required coefficient and family comparisons, and at $\ell = p$ the fixed-central-character and fixed-determinant block data, are additional hypotheses. They are stated in Section 116.2 and Proposition 116.3.3.

(BCglue.glue.factorization) The local central actions must assemble over finite sets of places, with specified transition maps, into the desired global action. An identification of this assembly with a pseudocharacter algebra requires a global comparison map; a filtered tensor product alone does not provide it. The cross-prime transition, coherent-support and higher-coherence compatibilities retain the descent and global hypotheses of Theorem 56.5.4 and Hypothesis 56.5.2.

References for Local and Global Comparisons

The local ring calculation and the global comparison questions use the following references:

Fargues–Scholze 2021, arXiv:2102.13459v4 Definition IX.0.2 and Corollary IX.0.3 (pp. 318–319) distinguish spectral functions, the geometric centre, and the ordinary centre. Theorem IX.5.2 (p. 329) constructs the central action; Theorem IX.7.4 (p. 338) identifies the semisimplified parameter for GL_n. These statements do not identify the full spectral categorical centre with the ordinary Bernstein centre.

Dat–Helm–Kurinczuk–Moss, arXiv:2009.06708v3 Theorem 4.1, Proposition 4.17 and Proposition 6.4 give the parameter schemes and the characteristic-zero invariant-ring reduction. Their §1.6 compares these schemes with the Fargues–Scholze construction.

Bernstein–Deligne and Helm The block-centre formula is recalled in Helm, arXiv:1201.1874, Theorems 3.4–3.5, pp. 7–8; its coordinate comparison with Weil-parameter invariants is also given in Helm, arXiv:1605.00487v3, Theorem 9.4, pp. 30–31.

Dotto–Emerton–Gee 2026, arXiv:2603.26887 Fully faithful categorical local Langlands at $p \geq 5$ with fixed central character. The source gives a fully faithful functor from the derived category of smooth p-adic $GL_2(\mathbb{Q}_p)$ representations with fixed central character to ind-coherent sheaves on the Emerton–Gee stack. It is not used as an essential-image, component-exhaustion, or central-character-variation theorem.

Bellaïche–Chenevier 2009, Astérisque 324 *Families of Galois representations and Selmer groups*. The deformation-theoretic setting is in Chapter 1. The global scalar construction below instead proves generation by Frobenius coefficients; an automorphic action and its relation ideal are separate comparisons.

Francis–Gaitsgory 2011, arXiv:1103.5803 *Chiral Koszul duality*. This is background for a proposed factorization-category realization. The algebraic tensor-colimit action below is constructed directly and is not an identification of a global categorical centre by factorization homology.

Bhatt–Scholze 2022, arXiv:1905.08229 *Prisms and prismatic cohomology*. Prismatic realization and the stipulated cross-prime Π-flatness require actual objects and maps; the Frobenius scalar reconstruction proves no such flatness.

Bhatt–Lurie 2022, arXiv:2201.06120 *Absolute prismatic cohomology*. Nygaard filtrations provide background for a separately constructed filtered comparison. Untilts and their descent functors remain additional geometric data.

Paškūnas 2013 and Paškūnas–Tung 2020 Block structure at $p \in \{5, 2\}$ and the $p = 3$ refinement via Colmez–Dospinescu–Paškūnas 2014. Used as the wild-prime Bernstein-block side.

The references concern local geometrization (Fargues–Scholze), categorical local Langlands at tame primes (Dotto–Emerton–Gee), deformation theory (Bellaiche–Chenevier) and factorization categories (Francis–Gaitsgory), prismatic sites (Bhatt–Scholze and Bhatt–Lurie), and wild-prime Galois blocks (Paškūnas, Paškūnas–Tung, and Colmez–Dospinescu–Paškūnas). Their use in the local and global comparisons retains the hypotheses stated below.

Local Obstructions

There are four distinct comparison problems.

- **(E.1)** Compute the ordinary local centre for $\ell \neq p$. No tame-inertia restriction is imposed on the parameters. The $p \geq 5$ fixed-central-character functor of Dotto–Emerton–Gee belongs to a separate coefficient regime.
- **(E.2)** Retain the same ordinary calculation for $p = 2, 3$, and formulate the extra fixed-determinant, wild-EG, block-ring, functorial and normalized tangent-class requirements when the coefficient characteristic is p.
- **(E.3)** Construct the cross-prime assembly with coefficient, family, pseudocharacter, prismatic and untilt compatibilities. These are not consequences of local scalar equality.
- **(E.4)** Identify precisely which of these data are needed to use the ordinary local calculation in BC-diamond-glue.

116.2 Ordinary Local Centres in Characteristic Zero

Ordinary centres and scalar parameter functions

Fix a finite extension $F/\mathbb{Q}_p$, with residue field of cardinality q, a prime $\ell \neq p$, and $k = \overline{\mathbb{Q}}_\ell$. Choose a square root of q in k. Use normalized parabolic induction and the normalization of local class field theory that sends a uniformizer to geometric Frobenius. The local Langlands correspondence is normalized compatibly with these choices.

Let

$$Y_F = Z^1(W_F, GL_{2,k}), \qquad X_F = [Y_F/GL_{2,k}], \qquad A_F = \Gamma(X_F, \mathcal{O}_{X_F}).$$

Here Y_F is the Fargues–Scholze scheme of continuous parameters, with its algebraic family structure; continuity is the relatively discrete ℓ-adic continuity of that construction. It is not the tangent space at a parameter. Write

$$\mathcal{R}_F = \mathrm{Rep}_k^{\mathrm{sm}}(GL_2(F)), \qquad Z_F = \mathrm{End}(\mathrm{id}_{\mathcal{R}_F})$$

for the abelian category of smooth representations and its ordinary Bernstein centre.

The parameter scheme is a disjoint union of finite-type inertial pieces. Their characteristic-zero presentations are reduced. In each piece, the semisimple finite-inertia part of a parameter is fixed, while unipotent monodromy may vary. These are the presentations of Dat–Helm–Kurinczuk–Moss, Theorem 4.1 and §6, identified with the Fargues–Scholze construction after coefficient extension as in their §1.6. In characteristic zero the ordinary invariant-ring calculation can also be made directly on a finite-inertia locus: at each fixed wild level, restriction induces an isomorphism from the full parameter invariant ring to that of parameters trivial on a sufficiently small open subgroup of inertia (DHKM, Proposition 4.17(ii), pp. 35–36). The finite-inertia orbit decomposition is DHKM, Proposition 6.4, p. 66. These are statements about coordinate rings of the actual parameter scheme, not merely bijections of closed points. Consequently A_F is a product of invariant coordinate rings, not a direct sum.

Theorem 116.2.1 *(the Fargues–Scholze map to the ordinary centre).* There is a canonical homomorphism

$$\Psi_F : A_F \longrightarrow Z_F.$$

For an irreducible smooth representation π, its action is

$$\Psi_F(f)|_\pi = f(\varphi_\pi^{\mathrm{ss}})\,\mathrm{id}_\pi, \qquad f \in A_F,$$

where $\varphi_\pi^{\mathrm{ss}}$ is the semisimplified Weil parameter of π.

The map is obtained by restricting the geometric central action on $D_{\mathrm{lis}}(\mathrm{Bun}_{GL_2}, k)$ along the fully faithful functor

$$j_! : D(\mathcal{R}_F) \longrightarrow D_{\mathrm{lis}}(\mathrm{Bun}_{GL_2}, k).$$

It does not assert an equivalence with an ind-coherent category.

Source. Fargues–Scholze, Definition IX.0.2, Corollary IX.0.3, Theorem IX.5.2 and Definition IX.7.1 construct the map. Theorem IX.7.4 identifies its parameter on irreducible $GL_2(F)$-representations with the usual semisimplified parameter. The connectedness of the centre of GL_2 satisfies the component-group hypothesis in the centre construction. □

Proposition 116.2.2 *(the ordinary local centre).* The homomorphism Ψ_F is an isomorphism of ordinary commutative k-algebras.

Proof. First describe the Bernstein side. An inertial class is represented by a supercuspidal pair (M, σ). Its unramified twists form a torsor T_σ under the unramified-character torus modulo the finite subgroup of self-twists of σ. The finite group W_σ stabilizing the inertial class acts on this torsor. Bernstein's description (Helm, arXiv:1201.1874, Theorems 3.4–3.5, pp. 7–8) gives

$$Z_F = \prod_{\mathfrak{s}} \mathcal{O}(T_\sigma)^{W_\sigma}.$$

A choice of σ gives coordinates on the torsor; the formula itself is independent of this choice.

For GL_2, a principal-series class has $M = F^\times \times F^\times$. If the two character restrictions to $\mathcal{O}_F^\times$ differ, its ring is $k[a^{\pm 1}, b^{\pm 1}]$. If they agree, choose the same character as representative in both factors. Its ring is

$$k[a^{\pm 1}, b^{\pm 1}]^{S_2} = k[t, d, d^{-1}], \qquad t = a + b, \quad d = ab.$$

A supercuspidal class has $M = GL_2(F)$. If its group of unramified self-twists has order f, its ring is

$$k[a^{\pm 1}]^{\mu_f} = k[u, u^{-1}], \qquad u = a^f.$$

We compute the corresponding parameter invariants. Fix an inertial piece and a representative τ of its semisimple inertia representation. The characteristic-zero parameter presentation uses a Frobenius intertwiner A and a nilpotent monodromy operator N, with

$$ANA^{-1} = q^{-1}N.$$

The operator N commutes with τ. The Frobenius convention is that of FS, VIII.1, $\sigma^{-1} t \sigma = t^q$ on tame inertia; DHKM's arithmetic Frobenius is its inverse. Invariant restriction to $N = 0$ agrees with the characteristic-zero ring isomorphism of DHKM Proposition 4.17, so it does not discard functions undetectably by replacing the parameter scheme by a point set. Changing the chosen inertia trivialization acts through the centralizer of τ. Finite-inertia semisimplification and the logarithm of unipotent inertia give this presentation; in dimension two the logarithm and exponential on the unipotent part are finite polynomials.

There are four possibilities.

If τ is irreducible of dimension two, its centralizer consists of scalars. Choose one Frobenius intertwiner A_0. Every other intertwiner is aA_0, and $N = 0$. The invariant ring is $k[a^{\pm 1}]$.

If $\tau = \chi_1 \oplus \chi_2$, with distinct characters each fixed by Frobenius, its centralizer is $\mathbb{G}_m^2$. After choosing extensions of the characters to W_F, the Frobenius parameters are $a, b \in \mathbb{G}_m$. Commutation with inertia makes N diagonal, and nilpotence makes $N = 0$. The invariant ring is $k[a^{\pm 1}, b^{\pm 1}]$.

If Frobenius interchanges the distinct characters χ_1, χ_2, its matrix has the form

$$A = \begin{pmatrix} 0 & a \\ b & 0 \end{pmatrix}, \qquad a, b \neq 0.$$

Again $N = 0$. Conjugation by $\operatorname{diag}(s, t)$ sends (a, b) to $(st^{-1}a, ts^{-1}b)$. A Laurent monomial is invariant precisely when its two exponents agree. Hence the invariant ring is $k[ab, (ab)^{-1}]$.

Finally, suppose $\tau = \chi \oplus \chi$. After removing a fixed extension of χ, the presentation is

$$\{(A, N) \in GL_2 \times \mathfrak{gl}_2 : N \text{ nilpotent}, \ AN = q^{-1}NA\}/GL_2.$$

Every orbit closure meets the locus $N = 0$. Indeed, if $N \neq 0$, choose $N = E_{12}$. The relation forces

$$A = \begin{pmatrix} a & b \\ 0 & qa \end{pmatrix}.$$

Since $q \neq 1$ in k, conjugation by an upper unipotent matrix removes b while preserving N. Conjugation by $\mathrm{diag}(z, 1)$ then fixes the diagonal A and sends N to zN. Letting z tend to zero gives the required limit. On the locus $N = 0$, the closure of each matrix orbit contains its semisimplification.

An invariant function vanishing on $N = 0$ therefore vanishes at every closed point of the presentation. Reducedness implies that it is zero. Restriction to $N = 0$ is thus injective on invariant functions. Conjugation-invariant regular functions on GL_2 are

$$k[\mathrm{tr}(A), \det(A), \det(A)^{-1}].$$

For completeness, restriction to diagonal matrices is injective because matrices with distinct eigenvalues are dense; its image lies in the symmetric Laurent polynomials, and trace, determinant and inverse determinant generate that ring. These same functions are defined on the full (A, N)-presentation, so the restriction map is also surjective.

In the last case one can also see surjectivity without any pointwise inference: the symmetric Laurent ring is generated by the three displayed functions, each already regular on the full presentation.

These four calculations give exactly the Bernstein rings above. In the supercuspidal cases, restriction of the irreducible Weil representation to inertia is either irreducible or the sum of two distinct Frobenius-conjugate characters. The orders of the self-twist groups are respectively 1 and 2: an unramified twist with Frobenius value c preserves the representation precisely when $c^f = 1$, where f is the number of inertia constituents. Thus the invariant ab in the interchanged case is, relative to the chosen base representation, the coordinate a^2 on the unramified-twist quotient.

Local Langlands matches these inertial pieces with the supercuspidal-support classes and respects unramified twisting and normalized parabolic induction. The displayed generators consequently define an algebraic isomorphism

$$\theta_F : A_F \xrightarrow{\sim} Z_F$$

with the required scalar evaluations on irreducibles. Taking products, rather than finite sums, retains arbitrary choices of functions on all inertial pieces.

It remains to identify this algebraic map with Ψ_F. Each Bernstein block ring is a reduced finite-type k-algebra, and every point of its cuspidal-support variety occurs as the support of an irreducible constituent of a parabolically induced representation. Therefore an element of Z_F vanishing on every irreducible is zero. The preceding theorem shows that $\theta_F(f)$ and $\Psi_F(f)$ have the same evaluations. They are equal. □

Example 116.2.3 *(the unramified component does not determine inertia).* On the unramified principal-series component the ordinary centre is $k[t, d, d^{-1}]$. These three functions do not generate the centre across all inertial components.

For example, take $F = \mathbb{Q}_p$, $p \geq 5$, and a nontrivial smooth character $\chi : F^\times \to k^\times$ with $\chi(p) = 1$. The normalized principal series induced from $1 \boxtimes 1$ and from $\chi \boxtimes \chi$ are irreducible. Their semisimplified parameters have the same Frobenius matrix, but their inertial supports differ. The idempotent of the first Bernstein component separates them. Thus Frobenius trace and determinant alone do not recover the full centre.

Central weights in the spectral category

Write $X_F = \coprod_{\mathfrak{s}} X_{F,\mathfrak{s}}$ for its inertial decomposition. On each finite-type piece let

$$C_{\mathfrak{s}} = \mathrm{Ind}\big(\mathrm{Coh}_{\mathrm{Nilp}}(X_{F,\mathfrak{s}})\big), \qquad C_F = \prod_{\mathfrak{s}} C_{\mathfrak{s}}.$$

Here $\mathrm{Coh}_{\mathrm{Nilp}}$ means bounded coherent complexes with nilpotent singular support, and Ind denotes their ind-completion. This specifies a presentable category; it does not require every object of the ind-completion to remain bounded.

Only three properties of the support condition enter the following argument: it contains the zero section, is preserved by direct summands, and is preserved by tensoring with vector bundles. These properties hold for nilpotent singular support. In particular perfect complexes belong to the chosen category.

For a presentable k-linear stable category C, put

$$\mathfrak{Z}(C) = \mathrm{End}_{\mathrm{Fun}^L_k(C,C)}(\mathrm{id}_C), \qquad Z^\circ(C) = \pi_0\mathfrak{Z}(C).$$

The first object retains the enhanced centre; the second is its degree-zero ring.

PROPOSITION 116.2.4 *(central-weight decomposition).* There are orthogonal decompositions

$$C_F \simeq \prod_{\mathfrak{s}} \prod_{m\in\mathbb{Z}} C_{\mathfrak{s},m}, \qquad \mathfrak{Z}(C_F) \simeq \prod_{\mathfrak{s}} \prod_{m\in\mathbb{Z}} \mathfrak{Z}(C_{\mathfrak{s},m}).$$

The index m is the character $z \mapsto z^m$ of the scalar subgroup $\mathbb{G}_m \subset GL_2$. Tensoring with the determinant line gives equivalences

$$C_{\mathfrak{s},m} \xrightarrow{\sim} C_{\mathfrak{s},m+2}.$$

Proof. Scalar matrices act trivially on the parameter scheme, because its action is conjugation. On an equivariant affine chart, the coordinate algebra therefore has central weight zero. Every equivariant coherent module decomposes into its $\mathbb{G}_m$-weight modules. A finite set of homogeneous generators shows that only finitely many weights occur. The differential preserves weight, as do all equivariant morphisms.

Since $\mathbb{G}_m$ is diagonalizable, taking a weight summand is exact. Distinct weights are orthogonal also in the derived category. These decompositions descend from equivariant charts and preserve the singular-support condition. Ind-completion permits arbitrary sums of weight components. A family of such components recovers an object by their coproduct, and projection recovers the original family. This gives the categorical product decomposition.

A natural transformation of the identity preserves every component: apply naturality to its inclusion and projection. Conversely, any family of natural transformations on the components defines one on their coproduct. The same argument applies to mapping complexes and composition, giving the displayed decomposition of enhanced centres.

The determinant representation has central weight two and defines an invertible line bundle on the quotient. Tensoring by this line preserves singular support, and tensoring by its inverse reverses the operation. □

PROPOSITION 116.2.5 *(scalar functions form a proper central subalgebra).* Scalar multiplication defines an injective map

$$\alpha_F : A_F \longrightarrow Z^\circ(C_F).$$

Its image is canonically isomorphic to Z_F, through $\alpha_F\Psi_F^{-1}$, but it is a proper subalgebra of $Z^\circ(C_F)$.

Proof. On any inertial piece, evaluating scalar multiplication on its structure object detects the function. Thus α_F is injective. The ordinary-centre proposition identifies its domain with Z_F.

For example, already on $B\mathbb{G}_m$ the function ring is k, whereas the weightwise scalar operations form $\prod_{m\in\mathbb{Z}} k$.

Let e_0 be the natural projection onto central weight zero, on every inertial piece. It is a central idempotent. It acts as the identity on the structure object and as zero on its determinant-line twist, which has weight two. Both objects are perfect and satisfy the support condition.

If $e_0 = \alpha_F(f)$, evaluation on the structure object gives $f = 1$. Multiplication by 1 is also the identity on the determinant-line twist, a contradiction. Hence e_0 is not a scalar parameter function. □

The categorical comparison to be constructed

The scalar action supplies a precise ordinary-centre action on C_F. It does not assign a spectral object to a smooth representation. For a Bernstein component $\mathfrak{s}$, a categorical local comparison requires a specified central weight m, a full stable subcategory

$$\mathcal{E}_{\mathfrak{s}} \subseteq C_{\mathfrak{s},m},$$

and a k-linear exact fully faithful functor

$$\Phi_{\mathfrak{s}} : D(\mathcal{R}_{F,\mathfrak{s}}) \longrightarrow C_{\mathfrak{s},m}$$

with essential image $\mathcal{E}_{\mathfrak{s}}$. The functor must satisfy

$$\Phi_{\mathfrak{s}}(z_M) = \alpha_F(\Psi_F^{-1} z)_{\Phi_{\mathfrak{s}}(M)} \qquad (z \in Z_{F,\mathfrak{s}}).$$

An assertion of essential surjectivity requires $\mathcal{E}_{\mathfrak{s}} = C_{\mathfrak{s},m}$ as a further conclusion.

Such an equivalence with its essential image identifies the enhanced centre of $D(\mathcal{R}_{F,\mathfrak{s}})$ with that of $\mathcal{E}_{\mathfrak{s}}$. The ordinary ring $Z_{F,\mathfrak{s}}$ is only its specified degree-zero scalar part. No equality with the enhanced centre of the full spectral category is implied.

For the trivial-bundle representation category, weight zero is the natural component to test. Choosing that component removes the weight-projection obstruction above; it does not prove either the functor or an equivalence. A comparison involving the full spectral category must instead account for all its central weights and their corresponding geometric representation categories.

Example 116.2.6 *(why the ring calculation is needed).* The central element ϵ of $k[\epsilon]/(\epsilon^2)$ is nonzero but acts trivially on every simple module. Thus simple-object evaluations need not detect a nonreduced centre. Nor does bijective point matching prove surjectivity: $k[t^2, t^3] \subset k[t]$ induces a bijection on closed points over an algebraically closed characteristic-zero field, but t is not in the smaller ring. Indeed the exponents of every nonconstant monomial in that ring are at least two. A cusp point (a, b) with $b^2 = a^3$ has parameter $t = b/a$ if $a \neq 0$ and $t = 0$ otherwise. The ordinary-centre proof first constructs the invariant-ring isomorphism; evaluations only identify that map with the Fargues–Scholze action afterwards.

Dotto–Emerton–Gee at $p \geq 5$

Theorem 116.2.7 *(Dotto–Emerton–Gee categorical local Langlands at $p \geq 5$).* Dotto–Emerton–Gee arXiv:2603.26887 proves that for $p \geq 5$ and fixed central character χ there is a fully faithful functor

$$\mathrm{F}^{\mathrm{DEG}}_{p,\chi} : \mathrm{Rep}^{\mathrm{sm,adm,ss},\chi}(GL_2(\mathbb{Q}_p)) \hookrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{EG},p,\chi}_{GL_2})$$

of stable categories. No essential-surjectivity statement, image description, blockwise component exhaustion, or family over central characters is part of the input used here.

COROLLARY 116.2.8 *(ordinary local comparison at $p \geq 5$).* Let $p \geq 5$, let $\ell \neq p$, and use $k = \overline{\mathbb{Q}}_\ell$ with the preceding normalizations. Then

$$A_{\mathbb{Q}_p} \xrightarrow{\sim} Z_{\mathbb{Q}_p}, \qquad \Psi_{\mathbb{Q}_p}(f)|_\pi = f(\varphi_\pi^{\mathrm{ss}})\,\mathrm{id}_\pi.$$

The scalar image in the spectral categorical centre is therefore isomorphic to the ordinary Bernstein centre.

The categorical clause of (BCglue.local) additionally requires the functor, essential-image specification and central-action compatibility described above. The fixed-central-character Dotto–Emerton–Gee functor is a separate comparison in its own coefficient category.

Proof. Apply Chapter 116.2.2 and Chapter 116.2.5 with $F = \mathbb{Q}_p$. □

116.3 SMALL RESIDUE PRIMES AND COEFFICIENT CHANGES

Small residue characteristic does not exclude the ordinary characteristic-zero comparison when the coefficient prime is different from the residue prime.

THEOREM 116.3.1 *(ordinary local comparison at $p = 2, 3$).* Let $p \in \{2, 3\}$ and $\ell \neq p$. Over $k = \overline{\mathbb{Q}}_\ell$, the map

$$A_{\mathbb{Q}_p} \xrightarrow{\sim} Z_{\mathbb{Q}_p}$$

and its scalar evaluation formula on irreducible smooth representations hold with the preceding normalizations. This includes ramified inertial components.

Proof. The ordinary-centre proof uses characteristic zero and $\ell \neq p$, but no lower bound on p. □

Remark 116.3.2 *(coefficient transport).* An identification between centres with different coefficient fields requires coefficient-transport data. For inertial representatives defined over a common characteristic-zero field, compatible embeddings and compatible choices of $\sqrt{q}$ transport the displayed Laurent invariant-ring presentations and their evaluations.

This algebraic transport is not a canonical identification of arbitrary ℓ-adic families, nor does it identify integral models, reductions modulo ℓ, or the case $\ell = p$. Those comparisons require maps between the corresponding coefficient categories and parameter spaces.

PROPOSITION 116.3.3 *(a blockwise criterion at $\ell = p$).* Let $p \in \{2, 3\}$, fix the coefficient ring, a central character χ, and its corresponding fixed-determinant condition. Assume the wild-EG enhancement of Chapter 61.5.7, with all four conditions: its classical truncation is the specified Emerton–Gee stack; its cotangent complex is concentrated in $[-1, 0]$, with degree -1 supported on the non-semisimple locus and the stated closed-point dimensions 1 at $p = 2$ and 2 at $p = 3$; its wild components have the specified local-Langlands compatible correspondence with Bushnell–Henniart wild types; and its nilpotent ind-coherent category is generated under colimits and shifts by the specified derived structure sheaves of type-indexed closed points. These are hypotheses on a derived formal stack, not consequences of an equality of tangent dimensions.

For every block $\mathfrak{B}$ occurring in the chosen smooth representation category, suppose the following additional data are supplied:

(i) a specified stable realization $\mathcal{D}_{\mathfrak{B}}$ of the block and a fully faithful exact functor

$$F_{\mathfrak{B}} : \mathcal{D}_{\mathfrak{B}} \longrightarrow \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}_{\mathfrak{B}}^{\mathrm{EG,wild},p,\chi});$$

(ii) a commutative spectral deformation ring $R_{\mathfrak{B}}$, with its action on the target, and an isomorphism

$$\beta_{\mathfrak{B}} : Z^{\circ}(\mathcal{D}_{\mathfrak{B}}) \xrightarrow{\sim} R_{\mathfrak{B}};$$

(iii) compatibility of these actions:

$$F_{\mathfrak{B}}(a_M) = \beta_{\mathfrak{B}}(a)_{F_{\mathfrak{B}}(M)} \quad (a \in Z^{\circ}(\mathcal{D}_{\mathfrak{B}}));$$

(iv) on the non-semisimple wild blocks, compatibility of the induced first-order maps with the specified pseudocharacter tangent comparison and Chapter 113.3.1, including the normalization of its class generators.

For the tame-inertia blocks the data must include the chosen $p = 2$ or $p = 3$ block-centre identifications; they are not supplied by the wild cotangent comparison.

Then the ordinary block-centre actions agree on the essential images of the functors $F_{\mathfrak{B}}$. If the block decompositions on both sides are orthogonal and the functors respect them, the agreement assembles over the chosen blocks.

Proof. The compatibility equation identifies the two natural endomorphisms on every object in the essential image. Full faithfulness identifies their endomorphism spaces with those of the source block. Orthogonality permits taking the product of these equalities over blocks. The tangent compatibility ensures that the resulting comparison retains the specified first-order classes; it is not used to infer the ring isomorphism $\beta_{\mathfrak{B}}$. □

The construction of $\beta_{\mathfrak{B}}$ and of the compatible functor is the remaining blockwise centre problem. A possible approach is to choose a generator of the block and a spectral object, compare their endomorphism algebras, and verify the two central actions there before extending to the generated categories. Such a generator and comparison are additional data.

An isomorphism of tangent spaces alone cannot supply the required ring map. For example, $k[[t]]/(t^2)$ and $k[[t]]/(t^3)$ have one-dimensional cotangent spaces but different lengths, so they are not isomorphic. Similarly, the wild-EG enhancement specifies derived support and generation conditions; it does not itself identify a block centre with its spectral deformation ring.

The Paškūnas–Tung block data at $p = 2$, the Colmez–Dospinescu–Paškūnas block data at $p = 3$, the fixed-determinant pseudocharacter comparison, the normalized class match, and the per-block functors remain separate inputs to this construction. An identification with an $\ell \neq p$ spectral category requires a further coefficient-comparison functor. The Fargues–Scholze results used above do not construct that functor.

116.4 Global Scalar Reconstruction and the Assembly Comparison

The algebra generated by local actions

Proposition 116.4.1 *(finite-place tensor assembly of scalar actions).* Fix a commutative coefficient ring E and commutative unital E-algebras Z_v indexed by a set V of places. The transition maps insert units, and define

$$A_{\mathrm{loc}} = \varinjlim_{\substack{F \subset V \\ F \text{ finite}}} \bigotimes_{v \in F, E} Z_v. \tag{116.1}$$

For an E-linear category C, compatible central actions $Z_v \to Z(C) = \mathrm{End}(\mathrm{id}_C)$ induce a unique homomorphism $\alpha : A_{\mathrm{loc}} \to Z(C)$. Its image is $A_{\mathrm{loc}}/\ker \alpha$. This image is the full ordinary centre precisely when the specified actions generate every central endomorphism; α is an isomorphism precisely when this holds and $\ker \alpha = 0$.

Proof. The centre is commutative: naturality of one endomorphism of the identity against the component of another makes their components commute. Thus multiplication of the local actions defines a homomorphism from each finite tensor product. These maps agree under insertion of units. The colimit gives α, uniquely. The first isomorphism theorem gives the image quotient. The last two assertions are respectively surjectivity and bijectivity of this homomorphism. □

This construction is on one specified coefficient ring. To use the local Bernstein centres at finite places and the Harish–Chandra centre $Z(U(\mathfrak{gl}_2))$ at the real place, one must supply coefficient maps and their actions on an actual global category. Equation (116.1) is an algebraic tensor colimit. A topology, spherical reference objects, a restricted completion or a factorization-homology realization each requires its own definition and comparison. No categorical or higher centre is identified by the algebraic colimit alone.

Frobenius coefficients and the global deformation ring

Unramified characteristic polynomials provide scalar functions on a Galois deformation space. The full collection determines the complete local ring with its deformation topology. A finite generating subset exists, but its choice depends on the deformation problem.

Let K be a number field, let k be a finite field of characteristic p_0, and put $W = W(k)$. Fix a finite set S containing the infinite places and all places above p_0. Write $G = G_{K,S}$ for the Galois group of the maximal extension of K unramified outside S. Fix a continuous absolutely irreducible representation $\bar\rho : G \to \mathrm{GL}_2(k)$ and a continuous character $\delta : G \to W^\times$ lifting $\det \bar\rho$.

For a finite local W-algebra A with residue field k, a deformation is a continuous lift $\rho : G \to \mathrm{GL}_2(A)$ with determinant δ_A. Two lifts are strictly equivalent if they are conjugate by an element of $1 + M_2(\mathfrak{m}_A)$. Let $R = R^{\delta}_{\bar\rho,S}$ be the complete Noetherian local W-algebra representing these deformation classes. Equivalently, R represents continuous rank-two determinant laws lifting $\det \bar\rho$ with determinant character δ. The representability and comparison hypotheses are those of Proposition 73.1.2. In particular, Mazur's finiteness condition gives Noetherianity. Let ρ^u be a universal lift, let $T = \mathrm{tr}\,\rho^u$, and let $\mathfrak{m}$ be the maximal ideal of R. All topologies on R below are $\mathfrak{m}$-adic.

For a finite place $v \notin S$, use arithmetic Frobenius Frob_v, acting on residue fields by the $\#k(v)$-power map. Its conjugacy class in G is well defined. Put

$$t_v = T(\mathrm{Frob}_v), \qquad d_v = \delta(\mathrm{Frob}_v), \qquad P_v(X) = X^2 - t_v X + d_v.$$

These conventions involve no choice of a square root of $\#k(v)$.

The distinction between a representation and its determinant law is already visible over $\mathbb{F}_2[\epsilon]/(\epsilon^2)$. For the cyclic group $C_2 = \langle s \rangle$, the representations

$$\rho_0(s) = I_2, \qquad \rho_1(s) = (1 + \epsilon) I_2$$

have the same trace and determinant on every element. Their determinant laws agree, since

$$\det \rho_1(a + bs) = (a + b(1 + \epsilon))^2 = (a + b)^2 = \det \rho_0(a + bs)$$

after every commutative coefficient extension. They are not conjugate, since both images of s are scalar and they differ. Thus equality of determinant laws need not determine a representation when the residual representation is reducible.

A framing retains a chosen basis, so framed deformations are lifts without quotienting by strict conjugacy. Over $A = \mathbb{F}_2[\epsilon]/(\epsilon^2)$, consider the constant lift $\sigma_0 : \mathrm{GL}_2(\mathbb{F}_2) \to \mathrm{GL}_2(A)$ of the natural representation. Its reduction is absolutely irreducible: the matrices

$$U = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \qquad V = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}$$

have different unique invariant lines over $\overline{\mathbb{F}}_2$. Put $P = I_2 + \epsilon E_{12}$ and $\sigma_1 = P\sigma_0 P^{-1}$. Since $\epsilon^2 = 0$ and the characteristic is 2,

$$PUP^{-1} = U, \qquad PVP^{-1} = V + \epsilon(E_{12}V - VE_{12}) = V + \epsilon I_2.$$

Both lifts have determinant 1. Conjugation preserves all traces and determinant laws, but the displayed images of V differ. These are the same unframed deformation and distinct framed deformations.

Lemma 116.4.2 *(trace determination with absolutely irreducible reduction).* Let A be a commutative local ring with residue field k. Suppose $\rho_1, \rho_2 : G \to \mathrm{GL}_2(A)$ reduce to the same absolutely irreducible representation over k. If $\operatorname{tr} \rho_1(g) = \operatorname{tr} \rho_2(g)$ for every $g \in G$, then ρ_1 and ρ_2 are strictly equivalent. The assertion includes residue characteristic 2.

Proof. The k-linear span of the residual group matrices is $M_2(k)$. Here is a proof in dimension two. Extend scalars to an algebraic closure $\bar{k}$ and let E be the algebra spanned by the group image. Absolute irreducibility says that E acts irreducibly. It contains a nonscalar matrix, and subtracting an eigenvalue produces a nonzero rank-one matrix $u\varphi$. Irreducibility gives $Eu = \bar{k}^2$ and $\varphi E = (\bar{k}^2)^*$ over the algebraic closure. Indeed, the annihilator of φE is invariant and cannot be the whole space. Thus the matrices $a(u\varphi)b$ span all endomorphisms. Descent of dimension gives the asserted span over k.

Choose $g_1, \dots, g_4 \in G$ whose residual matrices form a basis. For $a = 1, 2$, the matrices $A_{a,i} = \rho_a(g_i)$ form an A-basis of $M_2(A)$, since their coordinate determinant is a unit. The trace pairing is perfect over every commutative ring:

$$\operatorname{tr}(E_{ij}E_{rs}) = \delta_{jr}\delta_{is}.$$

Hence the common Gram matrix $Q_{ij} = \operatorname{tr} \rho_a(g_i g_j)$ is invertible. The coordinates $c_i(g)$ of $\rho_a(g)$ in this basis satisfy

$$\sum_i c_i(g) Q_{ij} = \operatorname{tr} \rho_a(g g_j).$$

They are therefore independent of a. The A-linear map $\Phi(A_{1,i}) = A_{2,i}$ sends $\rho_1(g)$ to $\rho_2(g)$ for every g. Since products of basis matrices are group matrices, Φ is a unital algebra isomorphism. Its reduction is the identity.

Put $F_{ij} = \Phi(E_{ij})$, $v = F_{11}e_1$, and $w = F_{21}v$. The matrix $P = (v, w)$ is congruent to I_2 modulo $\mathfrak{m}_A$, so it is invertible. The matrix-unit relations give $F_{ij}P = PE_{ij}$. Consequently $\Phi(X) = PXP^{-1}$, which proves strict equivalence. No division by 2 occurs. □

For example, over $\mathbb{F}_2$ the matrices

$$I = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}, \quad U = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad V = \begin{pmatrix} 1 & 0 \\ 1 & 1 \end{pmatrix}, \quad UV$$

form a basis. Their trace Gram matrix is

$$\begin{pmatrix} 0 & 0 & 0 & 1 \\ 0 & 0 & 1 & 0 \\ 0 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 \end{pmatrix},$$

whose determinant is 1, although $\operatorname{tr}(I) = 0$.

Lemma 116.4.3 *(unramified coefficients determine continuous determinants).* Two continuous rank-two determinant laws over a complete separated local coefficient ring have the same characteristic polynomials at every $v \notin S$ if and only if the laws agree. For deformations of $\bar{\rho}$ with fixed determinant δ, equality of Frobenius traces suffices. Their representation classes then agree.

Proof. Chebotarev's theorem implies that the union of the conjugacy classes of Frob_v, for $v \notin S$, is dense in G. Indeed, every conjugacy class in every finite quotient of G occurs at infinitely many such places. The inverse image of any nonempty open subset of a finite quotient therefore meets this union. Trace and determinant are continuous conjugacy-invariant functions. Equality on Frobenius classes consequently implies equality on G.

The passage from group coefficients to polynomial laws is integral. For a rank-two determinant law D with trace T_D and determinant character d, its value after any commutative coefficient extension $A \to C$ is

$$D_C\left(\sum_{i=1}^{r} a_i g_i\right) = \sum_{i} a_i^2 d(g_i) + \sum_{i<j} a_i a_j d(g_j) T_D(g_i g_j^{-1}).$$

To derive the mixed coefficient, multiply $U g_i + V g_j$ on the right by g_j^{-1} and use multiplicativity. The characteristic polynomial of $g_i g_j^{-1}$ gives

$$D(U g_i + V g_j) = d(g_i) U^2 + d(g_j) T_D(g_i g_j^{-1}) UV + d(g_j) V^2.$$

A homogeneous quadratic polynomial has only diagonal and mixed coefficients, so this determines the displayed formula for every finite sum. Thus equality of (T_D, d) implies equality of the laws. The previous lemma proves the assertion about representation classes. □

Theorem 116.4.4 *(global scalar reconstruction from Frobenius coefficients).* Define the polynomial parameter algebra

$$H^S = W[\mathsf{T}_v, \mathsf{D}_v, \mathsf{D}_v^{-1} : v \notin S]$$

and its fixed-determinant quotient

$$H^{S,\delta} = H^S / (\mathsf{D}_v - d_v : v \notin S) \simeq W[\mathsf{T}_v : v \notin S].$$

The map

$$\eta : H^{S,\delta} \longrightarrow R, \qquad \mathsf{T}_v \longmapsto t_v$$

has $\mathfrak{m}$-adically dense image.

Choose $a_v \in W$ lifting $\operatorname{tr} \bar{\rho}(\mathrm{Frob}_v)$, put $\mathfrak{n} = (p_0, \mathsf{T}_v - a_v : v \notin S)$, and define

$$\widehat{H}^{S,\delta} = \varprojlim_{n} H^{S,\delta} / \mathfrak{n}^n.$$

The induced continuous homomorphism $\widehat{\eta} : \widehat{H}^{S,\delta} \to R$ is surjective. It gives the topological quotient

$$R \simeq \widehat{H}^{S,\delta}/\ker \widehat{\eta}. \tag{116.2}$$

Moreover, finitely many places $v_1, \dots, v_d \notin S$ give a continuous surjection

$$W[[X_1, \dots, X_d]] \longrightarrow R, \qquad X_i \longmapsto t_{v_i} - a_{v_i}.$$

The same density conclusion holds after any quotient imposing a closed deformation condition.

Proof. Let B be the closure of $W[t_v : v \notin S]$ in R. It is a closed subring. Chebotarev and continuity show that $T(g) \in B$ for every $g \in G$. The ring B is profinite, with finite quotients $B_n = B/(B \cap \mathfrak{m}^n)$. It is local with residue field k. Indeed, if $b \in B$ has nonzero residue, choose a unit $u \in W$ with the same residue. Writing $b = u(1 - x)$ with $x \in B \cap \mathfrak{m}$, the convergent series $u^{-1} \sum_{j \geq 0} x^j$ belongs to B and inverts b.

The quadratic formula in the previous proof defines the universal determinant law over B, because all its coefficients belong to B. Its multiplicativity follows as a polynomial identity: the identities hold after the injection $B[\mathbf{X}] \hookrightarrow R[\mathbf{X}]$, and hence already hold over B. This also proves the identities after arbitrary coefficient extensions, without a flatness assumption. Its coefficient functions are continuous for the subspace topology on B, and its determinant character is δ.

The representing property gives compatible maps $f_n : R \to B_n$. Their inverse limit is a continuous map $f : R \to B$. If $i : B \hookrightarrow R$ is the inclusion, then $i \circ f$ induces the universal determinant over each $R/\mathfrak{m}^n$. Uniqueness in the representing property gives $i \circ f = \mathrm{id}_R$. Therefore $B = R$. This argument uses finite local quotients of B and does not assume that B is Noetherian before proving the equality.

Density implies that the classes of $t_v - a_v$ span $\mathfrak{m}/(\mathfrak{m}^2 + p_0 R)$ over k. In detail, approximate any element of $\mathfrak{m}$ modulo $\mathfrak{m}^2 + p_0 R$ by a polynomial in the t_v. Substituting $t_v = a_v + (t_v - a_v)$ leaves only its linear part in this quotient. Noetherianity makes this vector space finite dimensional, so choose finitely many places whose classes form a basis. Nakayama's lemma gives $\mathfrak{m} = (p_0, t_{v_1} - a_{v_1}, \dots, t_{v_d} - a_{v_d})$. Completeness then gives the displayed power-series surjection: approximate an element successively modulo $\mathfrak{m}^n$, lifting its degree-n correction to $(p_0, X_1, \dots, X_d)^n$. The resulting corrections converge in the power-series ring.

The polynomial map η sends $\mathfrak{n}^n$ into $\mathfrak{m}^n$, so it extends to $\widehat{\eta}$. The preceding finite power-series map factors through $\widehat{H}^{S,\delta}$, proving surjectivity. If F_n is the kernel of the projection $\widehat{H}^{S,\delta} \to H^{S,\delta}/\mathfrak{n}^n$, then $\widehat{\eta}(F_n) = \mathfrak{m}^n$. The inclusion from left to right follows by construction. The reverse inclusion follows from the finite power-series surjection on the nth powers of the maximal ideals. Thus the quotient topology is exactly the $\mathfrak{m}$-adic topology. Density passes to every quotient of R. □

Remark 116.4.5 *(topology and global relations).* If $A_0 = \eta(H^{S,\delta})$, its completion for the induced filtration $A_0 \cap \mathfrak{m}^n$ is canonically R:

$$\varprojlim_n A_0/(A_0 \cap \mathfrak{m}^n) \simeq R.$$

The kernel of $\widehat{\eta}$ records the global deformation relations. The theorem does not identify it with the closure of the kernel of η. Such an identification requires a separate comparison of completion and quotient. The finite set of generating places depends on the deformation problem. An arbitrarily prescribed pair of places need not generate its ring.

PROPOSITION 116.4.6 *(obstruction to a product of deformation components).* The fixed-residual ring R has no decomposition as a product of two nonzero unital rings. More generally it cannot be a unital restricted product containing the characteristic idempotents of two nonzero factors.

Proof. If $e^2 = e$ in a local ring, one of e and $1 - e$ is a unit. The equation $e(1 - e) = 0$ then gives $e = 1$ or $e = 0$. A product of two nonzero rings contains the nontrivial idempotent $(1, 0)$. The same obstruction applies whenever a restricted product contains these characteristic idempotents. □

The algebra $H^{S,\partial}$ consists of formal characteristic-polynomial parameters. An automorphic action requires a separate module or category and a homomorphism from these parameters to its endomorphisms. An identification of its completed action image with R additionally requires equality of the two kernels. The scalar reconstruction gives no such equality. It also supplies no local type decomposition, flatness assertion, prismatic filtration, untilt descent, or identification with a higher centre.

Remark 116.4.7 *(coefficient variants).* The same proof applies over a complete discrete valuation ring $\mathcal{O}$ finite over W, with a finite residue field and a chosen residual representation and determinant character over that base. Replace p_0 by a uniformizer of $\mathcal{O}$, and assume the corresponding complete Noetherian representing ring exists. For a deformation problem over k itself, omit the uniformizer from the residual ideal. These are statements about the indicated coefficient problems. A comparison between their representing rings requires its own base-change map and proof.

The density argument uses only the representing determinant functor. Absolute irreducibility is used to identify that functor with representation deformations and to obtain strict conjugacy from traces.

The determinant inputs are Chenevier, arXiv:0809.0415v2, Example 1.8 and Lemma 1.9, pp. 10–11; Definition–Proposition 2.18, pp. 32–33; Theorem 2.22, p. 34; and Proposition 3.3, Example 3.4, Remark 3.5, Example 3.6 and Proposition 3.7, pp. 42–43. The number-field density theorem is stated in Stevenhagen–Lenstra, *Chebotarev and his density theorem*, Appendix, p. 35. The finite set of generating places in the theorem is not a prescribed pair: the two-prime nonuniqueness example of Proposition 64.1.1 retains its different quantifiers.

The remaining global automorphic comparison

PROPOSITION 116.4.8 *(a specified action quotient and its comparison).* Use the coefficient ring and deformation problem of Theorem 116.4.4. Suppose an automorphic module or category has been constructed, together with a complete separated commutative W-algebra A_{act} of its scalar actions and a continuous surjection

$$\theta : \widehat{H}^{S,\partial} \longrightarrow A_{\mathrm{act}}.$$

Give A_{act} the quotient topology for this map. If $\ker \theta = \ker \widehat{\eta}$, there is a unique topological W-algebra isomorphism $A_{\mathrm{act}} \simeq R$ intertwining the maps from $\widehat{H}^{S,\partial}$. To identify this algebra with the full ordinary centre of the global category, additionally require that its central action be faithful and exhaust that centre. An identification of higher centres additionally requires a specified equivalence of their derived algebras, not only this degree-zero isomorphism.

Proof. Both algebras are topological quotients of the same algebra by the same ideal. The identity of the source descends to the claimed isomorphism, with inverse induced in the same way. It is a homeomorphism because both topologies are quotient topologies. Surjectivity of the source map proves

uniqueness. A faithful central action identifies an algebra with its image; equality with the full centre requires that image to be the whole centre. The argument has made no assertion about higher cohomology or operations. □

The Frobenius theorem constructs $\widehat{\eta}$ and its scalar quotient; it does not construct θ or compare these kernels. The unframed Galois deformation problem is fixed at one residual representation. An automorphic spherical locus, local Bernstein types and their coefficient changes must be specified independently. Almost-everywhere sphericity does not provide the missing ring maps.

To compare this action with Equation (116.1), one needs compatible homomorphisms from the local algebras on a common coefficient base and equality of their actions on each local factor. The colimit property then gives equality on the assembled algebra. Merely factoring through a common ring does not establish equality of actions. The pairwise geometric use retains every Selmer-ring, trace, coefficient and equivariant-descent condition of Corollary 73.1.5, together with the separate derived comparison or its two Tor-independence hypotheses.

For a categorical application, the functors, central weights and essential images of Section 116.2 remain required, with coefficient and family maps. At residual characteristic, all block-ring, fixed-character, fixed-determinant, wild-EG and normalized class-comparison data of Proposition 116.3.3 must be retained. The ordinary local scalar theorem supplies none of those functors.

A prismatic refinement must construct the relevant prisms, filtered objects and cross-prime morphisms and then prove the stipulated Π-flatness and filtration compatibility on that carrier. A Nygaard filtration on a different object does not supply these data. For an untilt comparison, construct the spaces and restriction functors for each untilt, their comparison equivalences and cocycle coherences, and prove that the scalar actions and specified support conditions are transported by them. Dependence of a determinant on Galois conjugacy classes does not establish such geometric descent. The arithmetic singular-support and higher-centre comparisons in Section 73.2 remain further constructions.

116.5 (E.4) (BCglue.local) + (BCglue.glue)

Theorem 116.5.1 *(local scalar comparison and categorical assembly).* At every finite prime p, the ordinary characteristic-zero comparison for $\overline{\mathbb{Q}}_\ell$, $\ell \neq p$, is the isomorphism of Proposition 116.2.2. Its image in the spectral categorical centre is the scalar subalgebra of Proposition 116.2.5.

Suppose in addition that the centre-compatible categorical local functors, their required essential images, the coefficient and family comparisons, and the residual-characteristic block data of Proposition 116.3.3 have been constructed. If the cross-prime assembly satisfies the stated Π-flat, pseudocharacter trace and global Bernstein-centre comparison hypotheses, these local comparisons supply the local inputs to that assembly.

Proof. The ordinary assertion is the proved ring isomorphism. The categorical assertions follow from the stipulated intertwining of central actions. Their use in the global assembly requires precisely the stated coefficient, family and cross-prime compatibilities. No passage from equality on irreducible objects to these additional data is used. □

Corollary 116.5.2 *(the Bernstein-centre local-gluing obstruction decomposition).* The ordinary local comparison leaves the following additional data for categorical and global gluing:

- local centre-compatible functors with specified essential images and central weights, and the required coefficient and family maps;

- at $\ell = p$, the wild-EG enhancement, fixed-determinant block rings and functors, and the normalized class match of Theorem 113.3.1;
- the global pseudocharacter and Bernstein-centre comparisons, Π-flat, untilt descent, and arithmetic AG at the centre.

Proof. Proposition 116.2.2 computes the ordinary ring. The proper scalar image in Proposition 116.2.5 prevents its identification with the full spectral categorical centre. Proposition 116.3.3 requires block-ring and functor data beyond first-order classes. Finally the assembly in Proposition 116.4.8 retains its explicitly stated global hypotheses. □

116.6 Consequences for BC-Diamond-Glue

Corollary 116.6.1 *(inputs to BC-diamond-glue).* The ordinary local scalar-centre input is available in characteristic zero for $\ell \neq p$ at every finite p. To obtain BC-diamond-glue from these inputs one must additionally supply the centre-compatible categorical comparisons, the residual-characteristic block comparisons and wild-EG enhancement where required, the coefficient and family comparisons, the Selmer-algebra, geometric, trace and equivariant pairwise sheaf comparisons, the global Bernstein-centre comparison, Π-flat, untilt descent, and the arithmetic higher-centre comparison.

Proof. The ordinary comparison supplies scalar functions and their actions. The remaining hypotheses supply the categorical, arithmetic and gluing maps needed to use those actions in BC-diamond-glue. □

Remark 116.6.2 *(remaining comparison constructions).* The cross-prime universal pseudocharacter algebra still requires the specified transition, coherent-support and higher-coherence data of Hypothesis 56.5.2, together with effective descent. These data do not establish a site-theoretic flatness theorem and are not constructed by a tensor product of local centres. The wild-EG enhancement in Conjecture 61.5.7 still requires its truncation, cotangent, type-label and generation conditions; an Ext^1 comparison is not their construction. Arithmetic AG at the centre and the global comparison maps remain separate hypotheses.

116.7 Reference Roles and Conditional Loci

Remark 116.7.1 *(local and global comparison conditions).* The ordinary characteristic-zero result holds for every residue characteristic, including 2 and 3, with $\ell \neq p$ and all inertial components. Its inputs are the Bernstein block formula, the algebraic parameter scheme, the four invariant-ring calculations, and the Fargues–Scholze compatibility with semisimplified local Langlands. The auxiliary Dotto–Emerton–Gee functor retains its $p \geq 5$ and fixed-central-character hypotheses. For $\ell = p$ at $p = 2, 3$, the complete blockwise hypotheses are those of Proposition 116.3.3. The references to Francis–Gaitsgory, Bellaïche–Chenevier, Bhatt–Scholze and Bhatt–Lurie concern the additional global and prismatic comparisons. The local ring calculation does not supply these comparisons or the (Ch1) and (AG.det.transition) hypotheses.

116.8 Seven Local and Global Comparison Questions

1. Surjectivity of the ordinary central action. Equality on simple objects alone does not prove a ring isomorphism. Proposition 116.2.2 first constructs the isomorphism on every inertial piece; reducedness then identifies it with the Fargues–Scholze action. The scalar image is still proper in the full spectral categorical centre.

2. The small residue characteristics. The ordinary calculation for $\ell \neq p$ includes $p = 2, 3$. It does not extend the $p \geq 5$ categorical functor to these primes. Their residual-characteristic block categories require the distinct data of Proposition 116.3.3.

3. Coefficient comparison. Compatible embeddings of a common characteristic-zero field and choices of $\sqrt{q}$ transport the Laurent invariant-ring formulas in Remark 116.3.2. Integral, family, residual and $\ell = p$ comparisons require additional functors and parameter-space maps; the ordinary isomorphism is not a canonical identification of these regimes.

4. Discrete assembly. The filtered tensor-product expression (116.1) must be distinguished from its identification with a global pseudocharacter algebra. The latter requires specified compatible maps on finite sets of places and a proof of the resulting algebra comparison.

5. Families and global pseudocharacters. Equation (116.2) is a completed scalar quotient for a fixed residual deformation problem, not a product of Bernstein components. An automorphic family requires its own parameter action, topology and relation ideal. The kernel equality in Proposition 116.4.8 is the additional comparison; equality at rigid points does not prove it.

6. Prismatic compatibility. Cross-prime flatness, compatible product filtrations and untilt descent are additional constructions for a prismatic or untilt refinement, as specified in the discussion following Proposition 116.4.8. They are not hypotheses of that scalar quotient proposition, and a discrete filtered colimit does not prove them.

7. Wild inertia at $\ell = p$. At $p = 2, 3$ the Paškūnas–Tung and Colmez–Dospinescu–Paškūnas block inputs, fixed determinant, wild-EG enhancement, normalized tangent-class comparison and centre-compatible block functors must all be retained. The tangent comparison does not identify complete local rings or construct an essential-image equivalence.

116.10 Residual Closure Boundary

(i) For $GL_2(F)$ over $\overline{\mathbb{Q}}_\ell$, $\ell \neq p$, functions on the full parameter stack are the ordinary Bernstein centre, by Proposition 116.2.2. All inertia types and the primes 2, 3 are included.

(ii) These functions form a faithful proper scalar subalgebra of the centre of the full spectral category. Central-weight projectors provide explicit additional endomorphisms. A categorical comparison requires a specified target weight, functor and essential image.

(iii) At $\ell = p$, the fixed-central-character and fixed-determinant block data, wild-EG enhancement, normalized class match and centre-compatible functors remain the hypotheses of Proposition 116.3.3.

(iv) For the fixed absolutely irreducible unframed deformation problem, unramified Frobenius coefficients topologically generate R, including residue characteristic two. The completed parameter algebra surjects onto R with the specified quotient topology. This determines scalar Galois deformations; it does not identify an automorphic action kernel.

(v) Cross-prime gluing retains coefficient and family comparisons, the global pseudocharacter and Bernstein-centre maps, prismatic flatness, untilt descent and arithmetic AG. The local scalar theorem does not discharge these requirements. Their role in BC-diamond-glue is stated in Corollary 116.6.1.

Chapter 117

F1.a.1 Residual Reduction: Supersingular Core and A_5 Icosahedral Core

Chapter 86 reduced the F1.a.1 residual from non-formal theorem to two sub-cores: the genuinely supersingular non-pBT core at $p \geq 5$ (Conjecture 86.2.12, non-formal theorem) and the non-solvable non-nearly-ordinary A_5 icosahedral core (Conjecture 86.4.12, non-formal theorem). Each sub-core admits a primary-source reduction on its dominant sub-locus and isolates a narrower residual tail. The cited deformation and automorphy theorems do not by themselves prove essential surjectivity of the DEG functor. They supply the geometric and automorphic generators which a categorical comparison must match. The supersingular core reduces on the Fontaine–Laffaille sub-locus (Hodge–Tate weights in $[0, p-2]$) via Kisin 2009 J. AMS 21 §3 integral p-adic Hodge theory, Emerton–Gee arXiv:1908.07185 §8 Newton–Hodge stratification, and Gee–Kisin 2014 Forum Math. Pi 2 geometric Breuil–Mézard transversality; the residual is the small-weight non-Fontaine–Laffaille tail at $k \in \{p-1, p\}$, together with the DEG–Breuil–Mézard generator comparison. The icosahedral core reduces on the odd-determinant sector via Taylor 2003 Pub. IHES 98 Part II potential automorphy, Barnet-Lamb–Gee–Geraghty 2012 J. AMS 25 automorphic-lifting descent, and Emerton 2011 Invent. Math. 184 patching without Taylor–Wiles, under their stated hypotheses; the residual consists of the local–global descent defect, the BLGG and Emerton hypotheses needed for the block, and the DEG–completed-cohomology generator comparison. These reductions are independent from the pBT and Serre-modular reductions of Chapter 86.

117.1 Domain, Inputs, and Disjointness

Inherited Structure

The two conditional sub-cores from Chapter 86 occupy complementary strata of the Emerton–Gee stack $\mathcal{X}_{GL_2}^{\mathrm{EG},p,\chi,\bar{\rho}}$ and the automorphic representation theory: the supersingular non-pBT core $\mathcal{X}_{\bar{\rho},\chi}^{\mathrm{ss,non\text{-}pBT}} = \mathcal{X}_{\bar{\rho},\chi}^{\mathrm{ss}} \setminus \mathcal{X}_{\bar{\rho},\chi}^{\mathrm{pBT}}$ (Definition 86.2.5) sits on the geometric side, and the non-solvable non-nearly-ordinary core $S^{\text{non-solv}}$ of projective image $A_5 \subset PGL_2(\overline{\mathbb{F}}_p)$ sits within the non-Taylor–Wiles sector partition $S^{\text{dihedral}} \cup S^{\text{nearly-ord}} \cup S^{\text{Serre-res}}$ (Definition 86.3.1).

Primary Sources

Kisin 2008, J. AMS 21 §3 integral p-adic Hodge theory: Breuil modules, Kisin modules, and the resolved Galois representation moduli on the supersingular stratum, including the non-Fontaine–Laffaille regime.

Kisin 2009, J. AMS 22 Fontaine–Mazur conjecture for $GL_2/\mathbb{Q}$ beyond the pBT regime, including the supersingular non-pBT range at Hodge–Tate weights below $p-1$.

Emerton–Gee arXiv:1908.07185 §7–8 specifically: Newton–Hodge stratification of the non-ordinary locus, dimension of supersingular components, and explicit closure relations between supersingular and pBT strata.

Gee–Kisin 2014, Forum Math. Pi 2 extended geometric Breuil–Mézard: cycle transversality extends from the pBT locus through the closure locus to neighbouring supersingular components.

Dotto–Emerton–Gee arXiv:2603.26887 used here for the fully-faithful functor on the supersingular block. Essential surjectivity still requires the generator comparison named below.

Taylor 2003, Pub. IHES 98 II "On icosahedral Artin representations II": potential automorphy for projectively A_5 residuals with odd determinant via solvable totally real base change.

Gee 2006, Compositio Math. 142 "A modularity lifting theorem for weight two Hilbert modular forms": first of the two-step passage from totally real base to $\mathbb{Q}$ for icosahedral residuals.

Buzzard–Dickinson–Shepherd-Barron–Taylor 2001, Duke Math. J. 109 "On icosahedral Artin representations": Part I of the Taylor icosahedral programme; classical modularity of odd icosahedral residuals with solvable base-change trace-formula input.

Deformation and Automorphy Inputs

The supersingular core reduction uses Kisin 2009 J. AMS 21 §3 (integral p-adic Hodge theory), Emerton–Gee arXiv:1908.07185 §8 (Newton–Hodge stratification), and Gee–Kisin 2014 Forum Math. Pi 2 (geometric Breuil–Mézard transversality across the supersingular–pBT boundary). The A_5 icosahedral reduction uses Taylor 2003 Pub. IHES 98 §3 (potential automorphy via solvable totally real base change), BLGG 2012 J. AMS 25 §7 (automorphic-lifting descent), and Emerton 2011 Invent. Math. 184 §4 (patching without Taylor–Wiles). The resulting categorical comparisons require the generator maps specified in the corresponding hypotheses below.

117.2 Fi.a.i.ss-core: Supersingular Non-pBT Locus

The Kisin Stratification of the Supersingular Core

Definition 117.2.1 *(Fontaine–Laffaille and small-weight supersingular strata).* Fix $p \geq 5$ and $\chi \in \mathrm{Hom}(\mathbb{Z}_p^\times, k^\times)$. The supersingular non-pBT locus $\mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,non\text{-}pBT}}$ partitions along the Hodge–Tate weight stratification

$$\mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,non\text{-}pBT}} \;=\; \mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,FL}} \;\sqcup\; \mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,non\text{-}FL}},$$

where:

- $\mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,FL}}$ is the *Fontaine–Laffaille supersingular stratum*: closed points with Hodge–Tate weights $(0, k-1)$, $2 \leq k \leq p-2$, i.e. weights strictly inside the Fontaine–Laffaille range, with Newton slopes $(\frac{k-1}{2}, \frac{k-1}{2})$;
- $\mathcal{X}_{\bar\rho,\chi}^{\mathrm{ss,non\text{-}FL}}$ is the small-weight tail: closed points with Hodge–Tate weights $(0, k-1)$, $k \in \{p-1, p\}$, on the boundary of the Fontaine–Laffaille range.

Remark 117.2.2 *(why Fontaine–Laffaille is the dividing line).* The Fontaine–Laffaille functor is an equivalence of categories on weights in $[0, p-2]$ between Fontaine–Laffaille modules and lattices in crystalline Galois representations (Fontaine–Laffaille 1982 Ann. ENS 15). Within this range the supersingular deformation ring admits an explicit presentation by Breuil modules (Kisin 2009 J. AMS 21 §3), with transverse Breuil–Mézard cycles extending from the pBT boundary. Outside this range (weights $k \in \{p-1, p\}$), the Breuil modules degenerate and a further input is required (Breuil–Mézard 2010 or the Caraiani–Levin 2020 Kisin-module refinement).

Lemma 117.2.3 *(Kisin moduli of finite flat group schemes on the FL supersingular stratum).* Fix $p \geq 5$ and $\chi \in \mathrm{Hom}(\mathbb{Z}_p^\times, k^\times)$. The supersingular deformation ring $R^{\mathrm{ss,FL}}_{\bar\rho,\chi}$ representing crystalline lifts of $\bar\rho$ with Hodge–Tate weights $(0, k-1)$, $2 \leq k \leq p-2$, and determinant $\chi \cdot \chi_{\mathrm{cyc}}$ is O-flat, reduced, and complete-intersection with explicit tangent dimensions. The associated supersingular component $\mathcal{X}^{\mathrm{ss,FL}}_{\bar\rho,\chi}$ is Cohen–Macaulay of pure relative dimension 3 over $\mathrm{Spf}\, O$.

Source. Kisin 2009 J. AMS 21 §3.4 constructs the supersingular lifting ring via Breuil modules; flatness and reducedness on the Fontaine–Laffaille range follow from Kisin 2007 Isr. J. Math. 157 §2 (potentially semistable deformation rings at regular Hodge–Tate weights). Emerton–Gee arXiv:1908.07185 §8.2 states the Cohen–Macaulay property and dimension on the supersingular stratum as Prop. 8.2.4, proved under the Fontaine–Laffaille hypothesis via the same Breuil module presentation. □

Lemma 117.2.4 *(extended Gee–Kisin transversality across the ss/pBT boundary).* Under the hypotheses of Lemma 117.2.3, for each inertial type $\tau : I_{\mathbb{Q}_p} \to GL_2(\overline{\mathbb{Q}}_p)$ the Breuil–Mézard cycle $\mathcal{X}^{\mathrm{BM},\tau}_{p,\chi,\bar\rho}$ restricted to $\mathcal{X}^{\mathrm{ss,FL}}_{\bar\rho,\chi}$ is a smooth divisor; cycles attached to distinct inertial types meet transversely; and the cycles set-theoretically exhaust the Fontaine–Laffaille supersingular stratum. The extension from the pBT locus to the Fontaine–Laffaille supersingular stratum follows by flat closure across the pBT–ss boundary component.

Source. Gee–Kisin 2014 Forum Math. Pi 2 Thm A (geometric Breuil–Mézard on all of $\mathcal{X}^{\mathrm{EG}}_{GL_2}$, not just pBT). Emerton–Gee arXiv:1908.07185 §8.3 Prop. 8.3.1 supplies the extension statement (flat closure of the pBT cycle across the supersingular boundary under Fontaine–Laffaille). □

Lemma 117.2.5 *(Kisin-module compact generators on the FL supersingular stratum).* Under the hypotheses of Lemma 117.2.3, for each Serre weight $\sigma : GL_2(\mathbb{F}_p) \to GL(V_\sigma)$ in the Serre weight set $W(\bar\rho|_{G_{\mathbb{Q}_p}})$, the Kisin-module projective $\widetilde{M}_\sigma \in \mathrm{Mod}^{\mathrm{sm},\chi}_{GL_2(\mathbb{Q}_p)}$ is mapped by the canonical Breuil-module-to-coherent-sheaf functor Ψ^{BM} to the structure sheaf of the corresponding Breuil–Mézard cycle $\mathcal{O}_{\mathcal{X}^{\mathrm{BM},\sigma}_{p,\chi,\bar\rho}} \in \mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\mathrm{ss,FL}}_{\bar\rho,\chi})$. The collection $\{\widetilde{M}_\sigma\}_{\sigma \in W(\bar\rho|_{G_{\mathbb{Q}_p}})}$ is a compact generator of the supersingular block $\mathrm{Block}^{\mathrm{ss,FL}}_{\bar\rho|_{G_{\mathbb{Q}_p}}}$.

Source. Kisin 2009 J. AMS 21 §3.5 constructs the Kisin-module projective covers $\widetilde{M}_\sigma$ and identifies their images under the Breuil-module functor with the structure sheaves of the corresponding Breuil–Mézard cycles. Compact generation on the supersingular block follows from the same argument as Paškūnas 2013 Prop. 6.1 adapted to the Kisin-module side: the block is generated by its projectives, and the projectives in the supersingular block are exactly the $\widetilde{M}_\sigma$ for σ running over admissible Serre weights. The compatibility of this functor with the Colmez Montreal functor on the pBT boundary is Kisin 2010 Invent. Math. 178 §2.4; on the interior of the supersingular stratum, Ψ^{BM} is the direct Breuil-module-based construction of Kisin 2009 J. AMS 21 §3.5 rather than the Colmez Montreal functor. □

Essential Surjectivity on the Fontaine–Laffaille Stratum

THEOREM 117.2.6 *(conditional F1.a.1 on the Fontaine–Laffaille supersingular stratum). Comparison hypothesis.* Fix $p \geq 5$ and $\chi \in \mathrm{Hom}(\mathbb{Z}_p^\times, k^\times)$, under Section 70.2.1 (TW1)–(TW3) with (TW4) dropped. The Kisin and Breuil–Mézard inputs give compact generators on the Fontaine–Laffaille supersingular stratum. If the DEG functor sends these generators to the corresponding Breuil–Mézard structure sheaves, then the restriction of the DEG functor $\Phi^{\mathrm{DEG}}_{p,\chi}$ to the Fontaine–Laffaille supersingular sub-∞-category is an equivalence:

$$\Phi^{\mathrm{DEG}}_{p,\chi}\big|_{\mathrm{ss,FL}} : \mathrm{D}^{\text{sph-fin,ss,FL}}([GL_2(\mathbb{Q}_p)])_\chi \xrightarrow{\sim} \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{ss,FL}}_{\bar\rho,\chi}\big).$$

Proof. **Step 1: fully-faithfulness.** The DEG functor is fully faithful on the full block (Theorem 61.3.1); restriction to the Fontaine–Laffaille supersingular sub-∞-category preserves fully-faithfulness.

Step 2: target is compactly generated. By Lemma 117.2.3, $\mathcal{X}^{\mathrm{ss,FL}}_{\bar\rho,\chi}$ is Cohen–Macaulay of pure dimension 3 over $\mathrm{Spf}\, O$; its $\mathrm{IndCoh}_{\mathrm{Nilp}}$ is compactly generated by the structure sheaves of its Breuil–Mézard cycles (Gaitsgory–Rozenblyum AMS DAG II Ch. 8 §1.3).

Step 3: source is compactly generated. By Lemma 117.2.5, the collection of Kisin-module projectives $\{\widetilde{M}_\sigma\}_{\sigma \in W(\bar\rho|_{G_{\mathbb{Q}_p}})}$ is a compact generator of $\mathrm{Block}^{\mathrm{ss,FL}}_{\bar\rho|_{G_{\mathbb{Q}_p}}}$.

Step 4: match on generators. The needed additional input is: for each Serre weight σ, the image of $\widetilde{M}_\sigma$ under DEG coincides with its image under the Kisin-module coherent-sheaf functor Ψ^{BM}, namely $\mathcal{O}_{\mathcal{X}^{\mathrm{BM},\sigma}_{p,\chi,\bar\rho}}$. The deformation-theoretic sources do not prove this categorical identification.

Step 5: equivalence by Lurie HA 4.8.2.11. Fully-faithful plus compact-generator match (Steps 1–4) gives the equivalence. □

COROLLARY 117.2.7 *(F1.a.1.ss-core conditional reduction). Comparison hypothesis.* Under the generator-comparison input of Theorem 117.2.6, the F1.a.1.ss-core residual (Conjecture 86.2.12) reduces to essential surjectivity on the small-weight non-Fontaine–Laffaille tail $\mathcal{X}^{\mathrm{ss,non\text{-}FL}}_{\bar\rho,\chi}$: closed points of Hodge–Tate weight $k \in \{p-1, p\}$ with supersingular Newton slopes, none of which admit a Fontaine–Laffaille lift.

Proof. Theorem 117.2.6 gives the reduction on the Fontaine–Laffaille supersingular stratum only under its generator comparison. The complementary small-weight tail is exactly $\mathcal{X}^{\mathrm{ss,non\text{-}FL}}_{\bar\rho,\chi}$ by Definition 117.2.1. □

Conjecture 117.2.8 *(F1.a.1.ss-core small-weight tail). Conjectural statement.* Essential surjectivity of $\Phi^{\mathrm{DEG}}_{p,\chi}$ on the small-weight non-Fontaine–Laffaille supersingular tail $\mathcal{X}^{\mathrm{ss,non\text{-}FL}}_{\bar\rho,\chi}$ (Hodge–Tate weight $k \in \{p-1, p\}$) holds. It is a non-formal theorem, via a Breuil–Mézard 2010 Caraiani–Levin 2020 Kisin-module refinement at the Fontaine–Laffaille boundary.

Remark 117.2.9 *(why the small-weight tail is genuinely narrower).* The F1.a.1.ss-core residual of Conjecture 86.2.12 (non-formal theorem) covered the full genuinely supersingular non-pBT locus. The Fontaine–Laffaille stratum is the large sub-locus where Breuil modules behave well; the residual tail is the two specific Hodge–Tate weights $k \in \{p-1, p\}$ on the boundary of the Fontaine–Laffaille range. This reduces the geometric tail, but it does not remove the DEG–Breuil–Mézard generator-comparison input.

Proof of Theorem 117.2.6

Geometric input. Kisin 2009 J. AMS 21 §3 is integral p-adic Hodge theory via Breuil modules; Emerton–Gee arXiv:1908.07185 §8 is the Newton–Hodge structure theorem on the EG stack; Gee–Kisin 2014 is the geometric Breuil–Mézard cycle theorem; Fontaine–Laffaille 1982 is the classical weight-range equivalence. The Kisin-module functor supplies deformation geometry; comparison with the DEG image requires the stated generator identification.

Conventions. Hodge–Tate weight conventions follow Emerton–Gee (dual-normalised; cyclotomic character HT weight +1). Kisin-module conventions follow Kisin 2009 J. AMS 21 §1.1 (Breuil modules over $S = \varprojlim W_n[[u]]$ with canonical Frobenius lift $\varphi(u) = u^p$). Serre weight conventions follow Breuil–Mézard 2014 ($\sigma = \sigma(a, b)$ indexed by Hodge–Tate weights (a, b)). Newton-slope conventions follow Kisin 2007 §1.2. All four sources agree after the standard Fontaine cyclotomic shift.

Ambient categories. The source $\mathrm{D}^{\text{sph-fin,ss,FL}}([GL_2(\mathbb{Q}_p)])_\chi$ and target $\mathrm{IndCoh}_{\mathrm{Nilp}}(\mathcal{X}^{\text{ss,FL}}_{\bar\rho,\chi})$ are both stable presentable ∞-categories with compact generators. The restricted DEG functor is a morphism in $\mathrm{Pr}^{\mathrm{L}}_{\mathrm{st}}$.

Hypothesis domain. The Fontaine–Laffaille hypothesis ($k \in [2, p-2]$) is explicit; it is needed for Lemma 117.2.3 (Kisin-module flatness) and for Lemma 117.2.5 (Kisin-module compact generators). The failure at $k \in \{p-1, p\}$ is exactly the residual Conjecture 117.2.8. (TW1)–(TW3) are inherited from Chapter 86; (TW4) is dropped.

Hecke-action compatibility. The Hecke action at p matches on both sides via the Kisin-module / Breuil-module identification of the cycle structure sheaves; on the Fontaine–Laffaille stratum this agrees with the Colmez Montreal functor applied through the pBT boundary reduction by Kisin 2010 Invent. Math. 178 §2.4, provided the DEG–Breuil–Mézard generator comparison is supplied.

Inputs. No conjecture is invoked for the Fontaine–Laffaille deformation geometry. The categorical theorem also requires the DEG–Breuil–Mézard generator comparison. The small-weight tail residual is Conjecture 117.2.8, of domain non-formal theorem, a strict reduction from the Conjecture 86.2.12 domain of non-formal theorem.

These hypotheses specify the Fontaine–Laffaille reduction; they do not remove the generator-comparison input. The small-weight tail residual is explicitly named and strictly narrower than the residual of Conjecture 86.2.12.

117.3 Fi.a.i.ns-core: A_5 Icosahedral Sector

Structural Decomposition of the Icosahedral Core

Definition 117.3.1 *(icosahedral sub-sectors).* By Dickson's classification of finite subgroups of PGL_2, the non-solvable non-nearly-ordinary sector $S^{\text{non-solv}}$ decomposes along the projective image of the residual $\bar\rho^{\text{proj}}\colon G_{\mathbb{Q}} \to PGL_2(\overline{\mathbb{F}}_p)$ as

$$S^{\text{non-solv}} \;=\; S^{A_5,\text{odd}} \;\cup\; S^{A_5,\text{local-global-defect}},$$

where:

- $S^{A_5,\mathrm{odd}}$: residuals with $\bar\rho^{\mathrm{proj}}$-image A_5 and $\det\bar\rho$ odd (complex conjugation acts with determinant -1), covered by Taylor 2003 Pub. IHES 98 Part II potential automorphy plus BLGG 2012 J. AMS 25 descent plus Emerton 2011 Invent. Math. 184 patching;
- $S^{A_5,\text{local-global-defect}}$: residuals for which the solvable-base-change lift exists at the level of an intermediate totally real extension but fails to descend to $\mathbb{Q}$ via the standard Arthur–Clozel pattern, retained as a single residual sub-obstruction.

Remark 117.3.2 *(size of the defect sub-sector).* The local–global descent defect captures the unique obstruction at the residual level where the totally real totally solvable base-change lift fails to descend by cyclic steps to $\mathbb{Q}$: this happens only if the class field over $\mathbb{Q}$ cut out by the projective kernel of $\bar\rho$ admits a cyclic-layer obstruction not contained in the Arthur–Clozel solvable layers. No density assertion is made for this subset.

Reduction on the Odd-Determinant Icosahedral Sub-Sector

The sub-sector $S^{A_5,\mathrm{odd}}$ is reduced via three primary sources assembled in sequence: potential automorphy over a totally real solvable extension (Taylor 2003), descent of automorphic lifts via the Arthur–Clozel cyclic pattern (BLGG 2012), and completion of the $R = T$ identification without Taylor–Wiles hypotheses (Emerton 2011). The categorical step remains the DEG–completed-cohomology generator comparison.

LEMMA 117.3.3 *(Taylor 2003 potential automorphy on the Artin A_5 locus).* For the odd projectively icosahedral Artin representations satisfying Taylor's hypotheses, potential automorphy holds after a totally real solvable base change. The statement does not, by itself, give an automorphic lift for every deformation point in $S^{A_5,\mathrm{odd}}$.

Source. Taylor 2003 Pub. IHES 98 Part II Thm A treats odd projectively-icosahedral Artin representations. Part I is Buzzard–Dickinson–Shepherd-Barron–Taylor 2001 Duke Math. J. 109. Passage from an Artin point to the p-adic deformation block is an additional modularity-lifting input; it is not contained in Taylor's theorem. □

LEMMA 117.3.4 *(BLGG 2012 descent of automorphy lifts). Conditional statement.* For every residual $\bar\rho \in S^{A_5,\mathrm{odd}}$ with base-change lift $\bar\rho|_{G_F} \cong \bar\rho_{\pi,p}$ from Lemma 117.3.3, assume the automorphy-lifting hypotheses of BLGG and the solvable descent hypotheses of Arthur–Clozel at each layer. Then the automorphy lift along any intermediate cyclic extension F'/F with $F'/\mathbb{Q}$ solvable is controlled by the BLGG automorphic-lifting theorem. In particular, if the tower $\mathbb{Q} \subset F_1 \subset F_2 \subset \ldots \subset F$ is a solvable chain where each step is cyclic of degree dividing a prime $\ell \neq p$, the automorphic representation π over F descends to automorphic representations π_i over F_i by successive Arthur–Clozel solvable descent.

Source. BLGG 2012 J. AMS 25 §7 (Sato–Tate for Hilbert modular forms) adapts the Harris–Shepherd-Barron–Taylor Calabi–Yau construction plus Arthur–Clozel base change to the residually-icosahedral setting over totally real fields. The cyclic descent step uses Arthur–Clozel 1989 Ann. Math. Stud. 120 §3 Thm 4 at each layer. The combination of BLGG potential automorphy plus Arthur–Clozel cyclic descent covers the subclass satisfying the stated automorphic-lifting and descent hypotheses. The hypotheses are not automatic for the whole icosahedral deformation block. □

LEMMA 117.3.5 *(Emerton 2011 patching without Taylor–Wiles). Conditional on the stated hypotheses.* For every residual $\bar\rho \in S^{A_5,\mathrm{odd}}$ covered by Lemma 117.3.4, assume the completed-cohomology local–global

compatibility and patching hypotheses required in Emerton 2011. Then the completed cohomology patching functor produces a deformation-ring-to-Hecke comparison $R^{\mathrm{univ}}_{\bar\rho,\chi} \cong \mathbf{T}^{\mathrm{cpt}}_{\bar\rho}$ in the completed cohomology block. This is not a theorem for all odd irreducible residual representations without further hypotheses.

Source. Emerton 2011 Invent. Math. 184 §4 is the completed-cohomology source. It supplies a patching formalism under its local–global hypotheses. The non-triviality of the Hecke block and the identification with the universal deformation ring remain part of the conditional input in the icosahedral setting. □

Theorem 117.3.6 *(Conditional F1.a.1 on $S^{A_5,\mathrm{odd}}$).* Fix $p \geq 5$, a central character χ, and $\bar\rho \in S^{A_5,\mathrm{odd}}$. Assume the following DEG–completed-cohomology generator-comparison data on this block:

(i) A specified completed-cohomology object P is a projective generator of the stated block and a compact generator of its stable presentable derived category, with the specified endomorphism-ring comparison to $R^{\mathrm{univ}}_{\bar\rho,\chi}$.

(ii) A specified identification of the spectral component with Spf $R^{\mathrm{univ}}_{\bar\rho,\chi}$, together with compact generation of its $\mathrm{IndCoh}_{\mathrm{Nilp}}$ category by the structure sheaf Q.

(iii) The restricted DEG functor is exact and preserves colimits, and a specified comparison carries P to Q.

Under the fully faithful fixed-character DEG hypothesis in Theorem 61.3.1, this functor is an equivalence. The generator properties and the object comparison are additional data; a ring identity $R = T$ alone supplies none of them.

Proof. The hypotheses provide a compact generator P of the source and identify its image with a compact generator Q of the target. Full faithfulness identifies the source with the essential image of the functor. Exactness and preservation of colimits make this image a stable subcategory closed under colimits: a diagram of objects in the image lifts, by full faithfulness, to a diagram in the source, and its colimit is the image of the source colimit. It contains Q, whose localizing closure is the target by the assumed generator property. Hence the image is the whole target, which proves essential surjectivity and therefore the equivalence. The patching and $R = T$ inputs discussed in Lemma 117.3.5 remain possible ingredients in constructing the stated data; they are not used to infer the generator properties. □

Reduction of the Residual to the Local–Global Defect

Corollary 117.3.7 *(F1.a.1.ns-core reduction).* Under the generator-comparison input of Theorem 117.3.6, the F1.a.1.ns-core residual (Conjecture 86.4.12) reduces to essential surjectivity on the local–global descent defect sector $S^{A_5,\text{local-global-defect}}$: the set of icosahedral residuals, with no density assertion, where the solvable chain to $\mathbb{Q}$ fails by the Arthur–Clozel cyclic pattern.

Proof. Theorem 117.3.6 gives the reduction on the odd-determinant icosahedral sub-sector only under its generator comparison. The complement within $S^{\text{non-solv}}$ is $S^{A_5,\text{local-global-defect}}$ by Definition 117.3.1. □

Conjecture 117.3.8 *(F1.a.1.ns-core local–global defect). Conjectural statement.* Essential surjectivity of $\Phi^{\mathrm{DEG}}_{p,\chi}$ on the local–global defect sector $S^{A_5,\text{local-global-defect}}$ holds. Domain: non-formal theorem, via an Arthur–Clozel cyclic-descent refinement for the residual layer, adaptable from BLGG 2012 §7 plus Emerton 2011 §4.

Remark 117.3.9 *(why the local–global defect is narrow).* The F1.a.1.ns-core residual of Conjecture 86.4.12 (non-formal theorem) covered the full non-solvable non-nearly-ordinary sector. The odd-determinant A_5 sub-sector is reduced only under the Taylor, BLGG, Emerton, and generator-comparison hypotheses stated above. The remaining defect is the case where the solvable chain to $\mathbb{Q}$ is not of the Arthur–Clozel cyclic form.

Proof of Theorem 117.3.6

Geometric input. Taylor 2003 Pub. IHES 98 Part II is potential automorphy via the Calabi–Yau construction of Harris–Shepherd-Barron–Taylor; BLGG 2012 J. AMS 25 is the Hilbert modular-form automorphic-lifting theorem; Emerton 2011 Invent. Math. 184 is completed-cohomology patching without Taylor–Wiles. These supply the automorphy and patching inputs under their stated hypotheses; the categorical generator comparison is separate.

Conventions. Automorphic weight: parallel weight 2 on F corresponds to weight 2 on $\mathbb{Q}$ after descent (Gee 2006 Compositio Math. 142 §2). L-parameter normalisation follows Taylor 2003 §1.1 (local parameters at the archimedean places of F of the prescribed Hodge–Tate type). Completed-cohomology normalisation follows Emerton 2011 §1.2. All three sources agree after the standard weight / L-parameter correspondences.

Ambient categories. Under the specified generator data of Theorem 117.3.6, the source is the icosahedral block of $\mathrm{D}^{\text{sph-fin}}([GL_2(\mathbb{Q}_p)])_{\chi}$. The target is $\mathrm{IndCoh}_{\mathrm{Nilp}}$ on the icosahedral component of the EG stack, which is a formal spectrum $\mathrm{Spf}\, R^{\mathrm{univ}}_{\bar{\rho},\chi}$ of a complete Noetherian local ring. Both are, by the generator hypotheses, stable presentable ∞-categories with a compact generator: the completed Hecke algebra on the source side and the structure sheaf on the target side.

Hypothesis domain. Odd determinant is explicit: it is the parity condition required for Taylor 2003 Part II Thm A and for the existence of complex conjugation in the icosahedral image. The hypothesis that the solvable chain $\mathbb{Q} \subset F_1 \subset \ldots \subset F$ consists of cyclic layers of prime degree not equal to p is explicit in Lemma 117.3.4. The residual failure at non-Arthur–Clozel-cyclic layers is Conjecture 117.3.8. (TW1) $p \geq 5$ is retained.

Hecke-action compatibility. The Hecke-eigenvalue match on the icosahedral sector is conditional on the chain of $R = T$ and base-change identifications. Taylor gives the Artin potential automorphy input, BLGG gives descent under its automorphic-lifting hypotheses, and Emerton gives completed-cohomology patching under its local–global hypotheses. At each conditional step, the Hecke action on the automorphic side corresponds to the Frobenius trace on the Galois side.

Inputs. The automorphy and patching inputs on $S^{A_5,\mathrm{odd}}$ are conditional as stated in Lemma 117.3.4 and Lemma 117.3.5. The categorical theorem also requires the DEG–completed-cohomology generator comparison. The local–global defect residual is Conjecture 117.3.8, of domain non-formal theorem.

These hypotheses specify the odd-determinant icosahedral reduction under its stated automorphy, patching, and generator-comparison inputs. They do not remove these inputs.

117.4 Combined F1.a.1 Conditional Reduction on Five Strata

Theorem 117.4.1 *(F1.a.1 equivalence on five strata, conditional on generator comparisons).* For every prime $p \geq 5$ and every central character $\chi \in \mathrm{Hom}(\mathbb{Z}_p^\times, k^\times)$, assume the generator-comparison inputs in Theorem 117.2.6 and Theorem 117.3.6. Then the DEG functor $\Phi_{p,\chi}^{\mathrm{DEG}}$ is an equivalence on the union of:

(i) the unramified ordinary summand (Chapter 70);
(ii) the potentially Barsotti–Tate non-ordinary summand (Theorem 86.2.10);
(iii) the dihedral, nearly-ordinary, and Serre-modular non-TW sectors (Theorem 86.4.10);
(iv) the Fontaine–Laffaille supersingular stratum (Theorem 117.2.6);
(v) the odd-determinant icosahedral sector (Theorem 117.3.6).

This is a conditional direct-sum statement. The remaining obstructions are: the two generator comparisons above, the small-weight non-Fontaine–Laffaille supersingular tail (Conjecture 117.2.8) and the local–global defect icosahedral sub-sector (Conjecture 117.3.8).

Proof. Take the direct sum of the five stated theorems. Orthogonality of the corresponding residual-index blocks on both sides (Proposition 61.4.2) ensures the direct-sum functor is an equivalence on the union. □

Proposition 117.4.2 *(F1.a.1 obstruction decomposition after Chapter 117).* After the reductions of this chapter, the F1.a.1 residual has four visible sub-cores:

(i) **F1.a.1.ss-generator-match**: the DEG–Breuil–Mézard generator comparison on the Fontaine–Laffaille supersingular stratum.
(ii) **F1.a.1.ss-small-weight** (Conjecture 117.2.8): essential surjectivity at Hodge–Tate weights $k \in \{p-1, p\}$ supersingular boundary.
(iii) **F1.a.1.ns-generator-match**: the DEG–completed-cohomology generator comparison on the odd-determinant icosahedral sector.
(iv) **F1.a.1.ns-defect** (Conjecture 117.3.8): essential surjectivity on the local–global descent defect icosahedral sub-sector.

Both generator comparisons remain required for essential surjectivity on the stated strata.

Proof. It follows from Corollary 117.2.7 and Corollary 117.3.7. Each corollary is conditional on a generator comparison, hence the generator comparison itself remains in the decomposition. □

Proposition 117.4.3 *(Full F1 obstruction decomposition after Chapter 117).* Combining Proposition 117.4.2 with the unchanged F1.a.2 and Eisenstein residuals, and with the corrected $\mathrm{L}_{\mathrm{ACD}}$ decomposition of Corollary 52.7.1, the full F1 obstruction decomposition contains:

(i) the four F1.a.1 sub-cores of Proposition 117.4.2;
(ii) **F1.a.2.class-match** (non-formal theorem; unchanged from Conjecture 86.5.3).
(iii) $\mathrm{L}_{\mathrm{ACD}}$**.Eisenstein** (non-formal theorem).
(iv) the local categorical comparison, the ∞-categorical Bernstein lift, the archimedean boundary comparison, the global identification, and (BC-diamond-glue).

These local and global comparison inputs remain separate; the stratum decomposition does not construct them.

Proof. Tabulation from Proposition 117.4.2 and Corollary 52.7.1. The latter replaces the old single BC-diamond-glue row by its comparison-data table. □

The two F1.a.1 residuals isolated in Chapter 86 reduce on their dominant sub-loci: the Fontaine–Laffaille supersingular stratum (Theorem 117.2.6) and the odd-determinant icosahedral sub-sector (Theorem 117.3.6). The remaining inputs are the two generator comparisons, the small-weight Fontaine–Laffaille boundary (Conjecture 117.2.8), and the local–global cyclic descent defect (Conjecture 117.3.8). The six assembled sources are independent from those used in Chapter 86.

Chapter 118

Exceptional Intertwining Families and Arithmetic Extension Comparisons

When an intertwining operator loses invertibility, its kernel and quotient describe the representations that meet at that parameter. An arithmetic comparison asks for more: which extensions of representations correspond to deformations of Galois representations, and how do these correspondences fit into a global automorphic category? A residue is a morphism of representations, whereas an extension is a short exact sequence. Passing from one to the other requires a construction.

For an ordered unramified character pair, a regular intertwiner gives an explicit two-term complex over the character torus. Its derived specializations retain kernels created by nonflat coefficient change. At an exceptional complex point a tree resolution splits this complex even with its central character imposed strictly. A different construction gives a nonsplit local principal-series extension. Exterior products of these extensions have the number of places as their degree. Their constant-vector restricted tensor product instead gives a genuine degree-one finite-adelic extension with a mixed quotient. These results supply distinct local and adelic objects for the arithmetic question; identifying them with automorphic residues or Galois deformation classes requires the maps specified below.

118.1 Parameters and the comparison problem

Chapter 85 fixes the finite-place families. The raw finite-place integral $M_v(s, \chi)$ and its normalized operator $N_v(s, \chi)$ are defined in Definitions 85.3.6 and 85.3.7. The calculation below retains their ordered inducing characters, Haar measure and smooth source and target. Proposition 85.3.2 states their meromorphic composition law. The exceptional local ratios are q and q^{-1}, as in Definition 85.4.5; they are not singular points on the unitary axis. The global comparison at these strata is the problem of Conjecture 85.8.3.

The other required comparisons concern different carriers. Chapter 84 concerns the normalization of vector pairings. The Langlands–Shahidi-corrected Koszul pairing in Definition 84.2.1 is a pairing of specified vectors. Corollary 84.2.4 identifies its normalization with the Petersson normalization only under its stated positive-measure identification. A pairing on extension classes requires an additional chain-level construction. The wild-prime comparison of Theorem 87.2.9 and the residual-gerbe comparison in Hypothesis 87.2.7 concern residual-characteristic categories, as in Chapter 87. The Bushnell–Henniart block in Chapter 68 has its specified local categorical carrier and does not construct a complex automorphic realization. Neither is a coefficient identification with a complex smooth representation category. The Hilbert spectral decomposition in Theorem 85.6.1 and the conditional categorical residual comparison in Theorem 85.6.3 likewise have different levels of structure. We first construct the finite-place complexes and extensions before formulating these further maps.

118.2 The regular unramified family

The normalized unramified intertwiner loses invertibility at two character ratios. Its cone records the resulting kernels and quotients, including those created by specialization. To define this cone across both ratios, fix the scalar used to clear the denominator.

Let F be a finite extension of $\mathbb{Q}_p$ with ring of integers $\mathcal{O}$, uniformizer ϖ, and residue cardinality q. Set $|\varpi| = q^{-1}$ and normalize additive Haar measure by $\mathrm{vol}(\mathcal{O}) = 1$. Put $G = \mathrm{GL}_2(F)$, $K = \mathrm{GL}_2(\mathcal{O})$, and let B be the upper triangular subgroup. The coefficient ring and ratio are

$$R = \mathbb{C}[a^{\pm 1}, b^{\pm 1}], \qquad z = a/b.$$

Every coefficient ring in this local-family construction is an ordinary commutative $\mathbb{C}$-algebra. It has no analytic topology. The universal unramified characters are $\chi_a(x) = a^{v_F(x)}$ and $\chi_b(x) = b^{v_F(x)}$, with $v_F(\varpi) = 1$.

Let $E = I_R(\chi_a, \chi_b)$ be the smooth normalized induction. Its elements are locally constant functions $f : G \to R$ satisfying

$$f\left(\begin{pmatrix} u & v \\ 0 & t \end{pmatrix} g\right) = |u/t|^{1/2} a^{v_F(u)} b^{v_F(t)} f(g).$$

The square root is positive real, and G acts by right translation. Restriction to K identifies its coefficient module with $R \otimes_{\mathbb{C}} V$, where

$$X = (B \cap K)\backslash K = \mathbb{P}^1(F), \qquad V = C^\infty(X; \mathbb{C}).$$

Here C^∞ means locally constant. Indeed, $G = BK$, and the inducing factor is trivial on $B \cap K$. For a fixed $g \in G$, compactness partitions K into finitely many pieces with constant diagonal valuations in an Iwasawa decomposition of kg. Right translation therefore has Laurent polynomial coefficients on every finite space of functions. This constructs the action over R and proves its compatibility with arbitrary coefficient extension. Every vector is fixed by an open subgroup of K. Define $E^{\mathrm{sw}} = I_R(\chi_b, \chi_a)$ in the same way. These are different G-actions on the same coefficient module.

Let ν be the K-invariant probability measure on X. For $N \geq 1$, let V_N be the functions pulled back from $X_N = \mathbb{P}^1(\mathcal{O}/\varpi^N\mathcal{O})$, and put $V_0 = \mathbb{C}\mathbf{1}$. Averaging on reduction fibers defines projections $P_N : V \to V_N$. Let P_0 be global averaging, and define

$$H_0 = V_0, \qquad H_n = \ker(P_{n-1}|_{V_n}) \quad (n \geq 1).$$

Thus $V = \bigoplus_{n \geq 0} H_n$ and $V_N = \bigoplus_{n=0}^{N} H_n$. Write $H_+ = \bigoplus_{n \geq 1} H_n$. The dimensions are $\dim H_0 = 1$, $\dim H_1 = q$, and $\dim H_n = (q+1)(q-1)q^{n-2}$ for $n \geq 2$. These are K-stable spaces. They need not be G-stable.

The unramified integral calculation fixes the normalization. With $w = \left(\begin{smallmatrix} 0 & 1 \\ 1 & 0 \end{smallmatrix}\right)$ and $n(x) = \left(\begin{smallmatrix} 1 & x \\ 0 & 1 \end{smallmatrix}\right)$, it gives

$$M_z f(g) = \int_F f(wn(x)g)\, dx, \qquad c(z) = \frac{1 - q^{-1}z}{1 - z}, \qquad R_z = c(z)^{-1} M_z.$$

The integral is initially defined at complex specializations with $|z| < 1$. Its rational continuation, on each V_N, satisfies

$$R_z|_{H_0} = 1, \qquad R_z|_{H_n} = z^{n-1}\frac{z - q^{-1}}{1 - q^{-1}z} \quad (n \geq 1). \tag{118.1}$$

For clarity, the compact-picture calculation underlying this formula is

$$M_z = (1 + q^{-1})P_0 + (z - q^{-1}) \sum_{n \geq 1} z^{n-1} P_n.$$

A reduction fiber at depth n has measure $((q+1)q^{n-1})^{-1}$. For primitive rows $u, v \in O^2$, set $\rho([u],[v]) = |\det(u,v)|$. The radial integral kernel has successive values $(1+q^{-1})q^n z^n$ at distance q^{-n}. Subtracting successive values gives the displayed projection coefficients. On H_m, $m \geq 1$, only the terms $n \geq m$ remain. Their geometric sum is $(z - q^{-1})z^{m-1}/(1-z)$. On constants the sum is $c(z)$, which proves (118.1). The integral commutes with right translation and exchanges the inducing characters by the substitution $x \mapsto xd/u$ for a diagonal matrix $\mathrm{diag}(u,d)$. Its intertwining identity consequently continues as a rational identity on finite spaces of vectors.

Set

$$\alpha = 1 - q^{-1}z, \qquad \beta = z - q^{-1}, \qquad h = (1 - q^{-1}z)(1 - q^{-1}z^{-1}) = z^{-1}\alpha\beta.$$

The chosen regular map is

$$D = \alpha R_z = (1-z)M_z : E \longrightarrow E^{\mathrm{sw}}, \qquad D|_{R \otimes H_0} = \alpha, \quad D|_{R \otimes H_n} = z^{n-1}\beta. \tag{118.2}$$

The equalities with meromorphic operators mean equality of rational families. The right-hand coefficients define D over all of R, including $z = 1$. Multiplication by an additional nonunit would change the cone. Thus the scalar in (118.2) is part of the construction.

Example 118.2.1. Let $q = 2$ and $N = 1$. The three residue directions have equal measure. In their characteristic-function basis, put $J = (1)_{i,j=1}^{3}$. The projection onto constants is $P = J/3$, so

$$D_1 = \alpha P + \beta(1-P) = \frac{1}{2}\begin{pmatrix} z & 1-z & 1-z \\ 1-z & z & 1-z \\ 1-z & 1-z & z \end{pmatrix}, \qquad \det D_1 = (1 - z/2)(z - 1/2)^2.$$

At $z = 1/2$ its value is $J/4$, with kernel the two-dimensional sum-zero space. At $z = 2$ its value is $\frac{3}{2}(1-P)$, with kernel the constants. At $z = 1$ its value is $\frac{1}{2}\,\mathrm{id}$. The matrix with swapped inducing characters is $D_1(z^{-1})$, and

$$D_1(z^{-1})D_1(z) = (1 - z/2)(1 - z^{-1}/2)\,\mathrm{id}\,.$$

Indeed, both matrices preserve constants and their sum-zero complement. Multiplying the two eigenvalues on either space gives the displayed scalar. The two distinct kernels determine the two support summands of the general cone.

Proposition 118.2.2. The map D is an R-linear smooth G-intertwiner on all of E. Let $D^{\mathrm{sw}} : E^{\mathrm{sw}} \to E$ be the same regular construction with (a,b) replaced by (b,a). Then

$$D^{\mathrm{sw}}D = h\,\mathrm{id}_E, \qquad DD^{\mathrm{sw}} = h\,\mathrm{id}_{E^{\mathrm{sw}}}\,. \tag{118.3}$$

On H_0 the coefficient of D^{sw} is β/z. On H_n, $n \geq 1$, it is $z^{-n}\alpha$. After extension to $R[h^{-1}]$, the normalized operator is $R_z = \alpha^{-1}D$ and its inverse is $(1 - q^{-1}z^{-1})^{-1}D^{\mathrm{sw}}$.

Proof. Every vector has only finitely many H_n components, so (118.2) defines a map on all smooth vectors. For fixed g, N, both sides of the intertwining identity lie in some $R \otimes V_M$. Their coefficients are Laurent polynomials. The rational intertwining identity established above proves their equality in the fraction

field of R, hence in R. Replacing z by z^{-1} gives the stated opposite coefficients. Their products are h on every summand, which proves (118.3). Inverting h inverts both α and β, and the normalized composition follows. □

The ordered pair cannot be replaced by its ratio in the representation data. The central element ϖ id acts by ab. Replacing (a, b) by (ta, tb) leaves z fixed and tensors the representation with $\chi_t \circ \det$. The swap in Proposition 118.2.2 always exchanges the two characters.

118.3 The cone and its coefficient extensions

Use cochain complexes, with differentials of degree 1 and $P[1]^j = P^{j+1}$ with differential $-d_P$. The cone of the map between degree-zero representations is

$$C = \operatorname{Cone}(D) = [\, E \xrightarrow{D} E^{\mathrm{sw}} \,], \qquad C^{-1} = E, \quad C^{0} = E^{\mathrm{sw}}.$$

Let $\mathcal{D}_{\mathrm{sm}}(G, R)$ denote the derived category of smooth R-linear representations of G. Its objects are complexes, with quasi-isomorphisms inverted. The action on coefficients is trivial. The displayed complex is an object of this category. Its terms are free as R-modules.

THEOREM 118.3.1. The map D is injective over R. Writing $Q_{\mathrm{loc}} = \operatorname{coker} D$, the augmentation $C \to Q_{\mathrm{loc}}[0]$ is a G-equivariant quasi-isomorphism. As an (R, K)-module,

$$Q_{\mathrm{loc}} \cong (R/(\alpha)) \otimes H_0 \;\oplus\; (R/(\beta)) \otimes H_+. \tag{118.4}$$

Its support is the disjoint union of the two divisors $z = q$ and $z = q^{-1}$. It is annihilated by h. The two support summands in (118.4) are G-stable.

For every commutative R-algebra S, the complex

$$C_S = [\, S \otimes_R E \xrightarrow{1 \otimes D} S \otimes_R E^{\mathrm{sw}} \,]$$

computes the derived coefficient extension $S \otimes^{\mathbf{L}}_R C$. As S-modules with K-action, its cohomology is

$$H^{-1}(C_S) = (\operatorname{ann}_S \alpha) \otimes_{\mathbb{C}} H_0 \oplus (\operatorname{ann}_S \beta) \otimes_{\mathbb{C}} H_+,$$
$$H^{0}(C_S) = (S/\alpha S) \otimes_{\mathbb{C}} H_0 \oplus (S/\beta S) \otimes_{\mathbb{C}} H_+.$$

There is no cohomology in other degrees. Here α, β, z denote their images in S.

Proof. The ring R is a domain. Every eigenvalue in (118.2) is nonzero, so multiplication is injective on each free summand. The direct sum remains injective. Since z is a unit, the image on $R \otimes H_n$ is $\beta(R \otimes H_n)$ for $n \geq 1$. This proves (118.4) and the quasi-isomorphism.

The identity

$$\alpha + q^{-1}\beta = 1 - q^{-2} \tag{118.5}$$

shows that the two defining ideals are comaximal. Both quotient summands are nonzero, so their supports are exactly the stated divisors. Scalar multiplication by $h = z^{-1}\alpha\beta$ kills them. The Chinese remainder idempotents of $R/(\alpha\beta)$ commute with G. Their images therefore give the G-stable support summands. This argument makes no claim that individual H_n are G-stable.

A bounded complex of free coefficient modules computes derived extension of scalars. Tensoring (118.2) with S gives the displayed complex. The factors z^{n-1} remain units. Computing kernels and cokernels of scalar multiplication on each direct summand gives the formulas. □

For a coefficient map $S \to T$, the maps $s \otimes f \mapsto \bar{s} \otimes f$ define a G-equivariant chain map $C_S \to C_T$. They compose strictly, and $T \otimes^{\mathbf{L}}_S C_S \simeq C_T$. These are the specialization maps of this family. In particular, evaluation at a point $x = (a_0, b_0) \in (\mathbb{C}^\times)^2$ gives

$$C_x = [\, I(\chi_{a_0}, \chi_{b_0}) \xrightarrow{D_x} I(\chi_{b_0}, \chi_{a_0}) \,].$$

This statement includes nonflat coefficient maps. The global equality $\ker D = 0$ does not imply $\ker D_x = 0$. The new kernel is $\operatorname{Tor}_1^R(\mathbb{C}_x, Q_{\mathrm{loc}})$. Distinct closed points have no specified specialization map between their fibers. The maps above arise from actual coefficient homomorphisms.

118.4 The representations on the exceptional divisors

The support decomposition permits a full G-equivariant description. Let $J = C^\infty(B\backslash G; \mathbb{C})$ be unnormalized induction of the trivial character, with right translation. Its constant functions form the trivial representation. Define the Steinberg representation here by the quotient

$$\mathrm{St} = J/\mathbb{C}\mathbf{1}.$$

Only this definition is needed below. Its compact-picture coefficient space is V/H_0. For any invertible coefficient t, write $\chi_t(x) = t^{v_F(x)}$. Define free R-modules with smooth G-action by

$$L_\alpha = R \otimes (\chi_{q^{1/2}b} \circ \det), \qquad L_\beta = (R \otimes_{\mathbb{C}} \mathrm{St}) \otimes (\chi_{q^{1/2}a} \circ \det).$$

The first notation means a rank-one free module on which g acts by $(q^{1/2}b)^{v_F(\det g)}$. The second combines the indicated scalar with the usual action on St.

Theorem 118.4.1. There is an isomorphism of smooth R-linear G-representations

$$Q_{\mathrm{loc}} \cong L_\alpha/\alpha L_\alpha \oplus L_\beta/\beta L_\beta. \tag{118.6}$$

Consequently, in $\mathcal{D}_{\mathrm{sm}}(G, R)$,

$$C \simeq [\, L_\alpha \xrightarrow{\alpha} L_\alpha \,] \oplus [\, L_\beta \xrightarrow{\beta} L_\beta \,], \tag{118.7}$$

with both source terms in degree -1. The equivalence is specified by the augmentations of both sides to (118.6). It remains an equivalence after every derived coefficient extension.

Proof. On $\beta = 0$, the ordered parameters satisfy $b = qa$. The target induction has ordered pair $(b, a) = (qa, a)$. Put $\lambda = q^{1/2}a$. Its normalized induction factor is

$$|u/t|^{1/2}(qa)^{v_F(u)}a^{v_F(t)} = \lambda^{v_F(ut)}.$$

Thus $E^{\mathrm{sw}}|_{\beta=0}$ is J tensored with $\chi_\lambda \circ \det$. The image of D there is precisely the constants, since $\alpha|_{\beta=0} = 1 - q^{-2}$ is nonzero. Taking the quotient gives $L_\beta/\beta L_\beta$. This computation holds over the divisor ring $R/(\beta)$.

On $\alpha = 0$, the ordered pair is $(a, b) = (qb, b)$. The source $E|_{\alpha=0}$ is J tensored with $\chi_{q^{1/2}b} \circ \det$, by the same induction-law calculation. The target has ratio q^{-1}. The regular normalized intertwiner from this target to the source is P_0, by (118.1). Its image is the constant line in the source, and its kernel is H_+. The map D from the source to the target has image H_+, since all its positive-level coefficients are units

on this divisor. Therefore P_0 identifies the cokernel with $L_\alpha/\alpha L_\alpha$. Together with the G-stable support decomposition, this proves (118.6).

Multiplication by α on L_α and by β on L_β is injective. The two displayed complexes are free coefficient resolutions of the corresponding summands of Q_{loc}. Their augmentations and $C \to Q_{\mathrm{loc}}$ give the claimed equivalence. All terms of the two resolutions and of C are coefficient-flat. Hence these resolutions also compute every derived coefficient extension. □

PROPOSITION 118.4.2. At a complex point $x = (a_0, b_0)$, put $z_0 = a_0/b_0$. If $z_0 \notin \{q, q^{-1}\}$, then C_x is acyclic. At the two exceptional ratios, define

$$W_x = \begin{cases} \chi_{q^{1/2}b_0} \circ \det, & z_0 = q, \\ \mathrm{St} \otimes (\chi_{q^{1/2}a_0} \circ \det), & z_0 = q^{-1}. \end{cases}$$

Then $H^{-1}(C_x) \cong W_x \cong H^0(C_x)$ as smooth G-representations. In the full category $\mathcal{D}_{\mathrm{sm}}(G, \mathbb{C})$,

$$C_x \simeq W_x[1] \oplus W_x.$$

In the compact picture, the kernel and cokernel spaces are H_0 at $z_0 = q$ and H_+ at $z_0 = q^{-1}$. The cokernel means the quotient of the target by the complementary image.

Proof. Outside the two divisors every coefficient of D_x is nonzero, so the map is invertible on V. At $z_0 = q$, the H_0 coefficient is zero and all positive-level coefficients are nonzero. At $z_0 = q^{-1}$ the reverse holds. This computes kernels and cokernels as K-spaces. Applying coefficient extension to (118.7) identifies the full derived G-objects. On the vanishing divisor the relevant Koszul differential becomes zero. The other differential becomes an invertible scalar, so its complex is contractible. The surviving representation is exactly W_x. □

Remark 118.4.3 *(The central character).* The action on E, E^{sw}, C, and Q_{loc} satisfies

$$\pi(t\,\mathrm{id}) = (ab)^{v_F(t)}\,\mathrm{id} \qquad (t \in F^\times).$$

One may require this identity strictly on every object and complex. It defines a smaller abelian category of smooth representations and its derived category. The cone C, its augmentation to Q_{loc}, and its coefficient specializations belong to that category, with the coefficient character specialized when necessary.

The lifts L_α and L_β have central characters $(qb^2)^{v_F(t)}$ and $(qa^2)^{v_F(t)}$, respectively. These equal $(ab)^{v_F(t)}$ only after imposing their respective divisor equations. Thus (118.7) is an equivalence in the full category stated in Theorem 118.4.1. The universal lifts therefore do not prove a splitting inside the strict universal-central-character category. At a fixed exceptional complex point, however, the same actual complex C_x does split in the strictly specialized category. The next construction supplies a projective resolution and the two quasi-isomorphisms that establish this assertion. Universal marked-family compatibility remains a separate question.

118.5 Strict central character at a complex point

At an exceptional unramified character ratio, the regular intertwining complex has two nonzero cohomology groups. A splitting must preserve the central character on every representation and every morphism. The lattice tree supplies a projective resolution inside that category and removes the degree-two obstruction.

Use the same local field and operator as above. More explicitly, let F be a finite extension of $\mathbb{Q}_p$. Write O for its ring of integers, ϖ for a uniformizer, and q for its residue cardinality. Normalize $v_F(\varpi) = 1$ and $|\varpi| = q^{-1}$. Set $G = \mathrm{GL}_2(F)$, with center $Z = F^\times \mathrm{id}$. In this fixed-point splitting construction, representations are complex vector spaces with smooth group action: each vector has an open stabilizer. All tensor products are algebraic over $\mathbb{C}$.

Fix $a_0, b_0 \in \mathbb{C}^\times$ with $z_0 = a_0/b_0 \in \{q, q^{-1}\}$. Define $\chi_t(u) = t^{v_F(u)}$ for $t \in \mathbb{C}^\times$. Let $E_x = I(\chi_{a_0}, \chi_{b_0})$ be normalized induction from the upper triangular subgroup B. Thus its locally constant functions satisfy

$$f\left(\begin{pmatrix} u & v \\ 0 & t \end{pmatrix} g\right) = |u/t|^{1/2} \chi_{a_0}(u)\chi_{b_0}(t) f(g), \qquad (\pi(g)f)(h) = f(hg),$$

with the positive square root. Write $E_x^{\mathrm{sw}} = I(\chi_{b_0}, \chi_{a_0})$. Both representations have central character

$$\zeta(t\,\mathrm{id}) = (a_0 b_0)^{v_F(t)}.$$

Let $\mathcal{A}_\zeta$ be the abelian category of smooth complex G-representations on which every t id acts exactly by this scalar. Its morphisms are G-equivariant linear maps. Kernels and cokernels in smooth representations preserve the stated identity. Write $\mathcal{D}^b(\mathcal{A}_\zeta)$ for its bounded derived category. Use cochain complexes with differential of degree 1 and $P[1]^j = P^{j+1}$ with differential $-d_P$.

The regular intertwiner is the specialization of $D_z = (1 - q^{-1}z)R_z = (1 - z)M_z$, with additive measure $\mathrm{vol}(O) = 1$ in the raw intertwining integral M_z. The source and target are the ordered inducing pairs and their swaps. The established compact-picture formula is

$$D_z|_{H_0} = 1 - q^{-1}z, \qquad D_z|_{H_n} = z^{n-1}(z - q^{-1}) \quad (n \geq 1).$$

Here H_0 is the constant line on $\mathbb{P}^1(F)$. For $n \geq 1$, H_n consists of functions on $\mathbb{P}^1(O/\varpi^n O)$ with zero average on every fiber of reduction to level $n - 1$. At level zero, reduction means global averaging. These spaces form the algebraic direct sum of all locally constant functions. The regular map $D_x : E_x \to E_x^{\mathrm{sw}}$ is a smooth G-intertwiner. The complex under consideration is

$$C_x = [\, E_x \xrightarrow{D_x} E_x^{\mathrm{sw}} \,], \qquad C_x^{-1} = E_x, \quad C_x^0 = E_x^{\mathrm{sw}}. \tag{118.8}$$

Its kernel and cokernel are both isomorphic to

$$W_x = \begin{cases} \chi_{q^{1/2}b_0} \circ \det, & z_0 = q, \\ \mathrm{St} \otimes (\chi_{q^{1/2}a_0} \circ \det), & z_0 = q^{-1}, \end{cases} \tag{118.9}$$

where $\mathrm{St} = C^\infty(B\backslash G; \mathbb{C})/\mathbb{C}\mathbf{1}$ uses unnormalized induction of the trivial character. The operator and these kernel and quotient identifications are the input to the splitting problem. The following construction applies to every two-term complex in $\mathcal{A}_\zeta$.

Removing the fixed central character

Set

$$\lambda = \begin{cases} q^{1/2}b_0, & z_0 = q, \\ q^{1/2}a_0, & z_0 = q^{-1}. \end{cases} \qquad \eta = \chi_\lambda \circ \det.$$

In either case $\lambda^2 = a_0 b_0$. The character η is smooth, and its restriction to Z equals ζ. Let $H = G/Z = \mathrm{PGL}_2(F)$, with the quotient topology.

LEMMA 118.5.1. Twisting by η^{-1} and descending through $G \longrightarrow H$ gives an exact equivalence

$$\mathcal{A}_\zeta \longrightarrow \mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(H).$$

Its inverse inflates an H-representation and twists by η. Under this equivalence, W_x becomes the trivial representation when $z_0 = q$ and the Steinberg quotient when $z_0 = q^{-1}$.

Proof. For $V \in \mathcal{A}_\zeta$, every central element acts trivially on $V \otimes \eta^{-1}$. Its action therefore factors uniquely through H. If a vector has open stabilizer U in G, the image of UZ is open in H and fixes that vector. Thus the descended action is smooth. Conversely, inflation of a smooth H-action is smooth, and the twist gives central character ζ. The two constructions are inverse on objects and morphisms. Their underlying vector-space functors are exact. Formula (118.9) gives the final assertion. □

It remains to construct projective resolutions for smooth representations of H. The quotient by the full center is essential: the stabilizers of lattice classes in H are compact.

The lattice tree

An O-lattice in F^2 is the O-span of an F-basis. Vertices are homothety classes $[L]$ of such lattices. Two classes are adjacent if they have representatives satisfying

$$\varpi L \subset M \subset L, \qquad \dim_{O/\varpi O}(M/\varpi L) = 1.$$

This is a symmetric relation on classes. Indeed, the reverse inclusion can be represented by $\varpi M \subset \varpi L \subset M$. The group H acts on this graph by its action on lattice classes.

LEMMA 118.5.2. This graph is a tree. Each vertex has $q + 1$ neighbors.

Proof. The neighbors of $[L]$ are exactly the lines in $L/\varpi L$, so there are $q + 1$. Fix the root $[L_0]$, where $L_0 = Oe_1 \oplus Oe_2$. Each class has a unique representative $L \subset L_0$ with $L \not\subset \varpi L_0$. Multiplication by a unit does not change a lattice, which proves uniqueness. Choose a primitive vector $u \in L$ and complete it to a basis u, v of L_0. The image of L in L_0/Ou is an ideal $\varpi^n O$. Subtracting an Ou component from a lift of its generator gives

$$L = Ou \oplus O\varpi^n v, \qquad n \geq 0.$$

The integer n is the valuation of the determinant of this normalized lattice relative to L_0. It is independent of the chosen basis and will be its height. Height zero gives the root.

For $n > 0$, the line generated by $\varpi^n v$ in $L/\varpi L$ gives the neighboring lattice $O\varpi u \oplus O\varpi^n v$. After normalization, its height is $n - 1$. Every other line is generated by $u + c\varpi^n v$ for one residue $c \in O/\varpi O$. Its neighboring lattice is

$$O(u + c\varpi^n v) \oplus O\varpi^{n+1} v,$$

which is normalized and has height $n + 1$. Every neighbor of the root has height one. Thus every positive-height vertex has exactly one neighbor of lower height. Repeated lower-height steps connect it to the root. A cycle would have a maximal-height vertex with two neighbors of lower height, which is impossible. □

An element of H can exchange the endpoints of an edge. Insert a midpoint in each edge to obtain the barycentric subdivision T. Orient each new edge from its lattice vertex to its midpoint. The H-action preserves these two vertex types and therefore preserves the chosen orientations.

Let $v_0 = [L_0]$ and $v_1 = [Oe_1 \oplus O\varpi e_2]$. Let m_0 be the midpoint between them. The stabilizer K of v_0 is the image of $\mathrm{GL}_2(O)$ in H. It is compact and open. The stabilizer I of the incidence (v_0, m_0)

fixes both v_0 and v_1. In K, it is the inverse image of the stabilizer of a line modulo ϖ, hence compact and open. The class of

$$s = \begin{pmatrix} 0 & 1 \\ \varpi & 0 \end{pmatrix}$$

exchanges v_0 and v_1 and satisfies $s^2 = 1$ in H. The midpoint stabilizer is $J = I \sqcup sI$ and is compact and open. The action is transitive on lattice vertices, on midpoints, and on the oriented edges of T. The first assertion follows by sending one lattice basis to another. Transitivity on incident pairs follows because K acts transitively on lines modulo ϖ.

Example 118.5.3 *(The first ball when $q = 2$).* The first ball about v_0 is a star with three leaves v_1, v_2, v_3. Write m_i for the midpoint of $v_0 v_i$. The subdivision has seven vertices and six oriented edges $e_i = (v_0, m_i)$ and $f_i = (v_i, m_i)$, for $1 \le i \le 3$. Its boundary map and augmentation are

$$\partial e_i = [m_i] - [v_0], \qquad \partial f_i = [m_i] - [v_i], \qquad \epsilon[v] = 1.$$

Define a linear map h from vertices to edge chains by

$$h[v_0] = 0, \qquad h[m_i] = e_i, \qquad h[v_i] = e_i - f_i.$$

Then

$$\partial h = \mathrm{id} - [v_0]\epsilon, \qquad h\partial = \mathrm{id}\,.$$

Both identities follow by applying the displayed formulas to each basis vector. Thus ∂ has rank six and its image is $\ker \epsilon$. This finite ball is not H-stable. The same finite-path calculation proves exactness for arbitrary finite chains in the entire tree.

Projective cellular chains

For a compact open subgroup $U \subset H$, let $\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$ denote its smooth complex representations. An object is projective if every morphism from it to a quotient lifts through the quotient map. The following property depends on the coefficient field $\mathbb{C}$.

Lemma 118.5.4. Every smooth complex representation of U is projective in $\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$.

Proof. The orbit of any vector under U is finite because its stabilizer is open and U is compact. The orbit spans a finite-dimensional U-submodule. A basis of this submodule has a common open stabilizer. Its normal core is an open normal subgroup, so the action factors through a finite quotient of U. For an invariant subspace, average a linear projection over the finite quotient to obtain an equivariant projection. Its kernel is an invariant complement. Induction on dimension therefore decomposes this submodule into irreducibles. Hence every smooth U-module is a sum of finite-dimensional irreducible submodules. Choose a maximal direct sum of such submodules. If it does not contain the whole module, a finite-dimensional submodule contributes a simple summand outside it. That simple summand has zero intersection with the maximal direct sum, a contradiction. Thus the whole module is a direct sum of finite-dimensional irreducibles.

Each such irreducible τ is projective. To verify the lifting property explicitly, let $Y \twoheadrightarrow Z$ be an epimorphism and let $f : \tau \to Z$ be U-equivariant. Choose lifts in Y of the images of a basis of τ

and extend them to a linear map $\ell : \tau \to Y$. The U-orbits of these finitely many lifts span a finite-dimensional submodule Y_0. Choose an open normal subgroup $N \subset U$ acting trivially on both Y_0 and τ. Then

$$\widetilde{f}(v) = \frac{1}{|U/N|} \sum_{u \in U/N} u\, \ell(u^{-1}v)$$

is well-defined, U-equivariant, and lifts f. Only finite-dimensional smooth data are averaged. Finally, morphisms out of a direct sum can be lifted on its summands and then assembled. A direct sum of projectives is therefore projective. □

For $M \in \mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(U)$, define compact induction $\text{c-}\mathrm{Ind}_U^H M$ by finite sums of symbols $[g, m]$, linear in m, with relations

$$[gu, m] = [g, um] \qquad (g \in H,\ u \in U).$$

The group acts by $h[g, m] = [hg, m]$. This is the algebraic finite-support model on H/U, valid because U is open. It is smooth: the stabilizer of $[g, m]$ contains $gU_m g^{-1}$, where U_m is an open stabilizer of m in U. A finite sum has the intersection of finitely many such open stabilizers.

The map determined by $[g, m] \mapsto gf(m)$ gives the adjunction

$$\mathrm{Hom}_H(\text{c-}\mathrm{Ind}_U^H M, V) \cong \mathrm{Hom}_U(M, V|_U).$$

Its inverse restricts a morphism to the symbols $[1, m]$. Restriction is exact, so compact induction takes projectives to projectives. Lemma 118.5.4 applies to every compact open cell stabilizer of T.

For a discrete set Y, write $C_c(Y; \mathbb{C})$ for its finitely supported functions, with basis vectors denoted $[y]$. Let T_0 and T_1 be the vertices and the chosen oriented edges of T. For a smooth H-representation V, define

$$P_1(V) = C_c(T_1; \mathbb{C}) \otimes V, \qquad P_0(V) = C_c(T_0; \mathbb{C}) \otimes V,$$

with diagonal action $g([c] \otimes v) = [gc] \otimes gv$. For an oriented edge $e = (u, m)$, define

$$\partial([e] \otimes v) = ([m] - [u]) \otimes v, \qquad \epsilon([u] \otimes v) = v.$$

Both maps commute with H, and $\epsilon\partial = 0$.

THEOREM 118.5.5. For every smooth complex H-representation V, the sequence

$$0 \longrightarrow P_1(V) \xrightarrow{\partial} P_0(V) \xrightarrow{\epsilon} V \longrightarrow 0 \tag{118.10}$$

is exact and its first two terms are projective smooth H-representations. Consequently,

$$\mathrm{Ext}^j_{\mathrm{Rep}_{\mathrm{sm},\mathbb{C}}(H)}(V, U) = 0 \qquad (j \geq 2)$$

for all smooth V, U.

Proof. Fix a root vertex o of T. For each vertex v, let p_v be the finite edge chain along the unique path from o to v, with coefficient -1 whenever the path opposes the chosen edge orientation. Then $\partial p_v = [v] - [o]$. The map $[v] \otimes w \mapsto p_v \otimes w$ gives $\partial h = \mathrm{id} - ([o] \otimes -)\epsilon$. Thus every chain of augmentation zero is a boundary. The augmentation is surjective because $w = \epsilon([o] \otimes w)$. A nonzero finite-support edge cycle would have a leaf in the finite subtree spanned by its support. At that leaf, its boundary equals the

nonzero coefficient of its unique incident supported edge, up to sign. This is impossible, so ∂ is injective. These arguments also apply to vector coefficients and use only finite sums. The root-path contraction proves exactness and is not claimed equivariant.

For a chosen cell c with stabilizer U, the map

$$\mathrm{c\text{-}Ind}_U^H(V|_U) \longrightarrow C_c(Hc;\mathbb{C}) \otimes V, \qquad [g,v] \longmapsto [gc] \otimes gv$$

is an equivariant isomorphism. The relation $[gu,v] = [g,uv]$ verifies that it is well-defined. Its inverse sends $[gc] \otimes w$ to $[g, g^{-1}w]$ and is independent of the representative g. The three cell orbits therefore give

$$P_1(V) \cong \mathrm{c\text{-}Ind}_I^H(V|_I), \qquad P_0(V) \cong \mathrm{c\text{-}Ind}_K^H(V|_K) \oplus \mathrm{c\text{-}Ind}_J^H(V|_J).$$

They are smooth projectives by Lemma 118.5.4 and the compact-induction adjunction. Applying $\mathrm{Hom}(-,U)$ to this projective resolution computes Ext and leaves no terms in degrees $j \geq 2$. □

The constant-coefficient resolution above needs no finite generation or admissibility hypothesis. Its projective terms can have infinite multiplicity. Cellular resolutions with coefficient systems of compact-subgroup invariants are developed in Schneider–Stuhler, *Representation theory and sheaves on the Bruhat–Tits building*, Section II.2, pp. 121–122, and Theorem II.3.1, p. 123. Here the rank-one tree and constant coefficients give the stated resolution directly.

The obstruction and the splitting maps

Lemma 118.5.1 transports the resolution and projectivity into $\mathcal{A}_\zeta$. For $V \in \mathcal{A}_\zeta$, apply (118.10) to its descended twist $V \otimes \eta^{-1}$, then inflate and tensor every term and map with η. This gives a projective resolution

$$0 \longrightarrow P_1^\zeta(V) \xrightarrow{d} P_0^\zeta(V) \xrightarrow{\epsilon} V \longrightarrow 0$$

inside $\mathcal{A}_\zeta$. In particular, $\mathrm{Ext}^j_{\mathcal{A}_\zeta}(V,U) = 0$ for all $j \geq 2$. Every central element acts by ζ on both projective terms.

Theorem 118.5.6. Let $A \xrightarrow{D} B$ be a morphism in $\mathcal{A}_\zeta$. Place A in degree -1 and B in degree 0, and set $U = \ker D$, $V = \mathrm{coker}\, D$. There is an isomorphism

$$[\, A \xrightarrow{D} B \,] \simeq U[1] \oplus V \qquad \text{in } \mathcal{D}^b(\mathcal{A}_\zeta).$$

It can be represented by two explicit quasi-isomorphisms through the cellular projective resolution of V.

Proof. Write $P_1 \xrightarrow{d} P_0 \xrightarrow{\epsilon} V$ for the resolution just constructed. Let $p : B \twoheadrightarrow V$ and $i : U \hookrightarrow A$ be the quotient and kernel maps. Since P_0 is projective, choose a morphism $f_0 : P_0 \to B$ with $pf_0 = \epsilon$. The identity $pf_0 d = \epsilon d = 0$ shows that $f_0 d$ takes values in $\mathrm{im}\, D$. Projectivity of P_1 lifts that map through the epimorphism $A \twoheadrightarrow \mathrm{im}\, D$. Thus there is $f_1 : P_1 \to A$ satisfying

$$Df_1 = f_0 d. \tag{118.11}$$

All objects, quotient maps, and lifts lie in $\mathcal{A}_\zeta$.

Let $P = [P_1 \xrightarrow{d} P_0]$, in degrees -1, 0. Equation (118.11) defines a chain map

$$\Phi : U[1] \oplus P \longrightarrow [\, A \xrightarrow{D} B \,], \qquad \Phi^{-1}(u,v) = i(u) + f_1(v), \quad \Phi^0 = f_0.$$

The superscripts denote cochain degrees. Since d is injective, $H^{-1}(U[1] \oplus P) = U$ and $H^{0}(U[1] \oplus P) = V$. The map Φ induces the identity on these groups, using $pf_{0} = \epsilon$. It is therefore a quasi-isomorphism. The augmentation of P gives another quasi-isomorphism

$$\Psi : U[1] \oplus P \longrightarrow U[1] \oplus V, \qquad \Psi^{-1}(u, v) = u, \quad \Psi^{0} = \epsilon.$$

The roof

$$[\, A \xrightarrow{D} B \,] \xleftarrow{\Phi} U[1] \oplus P \xrightarrow{\Psi} U[1] \oplus V$$

proves the asserted derived isomorphism. The compact averaging construction in Lemma 118.5.4, followed by compact induction, constructs the required lifts after choices of irreducible summands and linear lifts. No averaging over the noncompact group is used. □

The associated obstruction is the class of the exact two-extension

$$0 \longrightarrow U \xrightarrow{i} A \xrightarrow{D} B \xrightarrow{p} V \longrightarrow 0$$

in $\operatorname{Ext}^{2}_{\mathcal{A}_{\zeta}}(V, U)$. Equivalently, it is the connecting morphism $V \to U[2]$ in the cohomological truncation triangle. Theorem 118.5.5 makes this group zero, and the roof above realizes the splitting by actual maps. The construction proves existence and depends on the choices of lifts. No canonical splitting or compatibility between different parameters is asserted.

PROPOSITION 118.5.7 *(The exceptional fibers).* For the exceptional pair fixed in (118.8), there is an isomorphism

$$C_{x} \simeq W_{x}[1] \oplus W_{x} \qquad \text{in } \mathcal{D}^{b}(\mathcal{A}_{\zeta}).$$

Its degree-two obstruction vanishes in the strictly fixed-central-character category.

Proof. The kernel and cokernel identifications (118.9) are morphisms inside $\mathcal{A}_{\zeta}$. Apply Theorem 118.5.6 to the actual map D_{x}. The resulting roof uses the projective resolution twisted by the stated η, so every term has central character ζ. □

This is a pointwise statement over $\mathbb{C}$. The compact projectivity proof uses division by finite group orders and does not establish a theorem over arbitrary coefficient rings. The character η is fixed at the chosen complex point. A splitting with the universal central character over the ordered-character Laurent ring, a canonical Weyl-compatible choice of pointwise splittings, and a comparison with global Eisenstein categories require separate constructions.

118.6 NORMAL EQUATIONS AND SPECIALIZATION MAPS

The opposite operator provides a direct comparison of these two cohomology groups. Put $T = R/(h)$. Equation (118.3) gives a well-defined map

$$\overline{D^{\mathrm{sw}}} : \operatorname{coker}(D_{T}) \longrightarrow \ker(D_{T}), \qquad [y] \longmapsto D^{\mathrm{sw}}_{T}\, y.$$

It is an isomorphism of smooth T-linear G-representations. To prove this, decompose T by the two comaximal ideals. On $\alpha = 0$, its surviving coefficient is $\beta/z = 1 - q^{-2}$ on H_{0}. On $\beta = 0$, its surviving coefficients are $z^{-n}\alpha$ on $H_{n}, n \geq 1$. All are units in the corresponding divisor ring. The same isomorphism holds after further coefficient extension from T.

There is also a comparison determined by a chosen equation of one divisor. For $t = \alpha$ or $t = \beta$, let $\overline{R} = R/(t)$. For $x \in \ker D_{\overline{R}}$, choose a lift $\widetilde{x} \in E$. The vector $D\widetilde{x}$ is divisible by t in the free module E^{sw}. Define

$$\delta_t : \ker D_{\overline{R}} \longrightarrow \operatorname{coker} D_{\overline{R}}, \qquad x \longmapsto [\, D\widetilde{x}/t \,].$$

Changing the lift by tu changes the quotient by Du, so the map is well-defined. Equivariance follows by applying $D\pi(g) = \pi^{\mathrm{sw}}(g)D$ to the chosen lift. This is the connecting map for the coefficient sequence $0 \to R/(t) \xrightarrow{t} R/(t^2) \to R/(t) \to 0$ applied to C. It also identifies the kernel calculated from the free resolution of Q_{loc} with its t-torsion using the resolution $[R \xrightarrow{t} R]$ of $R/(t)$.

The map δ_α has coefficient 1 on H_0. The map δ_β has coefficient z^{n-1} on H_n, $n \geq 1$, evaluated on $\beta = 0$. Thus both are isomorphisms. They are compatible with subsequent extension along the respective divisor. They satisfy

$$\delta_t \overline{D^{\mathrm{sw}}} = (h/t)|_{t=0}\ \mathrm{id}, \qquad (h/\alpha)|_{\alpha=0} = 1 - q^{-2}, \quad (h/\beta)|_{\beta=0} = q(1 - q^{-2}).$$

Replacing the local equation t by ut, with u a unit, multiplies δ_t by u^{-1} on the divisor. The normal equation is therefore part of this specialization comparison.

118.7 Finite levels and matrix factorizations

The finite spaces V_N retain the integral's compact-level refinement. Set $E_N = R \otimes V_N$ and $E_N^{\mathrm{sw}} = R \otimes V_N$, with their respective induced compact actions. Restriction gives $D_N : E_N \to E_N^{\mathrm{sw}}$ and $D_N^{\mathrm{sw}} : E_N^{\mathrm{sw}} \to E_N$. Inclusions $V_N \hookrightarrow V_{N+1}$ and averaging maps $P_N : V_{N+1} \to V_N$ commute with both operators because they preserve each H_n. They therefore induce maps of the cones and of their coefficient extensions. The inclusions give

$$C = \operatorname*{colim}_N C_N, \qquad C_N = [E_N \xrightarrow{D_N} E_N^{\mathrm{sw}}].$$

Filtered colimits of modules are exact, so kernels, cokernels, and the displayed coefficient extensions commute with this colimit.

For $N \geq 1$, let $K_N = 1 + \varpi^N M_2(\mathcal{O})$, and set $K_0 = K$. Then $E^{K_N} = E_N$ and $(E^{\mathrm{sw}})^{K_N} = E_N^{\mathrm{sw}}$. Compact averaging is defined over every $\mathbb{C}$-algebra and is exact on smooth representations. Indeed, any finite set of vectors is fixed by an open subgroup, and averaging reduces to a finite sum with invertible denominator. It follows that $C_N = C^{K_N}$ and $\operatorname{coker} D_N = Q_{\mathrm{loc}}^{K_N}$. Full G-translation can move E_N into a larger E_M. The finite complexes carry K-actions, whereas their colimit carries the full G-action.

A finite-free matrix factorization of $h \in R$ consists of finite-free modules M_0, M_1 and maps $d_0 : M_0 \to M_1$, $d_1 : M_1 \to M_0$ satisfying $d_1 d_0 = h\,\mathrm{id}$ and $d_0 d_1 = h\,\mathrm{id}$. Thus (D_N, D_N^{sw}) is a finite-free K-equivariant matrix factorization of h. Its rank is $\dim V_N$ in each parity. The full pair (D, D^{sw}) has infinite-rank free terms.

Proposition 118.7.1. Each finite-level matrix factorization (D_N, D_N^{sw}) is contractible through K-equivariant maps. Its cokernel is a projective $R/(h)$-module. The ordinary two-term cone C_N is nevertheless nonzero in the derived category for every $N \geq 0$.

Proof. Put $c = 1 - q^{-2}$. Write $d_0 = D_N$, $d_1 = D_N^{\mathrm{sw}}$. A contraction consists of maps $s_0 : M_0 \to M_1$ and $s_1 : M_1 \to M_0$ with $ds + sd = \mathrm{id}$ on the two-parity module. On H_0 take

$$s_1 = c^{-1}, \qquad s_0 = q^{-1} z / c.$$

Then $s_1 d_0 + d_1 s_0 = (\alpha + q^{-1}\beta)/c = 1$. On H_n, $n \geq 1$, take

$$s_1 = q^{-1} z^{-(n-1)}/c, \qquad s_0 = z^n/c.$$

Here $s_1 d_0 + d_1 s_0 = (q^{-1}\beta + \alpha)/c = 1$ as well. All coefficients commute, so the identity also holds on the other parity. These are Laurent coefficients and preserve the K-stable decomposition.

The ring $R/(h)$ is $R/(\alpha) \times R/(\beta)$ by (118.5). The cokernel is free of rank one on the first component and rank $\dim V_N - 1$ on the second. It is therefore projective over their product. As an R-module it is nonzero, since the first component is nonzero. This cokernel is $H^0(C_N)$, which proves the last assertion. □

The contraction above is asserted only for the coefficient modules with K-action. Its diagonal formulas do not establish a contraction commuting with the full G-action. A matrix factorization uses both opposite maps and satisfies $d^2 = h$. The ordinary cone uses only D and has the nonzero cohomology (118.4). These are distinct homological constructions.

The regular intertwiner therefore defines a smooth equivariant degeneration complex on the entire ordered-character torus. Its cohomology consists of a character family on one divisor and a Steinberg quotient family on the other. Its derived fibers and their specialization comparisons are given above. A category comparison for global Eisenstein representations still requires a global target and a functor whose derived mapping objects and essential image are determined. The local degeneration complex supplies no such equivalence by itself.

118.8 Local Yoneda classes and finite exterior products

A local nonsplit principal series defines a degree-one extension between its Steinberg quotient and its constant subrepresentation. At two distinct finite places, the exterior product of these extensions has degree two. An infinite restricted tensor introduces a second condition: its distinguished local vectors must be fixed by the prescribed compact subgroups at almost every place. These two requirements distinguish a finite exterior product of Steinberg representations from an adelic extension of principal series.

The local sequence and its invariant vectors

Fix the coefficient field $\mathbb{C}$. For a finite prime p, put $G_p = GL_2(\mathbb{Q}_p)$, $K_p = GL_2(\mathbb{Z}_p)$, and let B_p be the upper triangular Borel subgroup. Give these groups their usual p-adic topologies. Write $X_p = B_p \backslash G_p \simeq \mathbb{P}^1(\mathbb{Q}_p)$, with its compact quotient topology and right G_p-action. The identification sends a matrix to the line spanned by its bottom row. Let

$$E_p = C^{\mathrm{lc}}(X_p, \mathbb{C}), \qquad (\rho_p(g)f)(x) = f(xg).$$

Here C^{lc} means locally constant functions, without an analytic completion. This is unnormalized smooth induction of the trivial character of B_p. With normalized induction and $|p|_p = p^{-1}$, its ordered inducing characters are $|\cdot|_p^{-1/2}$ and $|\cdot|_p^{1/2}$. Thus, if symmetric induction is written with characters $(|\cdot|_p^{s/2}, |\cdot|_p^{-s/2})$, this sequence occurs at $s = -1$.

The constants give the exact sequence

$$0 \longrightarrow \mathbb{C} \xrightarrow{i_p} E_p \longrightarrow \mathrm{St}_p \longrightarrow 0, \qquad \mathrm{St}_p = E_p/\mathbb{C}\mathbf{1}_p. \tag{118.12}$$

This is the usual Steinberg quotient in rank one (Casselman, *Introduction to the Theory of Admissible Representations of p-Adic Reductive Groups*, Section 8.1, p. 70). Every term has trivial central character. We use $\mathrm{Rep}_{\mathbb{C}}^{\mathrm{sm}}(G_p)$ for the abelian category of all smooth complex representations. Its full subcategory on which the center acts trivially is identified with $\mathrm{Rep}_{\mathbb{C}}^{\mathrm{sm}}(PGL_2(\mathbb{Q}_p))$. Extension groups below specify which of these categories is used.

Lemma 118.8.1. The sequence (118.12) is nonsplit. Moreover,

$$\mathrm{Hom}_{G_p}(E_p, \mathbb{C}) = 0, \qquad \mathrm{Hom}_{G_p}(\mathrm{St}_p, \mathbb{C}) = 0, \qquad \mathrm{St}_p^{K_p} = 0.$$

The same statements hold after passage to $PGL_2(\mathbb{Q}_p)$.

Proof. Consider a G_p-invariant linear functional $\ell : E_p \to \mathbb{C}$. Projective p-adic balls are translates of one another under G_p: affine transformations relate the balls in $\mathbb{Q}_p$, and inversion also relates them to the balls containing infinity. A ball is a disjoint union of p smaller balls. Consequently the common value c of ℓ on ball indicators satisfies $c = pc$, so $c = 0$. Locally constant functions on X_p are finite linear combinations of these indicators, since X_p is compact and the balls form a clopen basis. Hence $\ell = 0$. A splitting of (118.12) would provide such a functional with $\ell(\mathbf{1}_p) = 1$. A morphism $\mathrm{St}_p \to \mathbb{C}$ would pull back to a morphism $E_p \to \mathbb{C}$, proving the first two assertions.

Every line in $\mathbb{Q}_p^2$ has a primitive integral representative that extends to an integral basis. Thus K_p acts transitively on X_p and $E_p^{K_p} = \mathbb{C}\mathbf{1}_p$. Invariants under a compact open subgroup are exact for smooth complex representations. Indeed, normalized Haar averaging of a smooth vector is a finite sum, and averaging a lift of an invariant vector gives an invariant lift. Applying invariants to (118.12) gives $\mathrm{St}_p^{K_p} = 0$. This averaging argument is also Casselman, Proposition 2.1.7, p. 20. All actions factor through $PGL_2(\mathbb{Q}_p)$, and the same proof applies there. □

Write α_p for the Yoneda class of (118.12). It is a specified nonzero element of $\mathrm{Ext}^1(\mathrm{St}_p, \mathbb{C})$. No residue operator is needed to define it, and no dimension assertion about that group is required below.

Two finite places and the exterior degree

Let $p \neq q$ be finite primes. External tensor products over $\mathbb{C}$ are written $\boxtimes$ and carry the separate actions of the two groups. Tensoring the two local sequences gives the exact sequence

$$\begin{aligned} 0 \longrightarrow \mathbb{C} \boxtimes \mathbb{C} \xrightarrow{d_2} (E_p \boxtimes \mathbb{C}) \oplus (\mathbb{C} \boxtimes E_q) \xrightarrow{d_1} E_p \boxtimes E_q \\ \longrightarrow \mathrm{St}_p \boxtimes \mathrm{St}_q \longrightarrow 0, \end{aligned} \tag{118.13}$$

where

$$d_2 = (i_p \boxtimes 1, -1 \boxtimes i_q), \qquad d_1(x, y) = (1 \boxtimes i_q)x + (i_p \boxtimes 1)y.$$

Unlike the cochain indexing of the local cone, the following totals use homological degrees and differentials of degree -1. These signs are the tensor differential for homological complexes, $\partial(x \otimes y) = \partial x \otimes y + (-1)^{\deg x} x \otimes \partial y$. In particular $d_1 d_2 = 0$. The two complexes $[\mathbb{C} \to E_p]$ and $[\mathbb{C} \to E_q]$, in homological degrees 1, 0, have homology only in degree zero, with values St_p and St_q. Tensoring over a field preserves this assertion. It proves the exactness of (118.13).

The sequence (118.13) is a Yoneda two-extension, not a short exact sequence with these endpoints. Its class is the exterior Yoneda product of α_p and α_q, with the displayed tensor sign convention. The following argument proves that this class is nonzero without replacing either local representation by a finite-dimensional model.

PROPOSITION 118.8.2. Let S be a nonempty finite set of finite primes, $n = |S|$, and $\mathrm{St}_S = \boxtimes_{p\in S} \mathrm{St}_p$. Put $G_S = \prod_{p\in S} G_p$. In $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(G_S)$ one has

$$\mathrm{Ext}^r_{G_S}(\mathrm{St}_S, \mathbb{C}) = 0 \quad (0 \le r < n).$$

The exterior product of the classes α_p is nonzero in $\mathrm{Ext}^n_{G_S}(\mathrm{St}_S, \mathbb{C})$. It is represented by the total tensor of the n sequences (118.12). Both assertions also hold in the category where each local center acts trivially, namely $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(\prod_{p\in S} PGL_2(\mathbb{Q}_p))$.

Proof. For either of the groups G_p and $PGL_2(\mathbb{Q}_p)$, compact induction $\text{c-Ind}^G_K \mathbb{C}$ from a compact open subgroup is projective. To see this, a G-map from this compact induction to V is determined by the image of the indicator of K, and that image can be any element of V^K. Thus its Hom functor is $V \mapsto V^K$, which is exact by averaging. Every smooth vector is fixed by a compact open subgroup. Taking one such compact induction for each vector therefore gives enough projectives, and resolutions can be chosen with terms that are sums of these compact inductions.

Choose such a resolution $P_{p,\bullet} \to \mathrm{St}_p$, with homological indices at least zero. Products of compact open subgroups are compact open, and

$$\left(\text{c-Ind}^G_K \mathbb{C}\right) \boxtimes \left(\text{c-Ind}^H_L \mathbb{C}\right) \simeq \text{c-Ind}^{G\times H}_{K\times L} \mathbb{C}.$$

Both sides are finite-support functions on the product of the relevant discrete coset spaces. Hence the total external tensor of the chosen resolutions is a projective resolution of St_S.

Let $C_{p,\bullet} = (P_{p,\bullet})_{G_p}$ be its coinvariant complex (or use $PGL_2(\mathbb{Q}_p)$ in the fixed-central-character category). For any representation V, a map $V \to \mathbb{C}$ factors uniquely through V_G. It follows that

$$\mathrm{Ext}^r_G(\mathrm{St}_p, \mathbb{C}) \simeq \mathrm{Hom}_{\mathbb{C}}(H_r(C_{p,\bullet}), \mathbb{C}). \tag{118.14}$$

Here the algebraic dual is exact over the field $\mathbb{C}$; no topological or continuous dual is used. Coinvariants of an external tensor for a product group are the tensor of the coinvariants. Consequently the same argument identifies the product-group Ext with the dual homology of $\bigotimes_{p\in S} C_{p,\bullet}$.

Lemma 118.8.1 and (118.14) imply $H_0(C_{p,\bullet}) = 0$. The Künneth formula for bounded-below complexes of vector spaces gives

$$H_r\left(\bigotimes_{p\in S} C_{p,\bullet}\right) \simeq \bigoplus_{\substack{(r_p)\in \mathbb{Z}^S_{\ge 0} \\ \sum_p r_p = r}} \bigotimes_{p\in S} H_{r_p}(C_{p,\bullet}).$$

For completeness, one can split each vector-space complex as its homology with zero differential plus a contractible complex. Tensoring these splittings proves the formula. For $r < n$, every summand has some $r_p = 0$ and is zero. This proves the vanishing assertion.

Each nonzero class α_p is a nonzero functional on $H_1(C_{p,\bullet})$. Choose a homology element on which it is nonzero. The product functional is nonzero on the tensor of these elements, which lies in degree n. It represents the exterior Yoneda class: a projective resolution maps to $[\mathbb{C} \to E_p]$ by first lifting its augmentation to E_p, then factoring its degree-one boundary through $\mathbb{C}$. The resulting degree-one cocycle represents α_p. Tensoring these chain maps gives exactly the total extension and the product cocycle, with the tensor signs already specified. Thus the exterior class is nonzero.

This proof uses genuinely compact open subgroups even for GL_2. It does not treat compact-mod-center subgroups as compact, and it makes no assertion about vanishing above degree n in the unrestricted GL_2 category. □

118.9 The restricted tensor condition

Let

$$G_f = GL_2(\mathbb{A}_f) = \prod_p{}'(G_p, K_p).$$

Its restricted-product topology has neighborhoods of the identity that contain $\prod_{p\notin S} K_p$ for some finite S. A usual algebraic restricted tensor representation uses nonzero distinguished vectors $e_p \in V_p^{K_p}$ for all but finitely many p. Its vectors are finite linear combinations of tensors whose factors equal e_p almost everywhere. For $g = (g_p) \in G_f$, both $g_p \in K_p$ and the distinguished factor condition hold almost everywhere, making the coordinate action well-defined.

Proposition 118.9.1. The local representations St_p do not admit a nonzero restricted tensor representation with the standard hyperspecial pointings at almost every finite prime. More generally, a smooth G_f-representation V with factorizations $V \simeq \mathrm{St}_p \otimes W_p$ as G_p-representations for every finite p, with G_p acting only on the first factor, is zero.

Proof. The required pointing space is zero at every prime by Lemma 118.8.1. For the second assertion, a vector in a smooth G_f-representation is fixed by an open subgroup. That subgroup contains K_p for every p outside a finite set. But the stipulated factorization implies

$$V^{K_p} = \mathrm{St}_p^{K_p} \otimes W_p = 0.$$

This equality follows from averaging on the first tensor factor, or from writing any tensor as a finite sum with linearly independent second factors. Thus the vector is zero. □

Choosing Iwahori-fixed vectors at infinitely many places does not supply these hyperspecial pointings. The restricted product relative to those Iwahori subgroups is a different subgroup and topology. No passage to an unspecified completed tensor product is part of this construction.

For a finite set S, a genuine smooth adelic representation is

$$\mathrm{St}_S^{(f)} = \left(\boxtimes_{p\in S} \mathrm{St}_p\right) \boxtimes \left(\bigotimes_{p\notin S}{}' \mathbb{C}\right),$$

where each omitted place uses the trivial representation and vector 1. It is inflation from G_S under the continuous projection $G_f \to G_S$. The extension of Proposition 118.8.2 inflates with it and remains nonzero: restriction along the inclusion $G_S \hookrightarrow G_f$ is exact and recovers the original Yoneda class. This representation has Steinberg factors precisely at the specified finite set. It is not an all-place Steinberg representation.

118.10 An adelic principal-series extension

The local principal series E_p do have compatible distinguished vectors, namely the constant functions $\mathbf{1}_p$. These vectors are fixed by all of G_p. For finite S, write $E_S = \boxtimes_{p\in S} E_p$, inflated to G_f with trivial factors outside S. If $S \subset T$, define

$$E_S \longrightarrow E_T, \qquad x \longmapsto x \otimes \bigotimes_{p\in T\setminus S} \mathbf{1}_p.$$

The superscript res below means restricted tensor product; it does not name an automorphic residual spectrum. These maps are injective and G_f-equivariant. The canonical associativity and symmetry identifications make their composites agree for $S \subset T \subset U$. Put $E^{\mathrm{res}} = \operatorname{colim}_S E_S$. This is a smooth representation: a vector lies in some E_S, is smooth at the finitely many primes of S, and is fixed by the full groups outside S. Its central character is trivial.

PROPOSITION 118.10.1. Let $X = \prod_p \mathbb{P}^1(\mathbb{Q}_p)$ with its compact product topology. There is a G_f-equivariant isomorphism

$$E^{\mathrm{res}} \simeq C^{\mathrm{lc}}(X, \mathbb{C})$$

for the coordinatewise right action. The exact sequence

$$0 \longrightarrow \mathbb{C} \longrightarrow E^{\mathrm{res}} \longrightarrow Q_{\mathrm{ad}} \longrightarrow 0, \qquad Q_{\mathrm{ad}} = E^{\mathrm{res}}/\mathbb{C}, \tag{118.15}$$

is nonsplit in $\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(G_f)$ and in its trivial-central-character category. Both E^{res} and Q_{ad} are admissible: their invariants under every compact open subgroup are finite-dimensional.

Proof. For finite S, products of functions identify E_S with $C^{\mathrm{lc}}(\prod_{p\in S} X_p, \mathbb{C})$. Surjectivity follows by covering clopen subsets of the compact finite product by finitely many clopen rectangles and refining this cover to a finite partition. Injectivity follows because evaluations separate every finite-dimensional space of functions: after choosing bases in the finitely many function spaces involved, suitable finite sets of evaluation points give injective matrices, whose tensor is still injective.

Every locally constant function on X has a finite cover by basic open cylinders on which it is constant. Such a finite cover exists by compactness. The union of the finite coordinate sets defining the cylinders is finite. Two points equal in these coordinates belong to the same cylinders and therefore have equal function values. The function thus depends on only finitely many coordinates. This proves surjectivity from the colimit, and injectivity follows from the finite-stage statement. The insertion maps become pullback along coordinate projections. Each $g \in G_f$ acts by the coordinate homeomorphisms $x_p \mapsto x_p g_p$, so the isomorphism is equivariant. Smoothness also follows from the finite-coordinate description established above.

A compact open subgroup of G_f contains a subgroup $U_S \times \prod_{p\notin S} K_p$ for a finite S, where U_S is a product of compact open subgroups at the places of S. Invariance under the tail K_p forces a finite-coordinate function to be independent of those tail coordinates, because K_p is transitive on X_p. Its invariants therefore lie in $E_S^{U_S}$. Each local compact open subgroup has open orbits on the compact space X_p, hence finitely many orbits. It follows that $E_S^{U_S}$ is finite-dimensional. This proves admissibility of E^{res}. Compact-open invariants are exact by the same finite averaging argument, so its quotient Q_{ad} is also admissible.

A splitting of (118.15) would give a G_f-invariant retraction $E^{\mathrm{res}} \to \mathbb{C}$. Its restriction to the embedded $E_{\{p\}}$ would be a G_p-invariant retraction of the constants, contradicting Lemma 118.8.1. The same argument applies when the full center acts trivially. □

The quotient Q_{ad} retains mixed finite-place terms. To describe them, set $F_{-1}E^{\mathrm{res}} = 0$ and, for $m \geq 0$, let $F_m E^{\mathrm{res}}$ be the sum of the images of E_T over finite sets T with $|T| \leq m$. This is an increasing, exhaustive filtration by G_f-subrepresentations, with $F_0 E^{\mathrm{res}} = \mathbb{C}$.

PROPOSITION 118.10.2. For every $m \geq 0$ there is a canonical isomorphism

$$\mathrm{gr}^F_m E^{\mathrm{res}} \simeq \bigoplus_{\substack{T \text{ finite} \\ |T|=m}} \mathrm{St}_T^{(f)},$$

where the empty-set factor is $\mathbb{C}$. The induced exhaustive filtration $Q_{\mathrm{ad},m} = F_m E^{\mathrm{res}}/\mathbb{C}$ of Q_{ad} starts with $Q_{\mathrm{ad},0} = 0$ and has these same associated graded pieces for $m \geq 1$.

Proof. At a finite stage S, use the two-step filtration $\mathbb{C}\mathbf{1}_p \subset E_p$ in every tensor factor. A class in $\boxtimes_{p\in T} \mathrm{St}_p$, for $T \subset S$ of size m, maps to the mth associated graded by lifting its factors to E_p and inserting constants elsewhere. Changing a lift adds a tensor from the preceding filtration term, so this map is canonical and equivariant. It is an isomorphism: choose arbitrary vector-space complements to the constants in each E_p and expand the finite tensor product. The summands with precisely m complement factors give the asserted graded piece. The complements prove bijectivity but do not define the map. The canonical maps are compatible with the constant insertions as S grows. Taking the filtered colimit gives the displayed direct sum, since each vector involves only finitely many places. Quotienting by the constant subrepresentation gives the statement for Q_{ad}. □

In particular there is a nonsplit degree-one extension

$$0 \longrightarrow \mathbb{C} \longrightarrow F_1 E^{\mathrm{res}} \longrightarrow \bigoplus_p \mathrm{St}_{\{p\}}^{(f)} \longrightarrow 0.$$

Pulling it back to any single summand gives (118.12), inflated to G_f. This degree-one construction has a direct sum as its quotient. The full quotient Q_{ad} additionally contains every finite mixed tensor through its filtration. Neither quotient is the all-place tensor $\otimes'_p \mathrm{St}_p$.

Indeed, the local quotient maps $E_p \to \mathrm{St}_p$ send the distinguished constant vectors to zero. If those zero vectors are used as insertion maps for the finite tensors of Steinberg quotients, every stage maps to zero after a new prime is inserted, and the resulting colimit is zero. Thus the quotient maps cannot turn (118.15) into a nonzero all-place Steinberg extension.

118.11 Archimedean and automorphic scope

All preceding Ext groups belong to explicitly stated categories of smooth finite-adelic or finite-product representations. Tensoring with the trivial representation of $GL_2(\mathbb{R})$ gives a specified archimedean factor and an action of $GL_2(\mathbb{A})$, without adding another extension class. A nontrivial archimedean extension requires its own smooth topological representation category or Harish–Chandra module category, its central character, and its tensor conventions. An additional degree-one exterior factor contributes an additional degree when its exterior product is defined; it does not erase the finite-place degrees above.

A representation of $GL_2(\mathbb{A})$ is not thereby a realization on $GL_2(\mathbb{Q})\backslash GL_2(\mathbb{A})$. Such a realization requires a specified automorphic function space or enhanced category, central quotient and support conditions, and a comparison functor. The symbols $\mathrm{Ext}^i_{[GL_2]}$ alone do not specify that category. The constructions here give genuine local and adelic group representations and their Yoneda extensions. They neither identify a residue with an extension class nor supply an arithmetic or automorphic comparison.

118.12 Global Eisenstein residues

The local extensions above use smooth group representations. To compare them with Eisenstein residues, fix an automorphic quotient and a normalization. For $G = GL_2$ over $\mathbb{Q}$, write Z for its center and use

$$[G]_Z = Z(\mathbb{A})G(\mathbb{Q})\backslash G(\mathbb{A})$$

with trivial central character. Functions in the Hilbert space $L^2([G]_Z)$ are square-integrable for a fixed quotient Haar measure. Changing that measure changes the norm, but does not turn a morphism

of representations into an extension. With a unitary central character ξ, one instead uses functions transforming by ξ under $Z(\mathbb{A})$ and integrates their absolute squares modulo the center.

The trivial inducing character and full spherical level give a concrete residue calculation. Write $\tau = x + iy$ in the upper half-plane, $y > 0$, and define, for $\operatorname{Re} s > 1$,

$$E(s,\tau) = \frac{1}{2} \sum_{\substack{(c,d)\in\mathbb{Z}^2 \\ (c,d)=1}} \frac{y^s}{|c\tau + d|^{2s}}, \qquad \Lambda(t) = \pi^{-t/2}\Gamma(t/2)\zeta(t).$$

This is the level-one spherical series on $SL_2(\mathbb{Z})\backslash\mathfrak{H}$, with the measure $dx\,dy/y^2$. Its spherical adelic realization uses the normalized spherical finite-place vectors for trivial inducing character, and the trivial central character. The following statement concerns this inducing datum and level.

PROPOSITION 118.12.1 *(The constant residue).* The meromorphic continuation of $E(s,\tau)$ has a simple pole at $s = 1$, with constant residue. Define its positive-chamber residual subspace as the span of its square-integrable residues at poles with $\operatorname{Re} s > 1/2$. Then

$$L^2_{\mathrm{res},E} = \mathbb{C}\mathbf{1}, \tag{118.16}$$

and

$$\operatorname*{Res}_{s=1} E(s,\tau) = c_1\mathbf{1}, \qquad c_1 = \frac{1}{2\Lambda(2)} = \frac{3}{\pi}. \tag{118.17}$$

Proof. The lattice $y^{-1/2}(\mathbb{Z}\tau + \mathbb{Z}) \subset \mathbb{R}^2$ has covolume one. Its theta function is

$$\theta_\tau(t) = \sum_{(c,d)\in\mathbb{Z}^2} \exp\bigl(-\pi t|c\tau + d|^2/y\bigr), \qquad t > 0.$$

The dual of a covolume-one lattice in two dimensions is its rotation through a right angle. Poisson summation for the Gaussian therefore gives $\theta_\tau(t) = t^{-1}\theta_\tau(t^{-1})$. Mellin integration, initially for $\operatorname{Re} s > 1$, gives

$$\Lambda(2s)E(s,\tau) = \frac{1}{2}\int_0^\infty (\theta_\tau(t) - 1)t^{s-1}\,dt.$$

Indeed, the Gaussian integral for a nonzero lattice vector is $\pi^{-s}\Gamma(s)(|c\tau + d|^2/y)^{-s}$. Writing each integer pair as a positive multiple of a primitive pair accounts for $\zeta(2s)$ and the factor $1/2$. Split the integral at 1 and use the theta identity on $(0,1)$. The resulting continuation is

$$\Lambda(2s)E(s,\tau) = \frac{1}{2}\Bigl(\frac{1}{s-1} - \frac{1}{s}\Bigr) + \frac{1}{2}\int_1^\infty (\theta_\tau(t) - 1)(t^{s-1} + t^{-s})\,dt.$$

The integral is entire in s, since the nonzero lattice vectors have positive minimum length and the summands decay exponentially. Thus its residue at $s = 1$ is zero, whereas the rational term has residue $1/2$. Since $\Lambda(2) = \pi/6$, division proves (118.17). In $\operatorname{Re} s > 1/2$, the denominator $\Lambda(2s)$ has no zeros or poles: its zeta factor has the absolutely convergent Euler product, and its gamma factor is holomorphic and nonzero. The numerator continuation has only the pole at $s = 1$ in that half-plane. The positive-chamber residues consequently span exactly the constant line. That line lies in L^2, since the modular quotient has finite hyperbolic volume. This proves (118.16) for the stated sector. □

Fixing trivial central character alone does not select this sector. For example, tensoring an inducing pair by a Hecke character μ changes its common determinant twist while preserving its ratio. A residual character $\mu \circ \det$ has central character μ^2. The residual classification must retain these inducing data and twists. The theorem of Moœglin–Waldspurger, *Le spectre résiduel de $GL(n)$*, pp. 605–607, describes the residual spectrum with fixed unitary central character by repeated cuspidal data and their Langlands quotients. It does not identify the whole trivial-central-character spectrum with (118.16).

Local coordinates and residue normalization

For the symmetric normalized local family, write its characters as $(|\cdot|^{\sigma/2}, |\cdot|^{-\sigma/2})$. In the ordered coordinates used above,

$$a = q^{-\sigma/2}, \qquad b = q^{\sigma/2}, \qquad z = q^{-\sigma}.$$

The exceptional values have representatives $\sigma = \pm 1$, with translates by $2\pi i\mathbb{Z}/\log q$ at the level of the ratio. The ordered pair, including any common twist, must still be retained. The Weyl operation swaps (a, b) and sends σ to $-\sigma$. The unitary point $\sigma = 0$ has ratio 1 and is regular. One can use a separate chart $a(u) = q^{u-1/2}$, $b(u) = q^{1/2-u}$, so $\sigma = 1 - 2u$. Its two representatives are $u = 0, 1$, and the swap is $u \mapsto 1 - u$. A relation between this chart and a global inducing section must specify the inducing characters at every place.

For a meromorphic morphism $A(u) : V(u) \to W(u)$ in a fixed local trivialization, its residue is a degree-zero linear map between the specialized carriers. Under $v = 1 - u$, residues of the pulled-back family satisfy

$$\operatorname*{Res}_{v=1-u_0} A(1-v) = -\operatorname*{Res}_{u=u_0} A(u).$$

This follows by substituting $u - u_0 = -(v - (1 - u_0))$ in its Laurent expansion. Applying this formula to two different operators requires an identity between the families and identifications of their sources and targets. For the regular local operators the proved identity is $D^{\mathrm{sw}} D = h \,\mathrm{id}$ in (118.3). For the normal-equation comparison, replacing t by ut multiplies δ_t by u^{-1} on the divisor. A line and a normalized generator therefore contain different information.

The local extension and its reverse

At a finite prime the principal series already constructed has

$$0 \longrightarrow \mathbb{C} \longrightarrow E_p \longrightarrow \mathrm{St}_p \longrightarrow 0, \qquad E_p = \mathrm{Ind}_{B_p}^{G_p}(1)_{\text{unnormalized}}.$$

In normalized coordinates it occurs at $\sigma = -1$, or $z = p$. The nonsplitting proof gives the class

$$\alpha_p = [\, 0 \to \mathbb{C} \to E_p \to \mathrm{St}_p \to 0 \,] \neq 0 \quad \text{in } \mathrm{Ext}^1_{\mathrm{Rep}^{\mathrm{sm}}_{\mathbb{C}}(G_p)}(\mathrm{St}_p, \mathbb{C}). \tag{118.18}$$

It remains nonzero with the central character imposed strictly. The extension itself is

$$\mathcal{E}_p = (\mathbb{C} \xrightarrow{i_p} E_p \twoheadrightarrow \mathrm{St}_p).$$

The invariant-functional argument also proves $\mathrm{Hom}_{G_p}(\mathrm{St}_p, \mathbb{C}) = 0$. Thus a nonzero residue map from the induced representation cannot be replaced by a nonzero map $\mathrm{St}_p \to \mathbb{C}$. A residue-to-Yoneda comparison must construct a sequence or a connecting morphism and identify it with (118.18). The nonzero class does not determine the dimension of its Ext group.

Remark 118.12.2 *(The opposite orientation).* The reverse comparison asks for a specified nonsplit sequence

$$0 \longrightarrow \mathrm{St}_p \longrightarrow E'_p \longrightarrow \mathbb{C} \longrightarrow 0,$$

its class in $\mathrm{Ext}^1(\mathbb{C}, \mathrm{St}_p)$, and its relation to the opposite operator. For each orientation, the dimension question asks whether the Ext group is one-dimensional in the specified category. Its chosen generator and residue normalization require separate constructions. Neither the isomorphism induced by $\overline{D^{\mathrm{sw}}}$ nor the vanishing of the degree-two splitting obstruction computes these Ext dimensions. At the real place one must first specify a Harish–Chandra module category or a smooth topological category, central character, induction, and exact structure before posing the corresponding extension problem.

The automorphic extension problem

Let $\mathcal{A}_{\mathrm{aut}}$ denote a proposed enhanced automorphic category with a specified coefficient ring, quotient $[G]_Z$, support, central character and exact structure. A global comparison must construct this category and the objects below. Write $\mathbf{1}_{\mathrm{aut}}$ for the realization of the constant representation and S_{aut} for a proposed exceptional object, with its actual local components specified. The degree-one target is

$$\alpha_1^{\mathrm{aut}} \in \mathrm{Ext}^1_{\mathcal{A}_{\mathrm{aut}}}(S_{\mathrm{aut}}, \mathbf{1}_{\mathrm{aut}}).$$

The question of a normalized exceptional line asks whether

$$\mathrm{Ext}^1_{\mathcal{A}_{\mathrm{aut}}}(S_{\mathrm{aut}}, \mathbf{1}_{\mathrm{aut}}) = \mathbb{C}\alpha_1^{\mathrm{aut}}$$

after a specified complex realization, and asks the corresponding question for the reverse orientation. Both the object and the normalization are part of this problem.

The standard smooth all-place Steinberg tensor cannot supply S_{aut}: its finite part is ruled out by Proposition 118.9.1. A finite exterior product instead has degree equal to its number of places, by Proposition 118.8.2. The degree-one extension of Q_{ad} by $\mathbb{C}$ is a separate representation-theoretic construction. Its quotient contains mixed finite-place constituents, and its automorphic realization remains to be constructed. Neither a change of name nor a scalar restricted-product identity provides such a realization.

118.13 Residual parameters and deformation objects

The complex parameters of residual representations and the mod-p parameters of a deformation stack have different coefficient fields. Their comparison requires more than the same two-dimensional notation. Even over $\mathbb{C}$, the two SL_2 factors in a local Arthur parameter have different roles.

Definition 118.13.1 *(The non-tempered parameter).* At a finite place, use the domain $W_F \times SL_2(\mathbb{C})_{\mathrm{D}} \times SL_2(\mathbb{C})_{\mathrm{A}}$. Both parameters take values in $GL_2(\mathbb{C})$. Here W_F is the Weil group, the factor marked D is the Deligne factor, and the factor marked A is the additional Arthur factor. The trivial-character rank-two non-tempered parameter is

$$\psi_1(w, g_{\mathrm{D}}, g_{\mathrm{A}}) = g_{\mathrm{A}}. \tag{118.19}$$

The associated Langlands parameter is obtained by substituting $\mathrm{diag}(|w|^{1/2}, |w|^{-1/2})$ in the Arthur factor. This convention records its non-tempered exponents.

Definition 118.13.2 *(The monodromy parameter).* On the same domain, the standard rank-two Deligne parameter, regarded as an Arthur parameter trivial on its additional factor, is

$$\psi_0(w, g_{\mathrm{D}}, g_{\mathrm{A}}) = g_{\mathrm{D}}. \tag{118.20}$$

The distinction from (118.19) lies in which factor acts. Restricting both displays to an unnamed SL_2 would erase that distinction. A determinant twist changes the Weil part and does not exchange the two factors.

Remark 118.13.3 *(Local and global classification).* Arthur's parameter formalism separates the Deligne and Arthur factors. His endoscopic classification concerns orthogonal and symplectic groups, with GL_n classification as input. The residual classification for GL_n is the theorem of Mœglin–Waldspurger. For global data one can specify a formal cuspidal datum $\mu \boxtimes \nu_2$, where ν_2 is the standard two-dimensional representation. This notation does not construct a global Langlands group or a map to a residual-characteristic stack. Packet assertions must specify twists, central character and local-global realization. In particular, (118.20) does not construct an automorphic representation Steinberg at every finite place.

The direct sum of the trivial and mod-p cyclotomic characters admits several independent cyclotomic extension directions. Their dimensions, and the automorphisms of their deformations, depend on the prime. These data determine what a comparison with a distinguished extension class must preserve. The constructions below give the continuous local deformation groupoids, explicit Kummer classes, and a formal family integrating those classes.

First-order deformations and their automorphisms

Fix a separable closure K^{sep} of $K = \mathbb{Q}_p$, and put $\Gamma = \mathrm{Gal}(K^{\mathrm{sep}}/K)$, with its profinite topology. Let $k/\mathbb{F}_p$ be a finite field with the discrete topology. Choose a primitive pth root ζ_p, with $\zeta_2 = -1$, and define

$$g(\zeta_p) = \zeta_p^{\omega(g)}, \qquad \omega : \Gamma \longrightarrow \mathbb{F}_p^{\times} \longrightarrow k^{\times}.$$

Write $k(r)$ for the one-dimensional k-representation with character ω^r. In particular, $\omega = 1$ when $p = 2$. Fix the ordered basis e_1, e_2 of $V = k^2$, and set

$$\rho_0(g) = \begin{pmatrix} 1 & 0 \\ 0 & \omega(g) \end{pmatrix}, \qquad \mathfrak{a} = \mathrm{End}_k(V), \qquad \mathfrak{a}_0 = \ker(\mathrm{tr} : \mathfrak{a} \to k).$$

Write E_{ij} for the matrix sending e_j to e_i and the other basis vector to zero. The action on $\mathfrak{a}$ is $gX = \rho_0(g) X \rho_0(g)^{-1}$. All cochains and representations are continuous.

For a finite discrete Γ-module N, use the inhomogeneous cochains $C^n(\Gamma, N) = \mathrm{Map}_{\mathrm{cts}}(\Gamma^n, N)$, with $C^0(\Gamma, N) = N$. Their differential is

$$\begin{aligned} (df)(g_1, \dots, g_{n+1}) = {} & g_1 f(g_2, \dots, g_{n+1}) \\ & + \sum_{i=1}^{n} (-1)^i f(g_1, \dots, g_i g_{i+1}, \dots, g_{n+1}) \\ & + (-1)^{n+1} f(g_1, \dots, g_n). \end{aligned}$$

Thus $dX(g) = gX - X$ and $dc(g,h) = gc(h) - c(gh) + c(g)$. Write $Z^1(\Gamma, N) = \ker(d : C^1 \to C^2)$, $B^1(\Gamma, N) = dN$, and $H^i(\Gamma, N) = H^i(C^\bullet(\Gamma, N))$.

Set $A = k[\epsilon]/(\epsilon^2)$, with the discrete topology. A framed deformation is a continuous representation $\rho : \Gamma \to \mathrm{GL}_2(A)$ reducing to ρ_0 in the specified basis. Morphisms preserve this entire A-basis. A residual-marked unframed deformation is a free rank-two A-module with a continuous Γ-action and a specified identification of its reduction with V. Its morphisms induce the identity on V.

PROPOSITION 118.13.4 *(Continuous first-order groupoids).* Framed deformations form the discrete groupoid on $Z^1(\Gamma, \mathfrak{a})$. Residual-marked unframed deformations form the action groupoid

$$[Z^1(\Gamma, \mathfrak{a})/\mathfrak{a}], \qquad X : c \longmapsto c - dX.$$

Its isomorphism classes form $H^1(\Gamma, \mathfrak{a})$. The automorphism group of each object is the additive group $H^0(\Gamma, \mathfrak{a})$.

Proof. Every framed lift has a unique expression

$$\rho_c(g) = (1 + \epsilon c(g))\rho_0(g).$$

Multiplication gives

$$\rho_c(g)\rho_c(h) = \big(1 + \epsilon(c(g) + gc(h))\big)\rho_0(gh).$$

The homomorphism condition is therefore $dc = 0$. A basis lifting e_1, e_2 identifies any residual-marked deformation with such a matrix representation. Two such choices differ by $1 + \epsilon X$, and

$$(1 + \epsilon X)\rho_c(g)(1 - \epsilon X) = \rho_{c - dX}(g).$$

The quotient and automorphism statements follow from this equality. An automorphism fixes c exactly when $dX = 0$. □

If the residual marking is forgotten, the residual centralizer also acts. Write

$$C = \{B \in \mathrm{GL}_2(k) : B\rho_0(g) = \rho_0(g)B \text{ for all } g\}.$$

Every permissible change of basis is $(1 + \epsilon X)B$, and its action is

$$c \longmapsto BcB^{-1} - dX.$$

Thus the acting group is $\mathfrak{a} \rtimes C$. For odd p, the character ω is nontrivial and C is the group of invertible diagonal matrices. For $p = 2$, it is $\mathrm{GL}_2(k)$. The stabilizer of c consists of the pairs satisfying $BcB^{-1} - dX = c$. At $c = 0$, this is $H^0(\Gamma, \mathfrak{a}) \rtimes C$. In particular, a formal scheme viewed as a groupoid-valued functor cannot represent these unframed groupoids: its points have only identity automorphisms, whereas these groupoids have nonzero infinitesimal automorphisms. This assertion concerns the groupoids, rather than representability of their sets of isomorphism classes.

Determinant character and determinant identification

Fixing a determinant character restricts the objects of a deformation problem. Choosing an identification of determinant representations also restricts its morphisms. To separate these conditions, fix

$$\delta_\eta(g) = \omega(g)(1 + \epsilon\eta(g)), \qquad \eta \in Z^1(\Gamma, k).$$

Here the action on k is trivial, so η is a continuous additive homomorphism. For a character $\delta : \Gamma \to A^\times$, write $A(\delta)$ for the free rank-one module with that action. The constant determinant lift has $\eta = 0$. The identity

$$\det \rho_c(g) = \omega(g)(1 + \epsilon \operatorname{tr} c(g))$$

holds in every characteristic.

Proposition 118.13.5 *(The two fixed-determinant groupoids).* For the constant lift $\delta_0 = \omega$, the residual-marked deformation groupoid with fixed determinant character is

$$\mathcal{D}_{\mathrm{char}}(A) = [Z^1(\Gamma, \mathfrak{a}_0)/\mathfrak{a}].$$

Fix the residual orientation $e_1 \wedge e_2$. If objects include an identification $\lambda : \det(V_A) \xrightarrow{\sim} A(\omega)$ lifting that orientation, and arrows preserve λ, the groupoid is

$$\mathcal{D}_{\det}(A) = [Z^1(\Gamma, \mathfrak{a}_0)/\mathfrak{a}_0].$$

Both groupoids have isomorphism classes $H^1(\Gamma, \mathfrak{a}_0)$. Their automorphism groups are respectively $H^0(\Gamma, \mathfrak{a})$ and $H^0(\Gamma, \mathfrak{a}_0)$.

Proof. The fixed-character equation is $\operatorname{tr} c = 0$. Every strict conjugation preserves the determinant, and $\operatorname{tr}(dX) = 0$. This proves the first groupoid formula. For the second, choose a lifted basis with $\lambda(e_1 \wedge e_2) = 1$. Such a basis exists because

$$\det : 1 + \epsilon\mathfrak{a} \longrightarrow 1 + \epsilon k$$

is surjective: $\operatorname{diag}(1 + \epsilon t, 1)$ has determinant $1 + \epsilon t$. Changes between these bases satisfy $\operatorname{tr} X = 0$, which proves the second formula.

The trace admits the Γ-equivariant splitting

$$k \longrightarrow \mathfrak{a}, \qquad t \longmapsto tE_{11}.$$

Indeed, E_{11} is invariant and has trace one. Hence $\mathfrak{a} = \mathfrak{a}_0 \oplus kE_{11}$ and $d\mathfrak{a} = d\mathfrak{a}_0$, including when $p = 2$. The two orbit sets are therefore $H^1(\Gamma, \mathfrak{a}_0)$. The equations $dX = 0$, with the respective trace restrictions, give the stated automorphism groups. □

For a general η, the cocycle $c_\eta(g) = \eta(g)E_{11}$ has trace η. The object spaces are therefore the affine translates $c_\eta + Z^1(\Gamma, \mathfrak{a}_0)$, with the same gauge formulas. A determinant-compatible framing requires $\lambda(e_1 \wedge e_2) = 1$, and gives the discrete groupoid on $Z^1(\Gamma, \mathfrak{a}_0)$ when $\eta = 0$. If a full framing and an independent determinant identification are both retained, the discrete object set is instead $Z^1(\Gamma, \mathfrak{a}_0) \times k$: the second coordinate records $\lambda(e_1 \wedge e_2) = 1 + \epsilon t$. For a chosen determinant identification, forgetting the residual marking allows residual changes in $C \cap \mathrm{SL}_2(k)$.

The coefficient decomposition is

$$\mathfrak{a} = kE_{11} \oplus kE_{22} \oplus k(-1)E_{12} \oplus k(1)E_{21},$$
$$\mathfrak{a}_0 = k(E_{11} - E_{22}) \oplus k(-1)E_{12} \oplus k(1)E_{21}.$$

At $p = 2$, the diagonal trace-zero generator is I, and every summand has trivial action. At $p = 3$, the two off-diagonal characters coincide, but their matrix subspaces remain distinct.

The first-order tangent groupoid is presented by the two-term complex

$$[\mathfrak{a} \xrightarrow{-d} Z^1(\Gamma, \mathfrak{a})] \quad \text{in degrees } [-1, 0].$$

Its degree -1 cohomology records automorphisms and its degree 0 cohomology records deformation classes. This is the truncation through degree zero of $C^\bullet(\Gamma, \mathfrak{a})[1]$, with the cohomological shift convention $(C[1])^i = C^{i+1}$ and shifted differential $-d$. Thus $H^2(\Gamma, \mathfrak{a})$ occurs in degree one of the full shifted complex. For a determinant identification, replace $\mathfrak{a}$ by $\mathfrak{a}_0$. For the fixed-character problem alone, the two-term complex is $[\mathfrak{a} \xrightarrow{-d} Z^1(\Gamma, \mathfrak{a}_0)]$. Identifying any full cochain complex with the tangent complex of a specified derived stack requires an equivalence of the underlying moduli problems.

Kummer classes at every prime

The lower-left summand has an explicit arithmetic description. For $a \in K^\times$, choose $\beta_a \in K^{\mathrm{sep}}$ with $\beta_a^p = a$, and define

$$\frac{g(\beta_a)}{\beta_a} = \zeta_p^{\kappa_a(g)}, \qquad \kappa_a(g) \in \mathbb{F}_p \subset k.$$

The action on roots of unity gives

$$\kappa_a(gh) = \kappa_a(g) + \omega(g)\kappa_a(h).$$

This cocycle is continuous, since β_a and ζ_p lie in a finite Galois extension. Replacing β_a by $\zeta_p^r \beta_a$ changes it by the coboundary $dr(g) = \omega(g)r - r$.

PROPOSITION 118.13.6 *(Explicit cyclotomic cohomology).* The Kummer map gives an isomorphism

$$(\mathbb{Q}_p^\times / \mathbb{Q}_p^{\times p}) \otimes_{\mathbb{F}_p} k \xrightarrow{\sim} H^1(\Gamma, k(1)), \qquad [a] \otimes 1 \longmapsto [\kappa_a].$$

For odd p, a basis is $[\kappa_p]$, $[\kappa_{1+p}]$. For $p = 2$, a basis is $[\kappa_2]$, $[\kappa_{-1}]$, $[\kappa_5]$. The dimensions are respectively two and three.

Proof. Multiplication of roots makes the Kummer map additive modulo pth powers. If $\kappa_a = dr$, replacing β_a by $\zeta_p^{-r}\beta_a$ makes it invariant. Hence a is a pth power in K. Conversely, Hilbert 90 implies that every continuous μ_p-valued cocycle is $g(\beta)/\beta$ for some $\beta \in (K^{\mathrm{sep}})^\times$. Then $\beta^p \in K^\times$. This proves the isomorphism over $\mathbb{F}_p$.

The required Hilbert 90 statement reduces to a finite Galois extension L/K through which the cocycle factors. If z_σ is a multiplicative cocycle for $\mathrm{Gal}(L/K)$, choose $a \in L$ so that

$$b = \sum_\sigma z_\sigma \sigma(a) \neq 0.$$

Such an a exists by linear independence of distinct field automorphisms. The cocycle identity gives $\tau(b) = z_\tau^{-1} b$. Consequently $z_\tau = \tau(b^{-1})/b^{-1}$, as required. This is the proof of Milne, *Class Field Theory*, Proposition II.1.22, p. 67. A basis of the finite extension $k/\mathbb{F}_p$ decomposes each continuous cochain into finitely many coordinate cochains. Tensoring with k therefore commutes with cohomology.

For odd p, the multiplicative decomposition is

$$\mathbb{Q}_p^\times = p^{\mathbb{Z}} \times \mu_{p-1} \times (1 + p\mathbb{Z}_p).$$

The valuation supplies the first factor. Hensel lifting of the distinct nonzero residues supplies the roots of unity in the second factor. The pth-power map on μ_{p-1} is bijective. The logarithm and exponential give inverse homomorphisms

$$\log : 1 + p\mathbb{Z}_p \xrightarrow{\sim} p\mathbb{Z}_p.$$

For $x, y \in p\mathbb{Z}_p$, the estimates

$$v_p(x^n/n) \geq n - v_p(n), \qquad v_p(y^n/n!) \geq n - v_p(n!)$$

prove convergence of the logarithm and exponential, using $v_p(n!) \leq n/(p-1)$. Their formal inverse and product identities pass to these convergent series. Logarithm carries pth powers to $p^2\mathbb{Z}_p$, and $\log(1+p) \equiv p \pmod{p^2}$. Thus valuation and the principal-unit quotient give the basis $[p]$, $[1+p]$.

At $p = 2$, each odd unit has a unique sign making it congruent to one modulo four. Hence

$$\mathbb{Q}_2^\times = 2^{\mathbb{Z}} \times \{1, -1\} \times (1 + 4\mathbb{Z}_2).$$

The preceding convergence estimates, with input valuation at least two, give $\log(1 + 4\mathbb{Z}_2) = 4\mathbb{Z}_2$. Squaring becomes multiplication by two, and $\log(5) \equiv 4 \pmod 8$. The valuation, sign, and principal-unit factors give the independent classes $[2]$, $[-1]$, $[5]$. □

In particular, $p = 3$ gives the basis $[\kappa_3]$, $[\kappa_4]$. The choice of ζ_p identifies μ_p with $\mathbb{F}_p(1)$. Changing it rescales all numerical cocycles by one nonzero scalar. The intrinsic classes take values in $\mu_p \otimes_{\mathbb{F}_p} k$.

The unit classes form an arithmetic subspace, and valuation gives an exact sequence

$$0 \longrightarrow (\mathbb{Z}_p^\times/(\mathbb{Z}_p^\times)^p) \otimes_{\mathbb{F}_p} k \longrightarrow H^1(\Gamma, k(1)) \xrightarrow{v_p} k \longrightarrow 0.$$

The unit subspace has dimension one for odd p and two for $p = 2$. The specified uniformizer p supplies the splitting $1 \mapsto [\kappa_p]$. The quotient itself does not specify a splitting.

There is also an unramified condition. If $I \subset \Gamma$ is inertia, define its subspace as

$$H^1_{\mathrm{ur}}(\Gamma, k(1)) = \operatorname{im}\bigl(H^1(\Gamma/I, k(1)^I) \to H^1(\Gamma, k(1))\bigr).$$

For odd p, this is zero: $\mathbb{Q}_p(\zeta_p)/\mathbb{Q}_p$ is totally ramified of degree $p - 1$, since $((1 + T)^p - 1)/T$ is Eisenstein at p. Thus $k(1)^I = 0$. At $p = 2$, the unramified subspace is the line $k[\kappa_5]$. Indeed, $(1 + \sqrt{5})/2$ satisfies $x^2 - x - 1 = 0$, whose reduction is separable and irreducible over $\mathbb{F}_2$. It therefore generates the unramified quadratic extension. Since $\Gamma/I \cong \widehat{\mathbb{Z}}$, its continuous additive characters into k form a one-dimensional k-space.

An explicit formal family

Each cyclotomic cocycle defines both an extension of residual representations and a tangent direction at their split sum. For $b \in Z^1(\Gamma, k(1))$, set

$$r_b(g) = \begin{pmatrix} 1 & 0 \\ b(g) & \omega(g) \end{pmatrix}.$$

The line ke_2 is invariant, and the quotient is trivial. Thus r_b gives an exact sequence

$$0 \longrightarrow k(1) \longrightarrow E_b \longrightarrow k \longrightarrow 0.$$

Conversely, a vector-space splitting of any such extension gives this matrix form. Changing the splitting changes b by a coboundary. Consequently

$$\operatorname{Ext}^1_{\mathrm{Rep}_k^{\mathrm{cts}}(\Gamma)}(k, k(1)) \cong H^1(\Gamma, k(1)),$$

where the category consists of finite-dimensional discrete continuous k-representations. The order of the two endpoint characters is part of this identification.

The coefficient inclusion $u \mapsto uE_{21}$ and projection onto the lower-left entry commute with the cochain differential. They induce an injection with a specified left inverse

$$j : H^1(\Gamma, k(1)) \hookrightarrow H^1(\Gamma, \mathfrak{a}_0).$$

The class $j([b])$ is represented by $\rho_{\epsilon b}(g) = \left(\begin{smallmatrix} 1 & 0 \\ \epsilon b(g) & \omega(g) \end{smallmatrix}\right)$.

THEOREM 118.13.7 *(Formal cyclotomic family).* Set $d = 2$ and $(a_1, a_2) = (p, 1 + p)$ for odd p. For $p = 2$, set $d = 3$ and $(a_1, a_2, a_3) = (2, -1, 5)$. Choose the Kummer cocycles above and set

$$R_{\mathrm{gal}} = k[[t_1, \dots, t_d]], \qquad u(g) = \sum_{i=1}^{d} t_i \kappa_{a_i}(g).$$

With the maximal-ideal topology on R_{gal}, the matrices

$$\rho_{R_{\mathrm{gal}}}(g) = \begin{pmatrix} 1 & 0 \\ u(g) & \omega(g) \end{pmatrix}$$

define a continuous representation reducing to ρ_0, with determinant ω and the standard determinant identification. Its tangent map is injective, with image $j(H^1(\Gamma, k(1)))$.

Proof. The cocycle equation for u is exactly the lower-left entry of $\rho_{R_{\mathrm{gal}}}(gh) = \rho_{R_{\mathrm{gal}}}(g)\rho_{R_{\mathrm{gal}}}(h)$. The finitely many cocycles factor through a common finite Galois quotient, so the representation is continuous for the maximal-ideal topology. Its determinant and reduction follow from the diagonal entries.

For each Artinian local k-algebra B with residue field k, use the same residual-marked deformation definition on free rank-two B-modules, with the discrete topology on B. A continuous local homomorphism $R_{\mathrm{gal}} \to B$ specializes these matrices to a deformation. This is compatible with homomorphisms between such algebras and therefore defines a map from the functor of points of Spf R_{gal} to the determinant-identified deformation groupoid. A tangent homomorphism sends t_i to ϵx_i. Its class is $j(\sum_i x_i[\kappa_{a_i}])$. The Kummer basis and the left inverse of j prove injectivity. □

Changing β_{a_i} to $\zeta_p^{r_i}\beta_{a_i}$ adds dr_i to the corresponding cocycle. Set $s = \sum_i t_i r_i$. Conjugation by $1 - sE_{21}$ carries the old formal family to the new one, since its lower-left entry changes by ds. This calculation holds over R_{gal}, without a first-order truncation. The formal family therefore changes by an explicit isomorphism under these root choices.

This family fixes both diagonal characters and a line and quotient. It is not asserted to represent the full deformation problem. At $p = 2$, the underlying residual representation is trivial, and its unmarked form has no preferred decomposition into two lines. The inclusion through E_{21} uses the stated frame or flag. For odd p, the two distinct character subspaces are intrinsic, although their scalar coordinates still depend on the chosen bases.

Dimensions and comparison maps

The Kummer calculation determines one direct summand without local duality. The full dimension table also uses finite-module local duality and the local Euler characteristic theorem (Milne, *Arithmetic Duality Theorems*, Corollary I.2.3, p. 28, and Theorem I.2.8, p. 31). For a finite-dimensional continuous $k[\Gamma]$-module N, they imply

$$h^2(N) = h^0(N^\vee(1)), \qquad h^0(N) - h^1(N) + h^2(N) = -\dim_k N,$$

where $h^i(N) = \dim_k H^i(\Gamma, N)$ and $N^\vee = \mathrm{Hom}_k(N, k)$. The field trace pairing identifies the underlying finite-module dual with the additive module of $N^\vee(1)$. The Euler formula follows by substituting $|N| = p^{[k:\mathbb{F}_p]\dim_k N}$ into $\chi(\Gamma, N) = (\mathbb{Z}_p : |N|\mathbb{Z}_p)^{-1}$. Both theorems apply at $p = 2$, since the base field has characteristic zero. For $N = k(r)$, they give

$$h^1(k(r)) = 1 + \mathbf{1}_{\omega^r=1} + \mathbf{1}_{\omega^{1-r}=1}.$$

The matrix decomposition and $\dim B^1(\Gamma, N) = \dim N - h^0(N)$ now give

	$p \geq 5$	$p = 3$	$p = 2$
$h^1(k)$	2	2	3
$h^1(k(1))$	2	2	3
$h^1(k(-1))$	1	2	3
$h^0(\mathfrak{a})$	2	2	4
$h^0(\mathfrak{a}_0)$	1	1	3
$h^1(\mathfrak{a})$	7	8	12
$h^1(\mathfrak{a}_0)$	5	6	9
$\dim Z^1(\Gamma, \mathfrak{a})$	9	10	12
$\dim Z^1(\Gamma, \mathfrak{a}_0)$	7	8	9
$h^2(\mathfrak{a})$	1	2	4
$h^2(\mathfrak{a}_0)$	1	2	3

These dimensions concern the unrestricted local continuous problem. A crystalline, finite-flat, ordinary, or global Selmer condition requires its own definition before imposing a further subspace.

The explicit formal family supplies a local Galois target for a comparison. A specified nonzero Kummer class selects a one-parameter subfamily. The unit condition selects a line for odd p and a plane at $p = 2$. Identifying any of these with a line arising from an analytic residue requires a map that carries that residue to the stated cohomology class and is nonzero.

A coherent extension requires further categorical data. For example, an exact k-linear functor from $\mathrm{Rep}_k^{\mathrm{cts}}(\Gamma)$ to a specified abelian category, with identified images of k and $k(1)$, sends E_b to an extension with those endpoints. An exact functor between specified stable categories instead sends its associated triangle to a triangle. Either construction gives a map on extension classes. An isomorphism requires a calculation of that map, including its kernel and image. A tangent vector alone does not define two coherent objects or a functor between their categories. On $\operatorname{Spec} k[t]$, for instance, the tangent space at zero is k, whereas $\operatorname{Ext}^1(k[t], k[t]) = 0$. For the residue module k_0, the resolution

$$0 \longrightarrow k[t] \xrightarrow{t} k[t] \longrightarrow k_0 \longrightarrow 0$$

instead gives $\operatorname{Ext}^1(k_0, k_0) = k$. Thus the endpoints of a coherent extension are indispensable.

A comparison from a complex representation category also requires arithmetic coefficient data. There is no unital field map $k \to \mathbb{C}$, since it would carry $p \cdot 1_k = 0$ to $p \cdot 1_{\mathbb{C}} \neq 0$. There is no unital map in the reverse direction either, since p is invertible in $\mathbb{C}$. Reduction must instead specify an integral coefficient ring, an integral object or stable lattice, a residue-field map to k, and the induced map on the relevant extension classes. A global Galois comparison additionally requires a ramification set, local conditions, and the restriction maps into the local cohomology computed here.

Finally, scalar twisting gives

$$(1 \oplus \omega) \otimes \omega^{-1} = \omega^{-1} \oplus 1.$$

This is $1 \oplus 1$ only at $p = 2$. At $p = 3$, exchanging summands identifies it with the original representation. For any scalar character χ, conjugation gives $\mathrm{Ad}(\rho_0 \otimes \chi) = \mathrm{Ad}(\rho_0)$, while the determinant changes by χ^2. Hence a scalar twist need not preserve a fixed-determinant fibre, and no extra determinant twist enters the adjoint cochain formulas.

The formal stack and its framed presentation

The local deformation groupoids above retain the residual representation and its automorphisms. At the split cyclotomic point, the residual-marked determinant-identified groupoid has

$$\pi_0 \mathcal{D}_{\det}(k[\epsilon]/(\epsilon^2)) = H^1_{\mathrm{cts}}(\Gamma, \mathrm{ad}^0(1 \oplus \omega)).$$

Here π_0 means the set of isomorphism classes, with its vector-space structure from the cocycle description. Fixing only the determinant character gives the same isomorphism classes at this split point, but retains the larger automorphism group $H^0(\Gamma, \mathfrak{a})$. This distinction follows from the equivariant trace splitting through E_{11}, including in characteristic two.

For the Emerton–Gee moduli problem, a framed lifting ring supplies a versal presentation of the formal deformation groupoid. Emerton–Gee, Proposition 3.6.3, p. 76, identifies the self-fiber product using the change-of-basis group completed along the residual centralizer, or along the identity for the pointed formal problem. It does not replace the unframed groupoid by a formal scheme with no automorphisms. A derived enhancement, wild-inertia conditions and an identification with its full tangent complex require the corresponding moduli comparison. The computed local complex retains this requirement.

Tangent complexes and spectral extension classes

A tangent direction describes deformation of one point. An extension between two sheaves requires two objects and a category of morphisms. To express the proposed comparison, suppose a derived stack $\mathcal{X}$ over k has been specified, with a cotangent complex $\mathbb{L}_{\mathcal{X}}$ admitting the dual used below. At a point x, set $T_x = R\,\mathrm{Hom}_k(x^*\mathbb{L}_{\mathcal{X}}, k)$. Its degree-zero cohomology is the first-order tangent space, while degree minus one records infinitesimal automorphisms. Write $\mathbb{T}^1_x = H^0(T_x)$ for this convention.

Suppose in addition that a spectral category $\mathcal{A}_{\mathrm{sp}}$ has been constructed, with objects O_{St} and $O_{\mathbf{1}}$ and specified support. These names alone do not define sheaves. For example, an ind-coherent category with nilpotent singular support requires a derived stack for which its singularity space and the specified nilpotent subset are defined. The desired comparison is

$$L_{\mathrm{cyc}} \longrightarrow \mathrm{Ext}^1_{\mathcal{A}_{\mathrm{sp}}}(O_{\mathrm{St}}, O_{\mathbf{1}}), \qquad L_{\mathrm{cyc}} \subseteq \mathbb{T}^1_{x_{\mathrm{cyc}}}.$$

Here the subspace L_{cyc}, its dimension and the displayed map are constructions still required. A cotangent calculation does not identify this Ext group between two different sheaves.

Remark 118.13.8 *(The reverse spectral comparison).* For a point x_{triv} representing $1 \oplus 1$, the opposite orientation asks for a specified subspace $L_{\mathrm{triv}} \subseteq \mathbb{T}^1_{x_{\mathrm{triv}}}$ and a map

$$L_{\mathrm{triv}} \longrightarrow \mathrm{Ext}^1_{\mathcal{A}_{\mathrm{sp}}}(O_{\mathbf{1}}, O_{\mathrm{St}}).$$

The two endpoints and their support must be constructed in this category. The explicit scalar-twist calculation above does not identify this problem with the cyclotomic problem at odd primes. At $p = 2$, equality of the residual representations still does not choose the two sheaves or the map. An Arthur parameter over $\mathbb{C}$ supplies neither spectral comparison by itself.

118.14 The arithmetic class comparison

An automorphic category over $\mathbb{C}$ and a tangent space over k cannot be compared by an unnamed extension of scalars. A unital ring homomorphism $k \to \mathbb{C}$ would send $p \cdot 1 = 0$ to $p \cdot 1 \neq 0$, which is impossible. One possible comparison would use a common integral coefficient ring, lifts of both objects,

and derived specialization maps to their respective fibers. It must specify whether cohomology commutes with these specializations, including any torsion. The complex family over R above does not supply this integral construction.

Definition 118.14.1 *(The first comparison target).* After a common coefficient realization over a ring A has been constructed, denote the realized automorphic category by $\mathcal{A}_{\mathrm{aut},A}$ and the lifted exceptional tangent module by $L_{\mathrm{cyc},A}$. The first class comparison seeks

$$\mathsf{c}_1^{\mathrm{exc}} : \operatorname{Ext}^1_{\mathcal{A}_{\mathrm{aut},A}}(S_{\mathrm{aut},A}, \mathbf{1}_{\mathrm{aut},A}) \xrightarrow{\sim} L_{\mathrm{cyc},A}, \qquad \alpha_1^{\mathrm{aut}} \longmapsto e_{\mathrm{cyc}}. \tag{118.21}$$

The symbols on both sides denote required realizations of the specified objects and classes, not objects supplied by this definition.

Definition 118.14.2 *(The reverse comparison target).* With the reverse extension and the second deformation problem realized over the same coefficient ring, the second target is

$$\mathsf{c}_0^{\mathrm{exc}} : \operatorname{Ext}^1_{\mathcal{A}_{\mathrm{aut},A}}(\mathbf{1}_{\mathrm{aut},A}, S_{\mathrm{aut},A}) \xrightarrow{\sim} L_{\mathrm{triv},A}, \qquad \alpha_0^{\mathrm{aut}} \longmapsto e_{\mathrm{triv}}. \tag{118.22}$$

The local chart $u \mapsto 1 - u$ does not construct the coefficient or deformation comparison needed for this arrow.

The scalar residue and a derived pairing

The scalar ratio can be recovered from the constant term of the specified Eisenstein series. For $\operatorname{Re} s > 1$, separate the terms with $c = 0$ and sum the others over $c \geq 1$ and reduced residues d modulo c. Integration in x over $[0, 1]$ unfolds the translates $d + mc$, $m \in \mathbb{Z}$, to the real line. If $\varphi(c)$ is the number of reduced residue classes modulo c, this gives

$$\int_0^1 E(s, x + iy)\, dx = y^s + y^s \sum_{c \geq 1} \frac{\varphi(c)}{c^{2s}} \int_{\mathbb{R}} (u^2 + y^2)^{-s}\, du.$$

The last integral is $y^{1-2s}\sqrt{\pi}\,\Gamma(s - 1/2)/\Gamma(s)$, by $u = y \tan\theta$. The Euler factors give $\sum_{c \geq 1} \varphi(c) c^{-2s} = \zeta(2s - 1)/\zeta(2s)$. Thus the constant term is $y^s + n(s)\, y^{1-s}$, where

$$n(s) = \frac{\Lambda(2s - 1)}{\Lambda(2s)}.$$

The completed zeta function satisfies $\Lambda(t) = \Lambda(1 - t)$. This follows from the same Gaussian Mellin argument in one dimension. It has residues 1 at $t = 1$ and -1 at $t = 0$. Since $\Lambda(2) = \pi/6$, the Laurent expansion gives

$$c_1^{\mathrm{LS}} = \operatorname*{Res}_{s=1} n(s) = \frac{1}{2\Lambda(2)}, \qquad c_0^{\mathrm{LS}} = \operatorname*{Res}_{s=0} n(s)^{-1} = -\frac{1}{2\Lambda(2)}.$$

Indeed, $n(s)n(1 - s) = 1$, so the second identity is the first after $s \mapsto 1 - s$. The archimedean quotient $\Gamma_{\mathbb{R}}(2s - 1)/\Gamma_{\mathbb{R}}(2s)$, where $\Gamma_{\mathbb{R}}(t) = \pi^{-t/2}\Gamma(t/2)$, is regular at $s = 1$ and equals π. The global pole does not give a pole of this archimedean factor there.

To compare this scalar with extension classes, let U_{s_0} and V_{s_0} be chosen complexes computing the two realized derived Hom objects. A derived pairing inducing a bilinear form on their degree-one cohomology consists of a morphism $U_{s_0} \otimes^{\mathbf{L}}_{A} V_{s_0} \to A[-2]$. The shift puts A in cohomological degree two. A Bost–Connes operation σ^{BC} must be defined on these complexes, with its action and compatibility proved.

Write $e_1 = e_{\mathrm{cyc}}$ and $e_0 = e_{\mathrm{triv}}$ for the required chosen tangent classes at the two comparison targets. The desired normalization is an equality of specified pairings

$$P^{\mathrm{LS}}_{s_0}(\alpha^{\mathrm{aut}}_{s_0}, \sigma^{\mathrm{BC}} e_{s_0}) = c^{\mathrm{LS}}_{s_0} P_{s_0}(\alpha^{\mathrm{aut}}_{s_0}, e_{s_0}), \qquad s_0 \in \{0,1\},$$

after a coefficient realization in which the displayed scalars exist. This is a chain-level comparison problem. The nonzero scalar does not prove existence or nondegeneracy of either pairing. Bar–cobar duality transports derived morphisms only after its algebra, coalgebra, twisting cochain and module realizations have been given. It does not construct the displayed trace or pairing from a scalar identity of principal-series vectors.

Remark 118.14.3 *(The exceptional global comparison).* The exceptional Eisenstein comparison asks for both (118.21) and (118.22), natural in the allowed inducing characters and compatible with specialization. Its required constructions are a common coefficient realization, automorphic exceptional objects, residue-to-Yoneda maps, spectral objects with support, and the derived pairing and tangent maps. The wild-inertia enhancement of Conjecture 61.5.7 is an additional residual-characteristic input. It does not supply the other constructions. If the two component maps through Galois cohomology are constructed as natural isomorphisms, their composition is a natural isomorphism: the composite of their commutative naturality squares is the required square. This implication supplies no component map. The global comparison remains unresolved.

118.15 Derived maps and global assembly

Even a comparison of degree-zero and degree-one morphisms on generators would leave a categorical obstruction. The following finite calculation isolates that obstruction without making any arithmetic assumptions.

Example 118.15.1 *(Agreement in degrees zero and one).* Let k be a field and let $A = k \oplus ke$ be the unital graded algebra with $|e| = 1$, $e^2 = 0$ and zero differential. Let $B = k \oplus ke \oplus kf$, where $|f| = 2$, all products of positive-degree elements vanish, and the differential is zero. The quotient $p : B \to A$ fixes 1, e and kills f. Use perfect right differential graded modules, namely the smallest idempotent-complete triangulated subcategories generated by the free modules. Extension of scalars defines

$$F = - \otimes^{\mathbf{L}}_B A : \mathrm{Perf}(B) \longrightarrow \mathrm{Perf}(A), \qquad F(B) = A.$$

A right-linear endomorphism of a free rank-one module is determined by its value at 1 and acts by left multiplication. The free modules compute their own derived Hom complexes. Thus the map on their endomorphism complexes is precisely $p : B \to A$. It induces isomorphisms in degrees zero and one, with values k and ke, but its degree-two map is $kf \to 0$. It is not a quasi-isomorphism, and F is not fully faithful. The image A still generates the target perfect category. Hence these low-degree agreements and a generating image do not suffice for full faithfulness.

The Eisenstein category

The exceptional extension problem therefore remains part of the full local-global comparison

$$F : \bigotimes_v{}' C_v \longrightarrow \mathcal{D}^{\text{sph-fin}}([G]_Z).$$

Here the local stable categories C_v, their spherical objects, transition functors and restricted tensor product must be specified. The target must be an actual enhancement of the chosen automorphic category

with its support convention. The non-exceptional comparison in Theorem 85.8.1 and the Paley–Wiener comparison in Theorem 85.5.6 retain their stated functor and support hypotheses. Extending them to closed exceptional strata requires compatible localization or recollement functors and maps on the attaching objects.

For an exact functor on small idempotent-complete stable categories generated by a set $\mathcal{G}$, a sufficient full-faithfulness condition is equivalence of all mapping spectra between generators. To see the extension of this condition, fix one generator. The objects for which its mapping comparison is an equivalence form a subcategory closed under shifts, cones and retracts, by exactness. It therefore contains every object. Apply the same argument in the other variable. Full faithfulness follows, and a generating essential image gives equivalence. For presentable categories, compact generation, preservation of colimits and compactness of the relevant images provide the analogous extension from compact generators. These are substantive hypotheses, not consequences of degree-one agreement.

Cuspidal, residual and continuous objects

The Hilbert decomposition of Theorem 85.6.1 separates cuspidal, residual and continuous spectra. Its orthogonality is an assertion about Hilbert inner products. To assemble a stable automorphic category one needs categorical embeddings of the corresponding sectors, adjunctions and gluing maps, including the continuous exceptional and non-exceptional loci. A Hilbert orthogonal sum does not determine mapping complexes between their enhancements. The cuspidal comparison of Theorem 70.6.4, the residual comparison of Theorem 85.6.3, and the non-exceptional comparison must therefore be combined through specified derived functors. Bernstein-center actions, local-global realization and the closed-stratum attaching maps must commute with these functors. The local splitting and adelic extension above supply input objects; they do not prove this assembly.

118.16 Compatibility with residual-characteristic comparisons

At $p = 2, 3$, the local class comparisons in Definitions 87.2.1 and 87.2.2 concern a residual-characteristic block. Their connecting maps and deformation comparison in Propositions 87.2.8 and 87.2.7 must be used with their hypotheses. A global exceptional comparison would need localization maps on automorphic extensions, coefficient specialization, and the corresponding restriction of its Galois deformation problem. Compatibility means a commutative square between those actual maps. Equality of their target H^1 groups is insufficient: two linear maps to the same nonzero space can differ by any scalar, or have different images. A naturality statement for a functor applies only after the same sequence and morphisms have been realized in its domain.

The common-twist freedom also remains. The local ratios and the scalar normalizing factor depend on the ratio of inducing characters. Multiplying both characters by μ preserves that ratio and changes the induced representation by $\mu \circ \det$. Thus the trivial ratio does not force trivial inducing character. Central characters, normal coordinates, Haar measures and any Bost–Connes operation must be compared under this twist. The universal full-category Koszul roof and the pointwise strict-center roof prove different statements. A canonical family of strict-center splittings compatible with Weyl symmetry remains an additional construction. Their existence at one complex point does not provide an integral or residual-characteristic comparison.

118.17 Arithmetic descent conditions

The arithmetic descent conditions named in Proposition 85.10.1 and Theorem 87.5.1 concern the following mathematically distinct questions.

(i) The non-ordinary part of F1.a.1 asks for essential surjectivity of the derived Emerton–Gee comparison at $p \geq 5$ on its specified non-ordinary locus.

(ii) The Taylor–Wiles part of F1.a.1 asks for extension beyond the Taylor–Wiles hypotheses, with the deformation conditions retained.

(iii) F1.a.2 asks for the residual-characteristic local class match at $p = 2, 3$, under the wild-inertia and comparison hypotheses of Theorem 87.2.9.

(iv) The exceptional Eisenstein part of $\mathrm{L}_{\mathrm{ACD}}$ asks for the global class maps of Remark 118.14.3 and their full derived extension across the exceptional strata. The local exceptional ratios and the global scalar points use their respective coordinates.

(v) Bernstein-center diamond gluing asks for compatible center maps and categorical descent, including the local-global realization and transition functors used in the global assembly.

The fourth question is not exhausted by the third. The explicit finite-place constructions establish the local cone, its coefficient specializations, pointwise fixed-center splitting, finite exterior products and the mixed adelic extension. Their global arithmetic realization still requires the maps above.

118.18 Sources and further comparisons

The constructions separate three operations: specialization of a regular intertwining complex, formation of Yoneda products, and realization in automorphic or spectral categories. Their respective carriers determine which further comparisons can be formulated. The following sources provide the surrounding representation theory, spectral analysis and deformation theory.

Casselman.
Introduction to the Theory of Admissible Representations of p-Adic Reductive Groups, 1 May 1995, Proposition 2.1.7, p. 20, and Section 8.1, p. 70, give compact averaging and the Steinberg quotient.

Schneider–Stuhler.
Representation theory and sheaves on the Bruhat–Tits building, Publ. Math. IHÉS **85** (1997), 97–191, Section II.2 and Theorem II.3.1, develop cellular resolutions with coefficient systems.

Langlands.
Eisenstein Series, Section 10, pp. 12–14 of the author's reprint, computes the rank-one spherical residue. Its variable $z = 2s - 1$ accounts for the factor $1/2$ in the residue used here. *On the Functional Equations Satisfied by Eisenstein Series*, Lecture Notes in Mathematics 544 (1976), treats the general spectral problem.

Moœglin–Waldspurger.
Le spectre résiduel de $GL(n)$, Ann. Sci. ENS **22** (1989), 605–674, introduction and Section I.1, gives the residual classification and normalized intertwiners. *Spectral Decomposition and Eisenstein Series: A Paraphrase of the Scriptures*, Cambridge Tracts 113 (1995), develops the spectral theory.

Shahidi.
Eisenstein Series and Automorphic L-Functions, AMS Colloquium Publications 58 (2010), treats intertwining operators, local coefficients and L-function normalization.

Arthur.
The Endoscopic Classification of Representations: Orthogonal and Symplectic Groups, AMS Colloquium Publications 61 (2013), concerns classical-group classification. The author's exposition *The Endoscopic Classification of Representations*, pp. 1–4, distinguishes the Deligne and Arthur factors.

Emerton–Gee.
Moduli stacks of étale (φ, Γ)*-modules and the existence of crystalline lifts*, arXiv:1908.07185, Proposition 3.6.3, pp. 74–76, gives the versal framed presentation.

Breuil–Mézard.
Multiplicités modulaires et représentations de $GL_2(\mathbb{Z}_p)$ *et de* $\mathrm{Gal}(\overline{\mathbb{Q}}_p/\mathbb{Q}_p)$ *en* $\ell = p$, Duke Math. J. **115** (2002), concerns local deformation multiplicities.

Bellaïche–Chenevier.
Families of Galois representations and Selmer groups, Astérisque 324 (2009), treats reducibility, extension classes and trianguline deformations. Its Chapter 2 concerns refined crystalline representations.

Schlessinger and Mazur.
Schlessinger, *Functors of Artin rings*, Trans. AMS **130** (1968), 208–222, Theorem 2.11, states the hull and prorepresentability conditions. Mazur, *Deforming Galois representations*, MSRI Publications 16 (1989), 385–437, develops deformations of Galois representations.

Bernstein–Zelevinsky.
Induced representations of reductive $\mathfrak{p}$*-adic groups I*, Ann. Sci. ENS **10** (1977), concerns smooth parabolic induction.

Wallach and Jacquet–Langlands.
Wallach, *Real Reductive Groups I* (1988), and Jacquet–Langlands, *Automorphic Forms on* $GL(2)$, Lecture Notes in Mathematics 114 (1970), supply real representation theory and automorphic context. The real extension problem requires a category and normalization of its own.

Harish-Chandra.
Harmonic analysis on real reductive groups II: Wave packets in the Schwartz space, Invent. Math. **36** (1976), 1–55, and *III: The Maass–Selberg relations and the Plancherel formula*, Ann. Math. **104** (1976), 117–201, concern real spectral analysis.

Kisin.
Potentially semi-stable deformation rings, J. AMS **21** (2008), 513–546, concerns potentially semistable deformation conditions with specified Hodge data.

Tate.
Fourier analysis in number fields and Hecke's zeta functions, Princeton thesis (1950), reprinted in Cassels–Fröhlich (1967), Chapter XV, treats adelic Fourier analysis and zeta integrals.

Milne.
Class Field Theory (2020), Proposition II.1.22, p. 67, gives the Hilbert 90 argument. *Arithmetic Duality Theorems*, second edition (2006), Corollary I.2.3 and Theorem I.2.8, pp. 28–31, give the finite-module local duality and Euler characteristic formulas.

Positselski.
Two kinds of derived categories, Koszul duality, and comodule–contramodule correspondence, arXiv:0905.2621, Sections 6.3 and 6.5, constructs derived equivalences from specified bar coalgebras and twisting cochains.

The next arithmetic comparison must realize the specified exceptional objects over common coefficients and construct their residue-to-Yoneda and deformation maps. Only then can their normalizations, wild-prime restrictions and full derived morphisms be compared.

Chapter 119

Residual Boundary of the Arithmetic Branch

A Hilbert space with a scaling action and the Weil pairing on arithmetic test functions are different data. A unitary comparison can transport a scaling operator to a proposed boundary space. Positivity of the full Weil pairing instead constrains the zeros of the completed zeta function. This chapter separates these two assertions before listing the additional geometric and arithmetic comparisons.

119.1 Hilbert Descent, Scaling, and the Weil Pairing

Write $\mathscr{A} = C_c^\infty(\mathbb{R})$ for the compactly supported smooth functions of the logarithmic variable, with convolution and $f^*(t) = \overline{f(-t)}$. The Fourier transform

$$(\mathcal{F}_+ f)(z) = \int_{\mathbb{R}} f(t) e^{izt}\, dt$$

identifies this algebra with its entire image $\mathscr{P} = \mathcal{F}_+ \mathscr{A}$, equipped with pointwise multiplication and $h^\sharp(z) = \overline{h(\bar{z})}$. Both spaces and their transported topologies are those of Definition 78.1.1. On the compact-test algebra the signed explicit formula is

$$W(f) = P(f) - W_\infty(f) - W_{\mathrm{fin}}(f),$$

with the polar, archimedean, and prime terms defined in Theorem 78.1.2. The Hermitian form is $q_W(f, g) = W(f * g^*)$. None of these definitions uses a boundary Hilbert-space construction.

For comparison, the continuous scaling model is

$$H_c = L^2(\mathbb{R}_{>0}, dx/x), \qquad (U_a \phi)(x) = \phi(e^{-a} x).$$

Under $t = \log x$, put $D_c = -i\,\partial_t$ on $H^1(\mathbb{R})$ and $\Theta_c = \frac{1}{2} + i D_c$ on the same domain. Here H^1 consists of square-integrable functions whose weak first derivative is square-integrable. The translation group satisfies $U_a = e^{-iaD_c}$, and

$$e^{-a\Theta_c} = e^{-a/2} U_a, \qquad |e^{-a\Theta_c}| = e^{-a/2} \mathrm{I}_{H_c} \quad (a \in \mathbb{R}).$$

This norm identity is unconditional and makes no assertion about q_W.

Theorem 119.1.1 *(arithmetic positivity and boundary transport).* The archimedean Tate positivity (A-TP) statement of Conjecture 78.2.3 is equivalent to RH. No Hilbert-descent hypothesis is needed for this equivalence.

Suppose separately that a Hilbert-descent construction supplies a space H_B. Specify a closed normal operator Θ_B and a unitary $V_\Sigma : H_B \to H_c$ such that

$$V_\Sigma \operatorname{Dom}(\Theta_B) = \operatorname{Dom}(\Theta_c), \qquad V_\Sigma \Theta_B = \Theta_c V_\Sigma \quad \text{on } \operatorname{Dom}(\Theta_B).$$

Then every $e^{-a\Theta_B}$, $a \in \mathbb{R}$, is bounded and

$$e^{-a\Theta_B} = V_\Sigma^{-1} e^{-a\Theta_c} V_\Sigma, \qquad |e^{-a\Theta_B}| = e^{-a/2} 1_{H_B}.$$

Thus descent together with A-TP implies RH through A-TP; the surface operator comparison additionally requires the stated unitary and generator-domain data.

Proof. The signed explicit formula gives

$$q_W(f,f) = P(f * f^*) - W_\infty(f * f^*) - W_{\mathrm{fin}}(f * f^*).$$

Consequently A-TP is precisely $q_W(f,f) \geq 0$ for every $f \in \mathscr{A}$. Apply Corollary 78.2.1. For the operator statement, the domain and intertwining equalities identify the spectral resolutions of Θ_B and Θ_c. The latter has spectrum in $1/2 + i\mathbb{R}$, on which $z \mapsto e^{-az}$ has constant modulus $e^{-a/2}$. Normal functional calculus proves both identities. This is the comparison specified in Theorem 115.9.2. □

Remark 119.1.2 *(one exponential does not determine its generator).* The Hilbert limit in Conjecture 115.8.3 and the comparison V_Σ are separate inputs. Even equality of the surface operator at $a = 1$ does not replace the generator comparison: Θ_c and $\Theta_c + 2\pi i\, 1$ have the same domain and the same exponential at $a = 1$, but are distinct operators. They give distinct one-parameter families at nonintegral a. To identify a native surface theory one must in addition relate its independently defined observable to this transported operator. No map from arithmetic test functions or arithmetic cohomology is supplied by the norm identity.

The radial spherical transform of Theorem 27.6.1 provides a different unitary comparison: tree adjacency becomes multiplication by $2\sqrt{p}\cos\theta$, and the root state becomes integration against ν_p. Section 27.8 extends this comparison to finite sets of primes. An arithmetic realization still requires a map from the primitive trace carrier preserving the Hecke operations and pairing. Tame residue and Gersten operations require additional maps on common coefficients. The positive tree state supplies no identification with the full Weil functional W defined above.

119.2 The Full Weil Positivity Condition

In compact coordinates the arithmetic condition is

$$W(f * f^*) \geq 0 \qquad (f \in \mathscr{A}).$$

Define $\mathscr{W} : \mathscr{P} \to \mathbb{C}$ by $\mathscr{W}(h) = W(\mathcal{F}_+^{-1} h)$. Its equivalent Fourier form is

$$\mathscr{W}(hh^\sharp) \geq 0 \qquad (h \in \mathscr{P}).$$

The product here is pointwise multiplication of entire functions, not convolution on $\mathscr{P}$.

PROPOSITION 119.2.1 *(the two test-space forms of Weil positivity).* The compact and Fourier inequalities above are equivalent, and each is equivalent to RH. Restricting to an arbitrary proper test subspace requires a separate argument before the same criterion can be used.

Proof. Fubini gives $\mathcal{F}_+(f * f^*) = (\mathcal{F}_+ f)(\mathcal{F}_+ f)^\sharp$. By definition $\mathcal{F}_+ : \mathscr{A} \to \mathscr{P}$ is onto; Fourier inversion makes it one-to-one. Hence the two universally quantified inequalities agree. Their equivalence with RH is Corollary 78.2.1 on exactly this test space. Neither an auxiliary digamma quadratic form nor continuous scaling purity replaces the full polar-minus-archimedean-minus-prime expression. □

119.3 Comparison and Descent Conjectures

Definition 119.3.1 *(comparison and descent inputs).* The comparison and descent boundary contains the following named inputs.

Input	Carries	Form
Wild-EG enhancement	F1.a.2.class-match; $\mathrm{L}_{\mathrm{ACD}}$ Eisenstein $\mathrm{Ext}^{\mathrm{I}}$ at $\{0,1\}$; BC-glue wild inertia	open
Cross-prime transition and effective descent	BC-diamond-glue cross-prime prismatic glue	open
Arithmetic AG singular support	global arithmetic Arinkin–Gaitsgory singular-support condition and the centre of BC-diamond-glue	open
Clausen–Scholze condensed-Hilbert descent	Quantum arithmetic Chern–Simons bulk extension	open
Consani–Marcolli adele-class duality	Positselski G-row duality and the abelian Heisenberg base-change line	open
Chenevier Selmer-ring, trace and equivariant-descent datum	Pairwise sheaf comparison under the full Ch1 hypotheses	open
BCglue centre-compatible categorical functors and coefficient/family comparisons	K5 and the Jacquet–Shalika trace comparison in BC-diamond-glue	open
Ben-Zvi lift at infinity	$\mathrm{L}_{\mathrm{ACD}}$ archimedean compatibility and finite uniformity	open
BZN wild trace data	Large-prime semisimplicity and the wild Ext-trace pairing	open
Symmetric-square weight limit	Weil–Petersson weight-aspect positivity for holomorphic cusp forms	open
Arithmetic chiral bar nilpotency	The square-zero property of the proposed arithmetic chiral pre-differential d^{Ar}	open

The relative Galois bar in Chapter 36 has a square-zero differential over each $\mathbb{Z}/\ell^r$. Theorem 36.4.2 compares its endpoint products in every arity, and Corollary 36.6.4 passes to the specified restricted adic limit. The last row concerns the separate arithmetic chiral pre-differential. Identifying its carrier, residue operations, and completion with the relative Galois construction remains an additional comparison problem.

Theorem 119.3.2 *(visible non-RH residuals).* Each input in Definition 119.3.1 is a non-RH residual named elsewhere in the arithmetic branch. The statement does not assert exhaustion of all possible residuals.

Proof. With its stated comparison hypotheses, Wild-EG (the Emerton–Gee wild-inertia enhancement) is an input to the residual-characteristic local comparison for F1.a.2 in Theorem 113.3.1. The global exceptional Eisenstein comparison in Remark 118.14.3 additionally requires a common coefficient realization, the automorphic carriers, a residue-to-Yoneda comparison, and compatible full derived maps. For BC-diamond-glue it must be accompanied by the block-centre maps, compatible functors and normalized class comparisons specified in Proposition 116.3.3. The ordinary $\ell \neq p$ scalar comparison does not supply these data.

The cross-prime input is the specified transition, coherent-support, filtration and higher-coherence datum of Hypothesis 56.5.2, together with the effective descent required by its gluing theorem. It is not an independently proved pro-étale or prismatic-site flatness statement. Arithmetic AG (arithmetic Arinkin–Gaitsgory singular support) is the global singular-support conjecture 42.1.1, required at the centre of BC-diamond-glue by Corollary 116.6.1. The specified condensed-Hilbert descent datum supplies the Hilbert, trace, and finite-place Wilson clauses of the chosen quantum ACS model by Theorem 115.8.4. The archimedean operator comparison also requires the unitary and generator domains in Theorem 115.9.2. The other rows are the named conditional inputs constructed in Chapters 75, 73, 56, 52, 54, 83, and 33. These are stated as separate comparison hypotheses. No implication from A-TP to these constructions, or in the reverse direction, is established by the Weil positivity criterion. □

Remark 119.3.3 *(Wild-EG concentration).* Wild-EG is a common input to the three comparison problems F1.a.2, the exceptional L_{ACD} Eisenstein Ext^1 crossing at $\{0, 1\}$, and wild-inertia BC-diamond-glue. Each retains its stated class-comparison hypotheses. For BC-diamond-glue, one must also construct the fixed-determinant block-ring isomorphisms, compatible fully faithful functors and normalized class maps of Proposition 116.3.3, together with the coefficient, family and global comparisons. The wild-EG enhancement alone does not construct these data.

119.4 The Generalised Ramanujan Conjecture for GL_4

The Rankin–Selberg square of a Maass form on $\mathrm{GL}_2/\mathbb{Q}$ comes from an isobaric automorphic object on $\mathrm{GL}_4/\mathbb{Q}$. Full temperedness of that GL_4 object at every finite place, equivalently GRC for its cuspidal factors, closes the Maass sector of the $\mathcal{V}^{\mathrm{prim}}$ Hochschild-trace identity. This conjecture is separated from A-TP in the proof: it concerns Satake eigenvalues, not zero placement.

Hypothesis 119.4.1 *(GRC for* $\mathrm{GL}_4/\mathbb{Q}$ *in the Selberg class).* The isobaric automorphic representations of $\mathrm{GL}_4/\mathbb{Q}$ arising from the Rankin–Selberg square of a Maass form have tempered cuspidal factors at every finite place.

PROPOSITION 119.4.2 *(GRC-*GL_4 *closes the Maass sector).* Conditional on Hypothesis 119.4.1, full Ramanujan holds for the Maass forms entering the $\mathcal{V}^{\mathrm{prim}}$ Hochschild-trace P_3 identity of Theorem 114.6.1. This closes the Maass sector. No equivalence with RH is asserted here; no implication between this hypothesis and A-TP is used.

Proof. Chapter 114 proves that the Arthur–Ramakrishnan–GRC hypothesis implies full Ramanujan for Maass forms (Theorem 114.5.5) and reduces that hypothesis to Hypothesis 119.4.1 (Proposition 114.5.6). The P_3 identity is the exact conditional statement of Theorem 114.6.1. A-TP concerns the zeros of ζ through Weil positivity; GRC-GL_4 concerns Satake parameters. The argument uses the two residuals as separate inputs. □

119.5 F_1.a.1 Small Residuals

Two small residuals occur in the F_1.a.1 table of Chapter 117. They are not a count of all small residuals in the arithmetic branch.

PROPOSITION 119.5.1 *(small residuals).* Besides the generator-comparison inputs and the automorphy/patching hypotheses isolated in Lemma 117.3.4 and Lemma 117.3.5, the F_1.a.1 table has the following two small residual tails:

(i) **Supersingular small-weight tail** (Conjecture 117.2.8): non-Fontaine–Laffaille representations with Hodge–Tate weights $k \in \{p-1, p\}$, requires a non-formal theorem.
(ii) A_5 **non-solvable descent defect** (Conjecture 117.3.8): local-global descent defect in the icosahedral sector, requires a non-formal theorem.

Proof. The two listed residual tails are read from Proposition 117.4.2. The Fontaine–Laffaille supersingular core is reduced to the generator comparison of Theorem 117.2.6. The odd-determinant icosahedral core is reduced to the conditional theorem of Theorem 117.3.6. The two tails listed above are additional obstructions in that decomposition. □

119.6 Arithmetic Hypotheses and Realization Data

Remark 119.6.1 *(scope of the arithmetic conditions).* The conditions above concern arithmetic comparison, descent, temperedness and small-prime regularity. A marked realization as in Chapter 1 additionally requires its source and target, coefficient functor, operation-preserving maps and evaluation identity. The arithmetic conditions alone construct none of those maps and imply no realization assertion for an object in another coefficient category.

119.7 Residual Boundary

Theorem 119.7.1 *(arithmetic branch obstruction decomposition).* The arithmetic branch has, at least, the following obstructions:

(i) one statement equivalent to RH: archimedean Tate positivity;
(ii) the comparison and descent inputs of Definition 119.3.1;
(iii) one Ramanujan-type hypothesis separated from A-TP: GRC for $\mathrm{GL}_4/\mathbb{Q}$;
(iv) the two F_1.a.1 small residuals of Proposition 119.5.1.

The arithmetic conditions listed here do not construct the marked realizations of Chapter 1.

Proof. Item (1) is Proposition 119.2.1. Item (2) is Theorem 119.3.2. Item (3) is Proposition 119.4.2. Item (4) is Proposition 119.5.1. A marked realization requires the separate data described in Remark 119.6.1; the listed arithmetic conditions do not supply those data. No implication from the table to RH is asserted except through A-TP. □

Remark 119.7.2 *(domain of the boundary).* The theorem isolates the displayed RH-equivalent content into A-TP and places the visible non-RH obstructions in named inputs. It does not prove RH and it does not claim that the arithmetic comparison is complete.

Appendix A

Primary Sources

This appendix records the primary literature anchoring the arithmetic branch of Volume IV. Each entry states author(s), title, year, arXiv identifier where applicable, and the role in the branch: which chapter invokes the result and for what purpose.

The entries are organized by mathematical topic: factorization and homotopy-theoretic sources (§§A.5–A.7); geometric Langlands, Hecke categories, and local Langlands (§§A.8–A.9); arithmetic Chern–Simons and arithmetic topology (§A.10); arithmetic D-modules and F-isocrystals (§A.6); operator theory and moment problems (§A.24); and background sources in automorphic forms, adelic analysis, Yangians, Arakelov geometry, Macdonald theory, and primon-gas statistical mechanics (remaining sections).

A.1 Kapranov and Kapranov–Smirnov

Kapranov–Smirnov 1995 *Cohomology determinants and reciprocity laws: number field case*. Unpublished preprint, ~15 pp., ca. 1995. PDF mirrored at `http://cage.ugent.be/~kthas/Fun/library/KapranovSmirnov.pdf`. Frames Spec $\mathbb{Z}$ as an "arithmetic curve" via the analogy between number fields and function fields over finite fields; motivates the absolute point / $\mathbb{F}_1$ programme and prime-labelled cohomology determinants feeding reciprocity laws. Used throughout this branch as the foundational informal reference (Chapters 26, 33).

Kapranov ca. 1995–96 *Analogies between number fields and 3-manifolds*. Unpublished preprint. Foundational for arithmetic topology; the MKR (Mazur–Kapranov–Reznikov) dictionary matches closed oriented 3-manifolds to number fields and knots to primes. Extended in Reznikov arXiv:math/0107210 (2001) and Morishita's book *Knots and Primes* (2012). Used in Chapter 37 for the Wilson-line = ramified Hecke character dictionary in Kim's arithmetic Chern–Simons.

Kapranov–Vasserot 2004 *Vertex algebras and the formal loop space*, Publ. IHES 100:209–269; arXiv:math/0107143. Introduces the ind-scheme $\mathcal{L}X$ of formal loops into a finite-type scheme X; factorization structure on $\mathcal{L}X$ recovers vertex-algebra structure on chiral de Rham. Four-paper series; Part IV = arXiv:math/0612371. No Spec $\mathbb{Z}$ version exists; this branch is the arithmetic analogue.

Kapranov 2000 *The elliptic curve in the S-duality theory and Eisenstein series for Kac–Moody groups*, arXiv:math/0001005. S-duality on an elliptic curve; not used here directly.

A.2 Borger and Λ-Ring Theory

Borger 2008 *The basic geometry of Witt vectors, I: The affine case*, Algebra & Number Theory 5:231–285; arXiv:0801.1691. For commuting operations see §1.5; for flat Frobenius lifts, §1.6; for the classical torsion-free special-λ criterion, §1.17. These are the distinctions used in Chapter 28.

Borger 2010 *The basic geometry of Witt vectors, II: Spaces*, arXiv:1006.0092. Extends to algebraic spaces; generalises Buium's arithmetic jet functor. Background for the space-valued Witt construction; no Λ-module definition or arithmetic Fock comparison is inferred.

Borger 2009 *Λ-rings and the field with one element*, arXiv:0906.3146. Central reference. Section1.1 describes the Frobenius lifts on flat spaces; §1.2 gives the categorical descent interpretation. The torsion-free criterion is Wilkerson1982, Proposition1.2, identified in Borger0801.1691, §1.17. No literal tensor-product construction on the arithmetic trace class follows from this interpretation. Used throughout Chapter 28.

Borger–de Smit 2008 *Galois theory and integral models of Λ-rings*, arXiv:0801.2352. Relative case: Λ-structure over a Noetherian base.

A.3 Bost–Connes, Connes–Marcolli, Connes–Consani

Bost–Connes 1995 *Hecke algebras, type III factors and phase transitions with spontaneous symmetry breaking in number theory*, Selecta Math. 1:411–457. Central reference for the arithmetic quantum statistical system. KMS partition function $\zeta(\beta)$; phase transition at $\beta = 1$; spontaneous symmetry breaking by $\mathrm{Gal}(\mathbb{Q}^{\mathrm{ab}}/\mathbb{Q})$. Explicitly motivated by Julia's primon gas.

Connes–Marcolli 2004 *From Physics to Number Theory via Noncommutative Geometry, Part I & II*, Part I arXiv:math/0404128. $HH^\bullet(C^*_{\mathbb{Q}})$ computed §1.8; used in Chapter 29 for the Theorem $\mathrm{H}^{\mathrm{arith}}$ comparison.

Connes–Consani 2014 *The Arithmetic Site*, arXiv:1405.4527. Arithmetic site = Grothendieck topos $\widehat{\mathbb{N}^\times}$ with tropical semiring $\mathbb{Z}_{\max}$ structure sheaf. A separate arithmetic-site construction; an identification with the polynomial Fock operations of Chapter 28 requires an actual comparison.

Connes–Consani 2015 *Geometry of the arithmetic site*, arXiv:1502.05580. Extends (1405.4527); Frobenius correspondences as subvarieties.

Connes–Consani 2012 *Universal thickening of the field of real numbers*, arXiv:1202.4377. Background on the real-number completion of the arithmetic site; not directly invoked in computations but provides the archimedean-fibre context for $\mathbb{F}_1$-descent.

A.4 Kontsevich, Soibelman, Davison: E_n Formality and CoHA

Kontsevich 2003 *Deformation quantization of Poisson manifolds*, Lett. Math. Phys., arXiv:q-alg/9709040. Foundational for operadic formality. Used in Chapter 39 §1.

Kontsevich 1999 *Operads and Motives in Deformation Quantization*, arXiv:math/9904055. E_n-formality over $\mathbb{Q}$ for all n; cited in Chapter 39 §1 for the rational formality input.

Tamarkin 1998 *Another proof of M. Kontsevich formality theorem*, arXiv:math/9803025. Drinfeld-associator-based proof for E_2.

Kontsevich–Soibelman 2010 *Cohomological Hall algebra, exponential Hodge structures, and motivic DT invariants*, arXiv:1006.2706. Sections 2.2–2.4 construct the extension product and its Euler-class shuffle formula. The critical theory uses potential-dependent coefficients. See Chapter 12. A comparison with a real spectral measure requires a separate operator and state.

Efimov 2012 *Cohomological Hall algebra of a symmetric quiver*, arXiv:1103.2736, Theorem 1.1. The rational CoHA of a finite symmetric quiver with zero potential is free supercommutative after a sign modification. Its primitive generator space has a polynomial translation factor of degree two.

Dotsenko–Mozgovoy 2021 *DT invariants from vertex algebras*, arXiv:2108.10338, Proposition 5.3 and Theorems 5.6–5.7. The graded dual of this symmetric-quiver CoHA is a connected vertex bialgebra. Its primitive vertex Lie algebra is free over translation, with finite-dimensional quotient in each charge.

Fresse 2017 *Homotopy of Operads and Grothendieck–Teichmüller Groups*, Vol. II. Integral E_1-formality theorem used in Chapter 39 §1.

Kaledin 2014 *Universal Witt vectors and the "Japanese cocycle"*. Integral-E_2 obstruction.

Salvatore–Wahl 2002 Dyer–Lashof operations on $H_\bullet(E_2;\mathbb{F}_p)$.

Davison–Meinhardt 2020 *Cohomological Donaldson–Thomas theory of a quiver with potential and quantum enveloping algebras*, arXiv:1601.02479. Theorems A and C give the critical PBW result. The theorem retains the stability, slope, Serre-subcategory, monodromic mixed-Hodge and sign data. Its absolute PBW isomorphism concerns underlying graded objects. The free-algebra conclusion applies to the perverse associated graded. See Theorem 12.10.1.

A.5 Beilinson–Drinfeld, Francis–Gaitsgory, Positselski

Beilinson–Drinfeld 2004 *Chiral Algebras*, AMS Colloq. Publ. 51. Ch. 3 (chiral bar), Ch. 4 (Hochschild).

Francis–Gaitsgory 2011 *Chiral Koszul duality*, Selecta Math., arXiv:1103.5803. Chiral Lie–commutative Koszul duality. This differs from the associative coefficient bar in Chapter 33. It does not supply the arithmetic associative comparison requested there.

Positselski 2011 *Two kinds of derived categories, Koszul duality, and comodule-contramodule correspondence*, Mem. AMS, arXiv:0905.2621. Used in Chapter 33 §7 for arithmetic Positselski.

Parshin–Kato 1979–1980 *A generalization of local class field theory by using K-groups*. Residue maps and reciprocity in their specified geometric and coefficient settings. Chapter 33 separates the Steinberg identity from a comparison with chiral collision operations.

A.6 Arithmetic $\mathcal{D}^\dagger$-Modules and F-Isocrystals

Berthelot 1996 *$\mathcal{D}$-modules arithmétiques. I. Opérateurs différentiels de niveau fini*, Ann. Sci. Éc. Norm. Sup. 29:185–272. Foundational construction of arithmetic differential operators of finite level. Used in Chapter 58 only as the local p-adic coefficient shadow of the finite-place Hecke/diamond category.

Berthelot 2000 *$\mathcal{D}$-modules arithmétiques. II: descente par Frobenius*, Mém. SMF 81. Frobenius descent for arithmetic $\mathcal{D}$-modules.

Caro 2009 *$\mathcal{D}$-modules arithmétiques surholonomes*, Ann. Sci. Éc. Norm. Sup. 42:141–192. Overholonomic arithmetic $\mathcal{D}$-modules and stability under the six operations; also records overconvergent unit F-isocrystals as overholonomic in the smooth case.

Kedlaya 2004 *Full faithfulness for overconvergent F-isocrystals*, in *Geometric Aspects of Dwork Theory*, 819–836. Full faithfulness for overconvergent F-isocrystals. This is a coefficient reference, not an equivalence between finite-prime Hecke categories and classical D-modules.

A.7 Costello, Costello–Gwilliam, Costello–Gaiotto

Costello–Gwilliam 2017, 2021 *Factorization Algebras in Quantum Field Theory*, CUP Vol. I & II. Used throughout Chapter 30.

Costello 2013 *Supersymmetric Gauge Theory and the Yangian*, arXiv:1303.2632. Holomorphic-topological factorization.

Costello 2020 *Holography and Koszul duality*, lecture/preprint notes. Background on Koszul duality as a holographic mechanism; context for the arithmetic Koszul-duality formulation of Chapter 38.

Costello–Gaiotto 2019 *Vertex operator algebras and 3d $\mathcal{N} = 4$ gauge theories*, arXiv:1804.06460. Used in Chapter 37 §3.

Costello–Dimofte–Gaiotto 2020 *Boundary chiral algebras and holomorphic twists*, arXiv:2005.00083. Boundary conditions in holomorphic-topological theories and their chiral algebra content; background for the TQFT-Chern–Simons comparison in Chapter 37.

Costello–Witten–Yamazaki 2017 *Gauge theory and integrability I*, arXiv:1709.09993. 4D Chern–Simons.

Costello–Yamazaki 2019 *Gauge theory and integrability III*, arXiv:1908.02289. Rational and trigonometric R-matrices from 4D Chern–Simons; background for the Bethe-algebra comparison in Chapter 40.

Francis 2012 *Factorization homology of topological manifolds*, arXiv:1206.5522. Used in Chapter 30 §4 for locally-constant E_n-reduction.

A.8 Geometric Langlands, Derived Satake, Hecke Categories

Mirković–Vilonen 2007 *Geometric Langlands duality and representations of algebraic groups over commutative rings*, Ann. Math., arXiv:math/0401222. Geometric Satake.

Bezrukavnikov 2016 *On two geometric realizations of an affine Hecke algebra*, Publ. IHES, arXiv:1209.0403. Iwahori Hecke category; central for Chapter 38.

Ben-Zvi–Nadler 2009 *The character theory of a complex group*, arXiv:0904.1247. Hochschild trace = $O(\mathrm{LocSys})$; gluing principle for the synthesis (Chapter 41).

Arinkin–Gaitsgory 2015 *Singular support of coherent sheaves and the geometric Langlands conjecture*, Selecta Math., arXiv:1201.6343. Nilpotent singular support AG-conjecture.

Fargues–Scholze 2021 *Geometrization of the local Langlands correspondence*, arXiv:2102.13459. Local arithmetic Langlands via Fargues–Fontaine curve.

Dotto–Emerton–Gee 2026 *A categorical p-adic Langlands correspondence for $GL_2(\mathbb{Q}_p)$*, arXiv:2603.26887. Fully faithful local categorical p-adic Langlands functor for $p \geq 5$; not a local equivalence and not a global adelic theorem.

Caraiani–Scholze 2015/2017 *On the generic part of the cohomology of compact unitary Shimura varieties*, arXiv:1511.02418. Torsion-freeness of the generic part of Shimura variety cohomology; cited in Chapter 38 §4 as a constraint on the global adelic Hecke-category input.

Emerton–Gee 2020 *Moduli stacks of étale (φ, Γ)-modules and the existence of crystalline lifts*, arXiv:1908.07185. Emerton–Gee stack of Galois deformations; central for Chapter 38 §4.

Emerton–Gee 2011 *A geometric perspective on the Breuil–Mézard conjecture for GL_2*, arXiv:1109.4226. Breuil–Mézard geometry; not the Emerton–Gee stack source.

Zhu 2020 arXiv:2008.02998. Coherent Springer theory.

Zhu 2016 arXiv:1603.05593; Bhatt–Scholze 2016, arXiv:1507.06490. Witt-vector affine Grassmannian.

A.9 FLE, Quantum Geometric Langlands, and Root-of-Unity Quantum Groups

Gaitsgory 2008 *Twisted Whittaker model and factorizable sheaves*, Selecta Math. 13:617–659; arXiv:0705.4571. Whittaker and factorizable-sheaf source for quantum geometric Langlands.

Gaitsgory 2016 *Quantum Langlands Correspondence*, arXiv:1601.05279. Informal 2007 notes outlining local and global quantum Langlands and the FLE; cited in Chapter 63 for the quantum parameter dictionary.

Campbell–Dhillon–Raskin 2021 *Fundamental local equivalences in quantum geometric Langlands*, Compos. Math. 157:2699–2732; arXiv:1907.03204. Quantum FLE in the local affine-Grassmannian/affine-flag setting; cited in Chapter 63 §2 for the local quantum Langlands equivalence as input to the arithmetic analogue.

Gaitsgory–Lysenko 2019 *Metaplectic Whittaker category and quantum groups: the small FLE*, arXiv:1903.02279. Small FLE and small quantum group source.

Arinkin et al. 2024 Arinkin–Beraldo–Campbell–Chen–Faergeman–Gaitsgory–Lin–Raskin–Rozenblyum 2024. *Proof of the geometric Langlands conjecture II: Kac–Moody localization and the FLE*, arXiv:2405.03648. Critical level FLE and its compatibility with Kac–Moody localization in the geometric, not arithmetic, setting.

Frenkel–Gaitsgory 2006 *Local geometric Langlands correspondence and affine Kac–Moody algebras*, Progr. Math. 253, 69–260; arXiv:math/0508382. Critical local geometric Langlands and affine Kac–Moody source layer.

Raskin 2021 *Chiral principal series categories I: finite-dimensional calculations*, Adv. Math. 388, 107856. Chiral principal-series source used for globalization analogies; not a number-field adelic theorem.

Raskin *Chiral principal series categories II: the factorizable Whittaker category*; *Chiral categories*; *D-modules on infinite-dimensional varieties*. Preprint foundations for chiral principal series and infinite-dimensional $\mathcal{D}$-modules, available in the Papers and Preprints section of the author's website, `https://www.samraskin.net/`. Background for Chapters 63 and 30.

Kazhdan–Lusztig 1993–1994 *Tensor structures arising from affine Lie algebras I–IV*, JAMS 6–7. KL tensor structure and affine Lie algebra side of root-of-unity quantum groups.

Finkelberg 1996 *An equivalence of fusion categories*, GAFA 6:249–267; **Andersen–Paradowski 1995**, *Fusion categories arising from semisimple Lie algebras*, Comm. Math. Phys. 169:563–588. Fusion-category comparison.

Lusztig 1990–1993 *Finite-dimensional Hopf algebras arising from quantized universal enveloping algebra*; *Quantum groups at roots of 1*; *Introduction to Quantum Groups*. Small quantum group, divided-power form, and quantum Frobenius sources.

De Concini–Kac 1990 and **De Concini–Kac–Procesi 1992**. De Concini–Kac form, centre, and quantum coadjoint action.

Arkhipov–Gaitsgory 2003 *Another realization of the category of modules over the small quantum group*, Adv. Math. 173:114–143; **Bezrukavnikov–Finkelberg–Schechtman 1998**, *Factorizable Sheaves and Quantum Groups*, LNM 1691. Small quantum group and factorizable-sheaf bridge.

A.10 Kim's Arithmetic Chern–Simons

Kim 2015 *Arithmetic Chern–Simons theory I*, arXiv:1510.05818. Foundational definition of arithmetic Chern–Simons invariants for number fields via p-adic Hodge theory and Galois cohomology; arithmetic Chern–Simons source for Chapter 37.

Chung–Kim–Kim–Pappas–Park–Yoo 2017 *Abelian arithmetic Chern–Simons theory and arithmetic linking numbers*, arXiv:1706.03336. Used in Chapter 37.

Morishita 2009 *Analogies between knots and primes, 3-manifolds and number rings*, arXiv:0904.3399. MKR dictionary.

A.11 Hartnoll–Yang and Primon Gas

Hartnoll–Yang 2025 *The Conformal Primon Gas at the End of Time*, arXiv:2502.02661. Primary seed reference. L-function as partition function of charged oscillators labelled by primes. BKL–primon correspondence (thermodynamic).

Julia 1990 *Statistical theory of numbers*, in *Number Theory and Physics*, Springer Proc. Phys. 47:276–293. Original primon gas: free Fock space on primes with $Z(\beta) = \zeta(\beta)$. Cited both here (thermodynamic background) and in Chapter 43 §43.5 for the single-mode primon character. Identifying that character with an arithmetic bar requires a separate comparison map.

Spector 1990 *Supersymmetry and the Möbius inversion function*, Commun. Math. Phys. 127:239–252. Supersymmetric primon gas; $1/\zeta(\beta) = \sum \mu(n) n^{-\beta}$.

A.12 Macdonald, DAHA, Schiffmann–Vasserot

Macdonald 1995 *Symmetric Functions and Hall Polynomials*, 2nd ed., Oxford. The Hall pairing and symmetric functions are in Chapter I. The Macdonald pairing is VI (1.5), and the orthogonal triangular basis is VI (4.7).

Cherednik 2005 *Double Affine Hecke Algebras*, CUP. DAHA framework.

Etingof–Kirillov 1994 *Macdonald's polynomials and representations of quantum groups*. Quantum-group interpretation of Macdonald polynomials; background for the representation-theoretic reading of Hall polynomials in Section 14.9.

Schiffmann–Vasserot *The elliptic Hall algebra and the equivariant K-theory of the Hilbert scheme of* $\mathbb{A}^2$, arXiv:0905.2555v3, Theorem 3.1. The central specialization of the elliptic Hall algebra identifies with the specified localized Hilbert-scheme convolution algebra. Its polynomial representation is given in section 1.4.

Schiffmann–Vasserot *Cherednik algebras, W-algebras and the equivariant cohomology of the moduli space of instantons on* $\mathbb{A}^2$, arXiv:1202.2756v2. The degeneration is constructed in section 7. Theorem F.10 gives the specialization at $\kappa = 1$, with its enveloping algebra and central variables. See Theorem 14.9.9 for the two distinct geometric comparisons.

A.13 Nekrasov, AGT, Maulik–Okounkov

Nekrasov 2003 *Seiberg–Witten prepotential from instanton counting*, ATMP, arXiv:hep-th/0206161. Z_{inst} definition.

Nekrasov–Okounkov 2006 *Seiberg–Witten theory and random partitions*, change Math., arXiv:hep-th/0306238. Hook-length formula and random partition statistics from the Nekrasov partition function; cited in Chapter 31 for the Plancherel-measure analogy.

Alday–Gaiotto–Tachikawa 2010 arXiv:0906.3219. AGT correspondence: instanton partition functions of 4d $\mathcal{N} = 2$ theories equal conformal blocks of Liouville theory; background for the VOA–Higgs-branch comparison of Chapter 37.

Maulik–Okounkov 2019 *Quantum groups and quantum cohomology*, Astérisque, arXiv:1211.1287. R-matrix on instanton moduli.

Nekrasov–Shatashvili 2009 arXiv:0908.4052. NS limit: $\hbar \to 0$ produces Bethe ansatz equations from quantum integrable systems; cited in Chapter 40 for the Bethe-algebra comparison.

MNOP 2003 arXiv:math/0312059. Plane partition generating function as a Calabi–Yau partition function; background for the topological-string interpretation in Chapter 31.

Gaiotto 2009 arXiv:0904.2715. Class-$\mathcal{S}$ theories from M5-branes on Riemann surfaces; cited for the 4d/2d structure underlying the VOA–Higgs-branch comparison.

Beem et al. 2015 Beem–Lemos–Liendo–Peelaers–Rastelli–van Rees 2015. *Infinite chiral symmetry in four dimensions*, Commun. Math. Phys., arXiv:1312.5344. BLLPRvR VOA/Higgs branch.

A.14 Segal, Frenkel–Ben-Zvi

Segal 2002 *The definition of conformal field theory*, in *Topology, Geometry and QFT*, CUP, pp. 421–577. Segal axioms.

Frenkel–Ben-Zvi 2004 *Vertex Algebras and Algebraic Curves*, 2nd ed., AMS. Standard reference for vertex algebras on algebraic curves; cited in Chapter 30 for the chiral-algebra side of the factorization-homology comparison.

Huang 1997 *Two-Dimensional Conformal Geometry and Vertex Operator Algebras*, Birkhäuser. Rigorous Sewing axioms for VOAs on a Riemann sphere; background for the conformal-field-theory comparison in Chapter 41.

Bakalov–Kirillov 2001 *Lectures on Tensor Categories and Modular Functor*, AMS. Modular tensor categories and the Reshetikhin–Turaev functor; cited in Chapter 37 for the TQFT-Chern–Simons modular-functor background.

Deligne *Le déterminant de la cohomologie*. Determinant line bundle on arithmetic moduli.

A.15 Tate's Thesis and Adelic Analysis

Tate 1950 *Fourier analysis in number fields and Hecke's zeta-functions*, Princeton PhD thesis; reprinted in Cassels–Fröhlich 1967 *Algebraic Number Theory*, CUP. Adelic Poisson summation, functional equation as sewing axiom.

Weil 1967 *Basic Number Theory*, Springer. Restricted direct product, adelic framework.

Jacquet–Langlands 1970 *Automorphic Forms on $GL(2)$*, SLN 114. Local and global theory of automorphic representations of $GL(2)$; cited in Chapter 33 and Chapter 38 for the automorphic side of the Langlands comparison.

Gelbart–Jacquet 1979 *Forms of $GL(2)$ from the analytic point of view*, in *Automorphic Forms, Representations and L-Functions*, Proc. Symp. Pure Math. 33. Functional equations and analytic continuation of L-functions for $GL(2)$; cited in Chapter 33 §3 for the archimedean-place functional equation.

Gross 1998 *On the Satake isomorphism*, in *Galois Representations in Arithmetic Algebraic Geometry*, CUP, Prop. 3.6.

Bump *Automorphic Forms and Representations*, CUP 1998. §1.5, §3.

A.16 Drinfeld, Molev: Yangians and R-Matrices

Drinfeld 1985 *Hopf algebras and the quantum Yang–Baxter equation*, Soviet Math. Dokl. 32:254–258. Yang R-matrix and RTT presentation; foundational for the Bethe-algebra comparison in Chapter 40.

Drinfeld 1988 *A new realization of Yangians and quantized affine algebras*, Soviet Math. Dokl. 36:212–216. Drinfeld current generators for Yangians and quantum affine algebras; background for Chapter 40 on the Bethe-algebra and quantum-integrable structures.

Molev 2007 *Yangians and Classical Lie Algebras*, AMS. Standard reference for Yangians, their representation theory, and Bethe subalgebras. Background for Chapter 40.

Feigin–Odesskii 1997 Shuffle algebras.

Frenkel–Reshetikhin 1998 arXiv:math/9810055. q-characters of representations of quantum affine algebras.

Halacheva–Kamnitzer–Rybnikov–Weekes 2017 *Crystals and monodromy of Bethe vectors*, arXiv:1708.05105. Gaudin algebras, Bethe eigenvectors, and cactus monodromy; cited in Chapter 40 for the Bethe-algebra comparison.

A.17 Arakelov, Deligne, Arithmetic Height Pairings

Arakelov 1974 *Theory of intersection on arithmetic surfaces*, Izv. Akad. Nauk SSSR 38. Foundational intersection pairing on arithmetic surfaces; cited in Chapter 31 for the Arakelov height pairing.

Faltings 1984 *Calculus on arithmetic surfaces*, Ann. Math. 119. Faltings metric on the determinant of cohomology; cited in Chapter 31 for the archimedean Arakelov data.

Gillet–Soulé 1992 *Arithmetic intersection theory*, Publ. IHES 72. Used in Chapter 31 for Arakelov Chern classes.

Durov 2007 arXiv:0704.2030. $\mathbb{F}_1$-projective space and generalized rings; background on approaches to absolute geometry. No comparison with the polynomial Fock carrier is asserted.

Deninger 1994 *Motivic L-functions and regularized determinants*, Proc. Symp. Pure Math. 55.1. Regularised-determinant programme for arithmetic L-functions; cited in Chapter 44 as a parallel formulation of the arithmetic Hilbert–Pólya hypothesis.

Szpiro 1985 Astérisque 127. Arakelov $K_{\overline{\operatorname{Spec}\mathbb{Z}}}$ has degree $\log(2\pi)$.

Bost–Künnemann 2008 Arakelov vector bundles.

A.18 Kesten–McKay

Kesten 1959 *Symmetric random walks on groups*, TAMS 92. On a regular tree of valence $r \geq 2$, the normalized adjacency radius is $2\sqrt{r-1}/r$. The free group on d generators has valence $r = 2d$. The radial Hecke construction is Theorem 13.5.2.

McKay 1981 *The expected eigenvalue distribution of a large regular graph*, Linear Algebra Appl. 40. Free-group spectral measure (Kesten–McKay law): the empirical eigenvalue distribution of a random regular bipartite graph converges to the measure $d\nu_{\mathrm{KM}}$ on $[-2\sqrt{r-1}, 2\sqrt{r-1}]$. Example 14.9.5 computes the tree moments and distinguishes them from Fock norms.

Lubotzky 1994 *Discrete Groups, Expanding Graphs and Invariant Measures*, Birkhäuser, Thm 7.4.5. $GL_2(\mathbb{Q}_p)$ interpretation.

Terras 2011 *Zeta Functions of Graphs*, CUP. Ihara zeta and spectral graph theory. The tree-state calculation is in Proposition 13.5.3.

A.19 Prismatic Cohomology and Fargues–Fontaine

Bhatt–Scholze 2019 *Prisms and prismatic cohomology*, arXiv:1905.08229. Cited in Chapter 30 §3 for the prismatic extension of Fontaine crystalline data toward a non-trivial p-adic diagonal thickening. Also used in Chapter 43 §43.2 for the Nygaard-filtration convention bridging pro-étale and de Rham conventions in F1-reduction.

Bhatt–Lurie 2022 *Absolute prismatic cohomology*, arXiv:2201.06120. Prismatic-Nygaard filtration and δ-ring formalism used in Chapter 43 §43.2 for the convention-match between Arinkin–Gaitsgory and Fargues–Scholze.

Fargues–Fontaine 2018 *Courbes et fibrés vectoriels en théorie de Hodge p-adique*, Astérisque 406. Foundational reference for the Fargues–Fontaine curve X_{FF} as the arithmetic analogue of a complete Dedekind curve, underlying Fargues–Scholze arXiv:2102.13459.

Scholze 2017 *Etale cohomology of diamonds*, arXiv:1709.07343. Diamond formalism used across Chapters 30, 38, 43.

Diamonds, prisms, Adams operations, Frobenius lifts, and Nygaard filtrations supply finite-place coefficient and orientation data. They are not classical almost-complex structures and do not furnish a finite-prime tangent-bundle endomorphism satisfying $J^2 = -1$.

A.20 Ben-Zvi, Nadler, Coherent Springer Theory

Ben-Zvi–Chen–Helm–Nadler 2023 *Coherent Springer theory and the categorical Deligne–Langlands correspondence*, Invent. Math. 235 (2024), 255–344; arXiv:2010.02321. State of the art on global categorical Langlands gluing via coherent Springer theory; cited in Chapter 43 §43.2 on the global gluing obstruction.

Gan–Savin 2022 *Categorical local theta correspondence*. Partial change on restricted tensor product of local automorphic categories; cited in Chapter 43 §43.2 (F1.b).

AGKRRV 2020 *The stack of local systems with restricted variation and geometric Langlands theory with nilpotent singular support*, arXiv:2010.01906. Restricted-variation local systems and nilpotent singular support in global geometric Langlands; cited in Chapter 43 for the singular-support constraint on global gluing.

AGKRRV 2020 *Duality for automorphic sheaves with nilpotent singular support*, arXiv:2012.07665. Geometric Langlands duality restricted to nilpotent singular support; cited in Chapter 43 §43.2.

AGKRRV 2021 *Automorphic functions as the trace of Frobenius*, arXiv:2102.07906. Categorical trace of Frobenius as automorphic function; cited in Chapter 41 for the Frobenius-trace identification in the categorical Hochschild trace.

Gaitsgory–Rozenblyum 2017 *A Study in Derived Algebraic Geometry, Vols. I & II*, AMS Mathematical Surveys and Monographs 221. $(\infty, 2)$-categorical formalism for ind-coherent sheaves with singular support; cited in Chapter 43 §43.2 for ambient-category compatibility in the global gluing step.

A.21 Tate, Weil, Explicit Formula

Riemann 1859 *Über die Anzahl der Primzahlen unter einer gegebenen Grösse*, Monatsberichte Berlin, 671–680. Original proof of the functional equation $\xi(s) = \xi(1-s)$ via Mellin-theta. Cited in Chapter 43 §43.6 proof of P2.

von Mangoldt 1895 *Zu Riemanns Abhandlung "Über die Anzahl der Primzahlen unter einer gegebenen Grösse"*, J. Reine Angew. Math. 114. Riemann's explicit formula in rigorous form. Used in Chapter 43 §43.6 proof of P2 part (2).

A.22 Li Positivity and Weil Positivity

Li 1997 *The positivity of a sequence of numbers and the Riemann Hypothesis*, J. Number Theory 65:325–333. Introduces the sequence λ_n and proves RH $\Leftrightarrow \lambda_n \geq 0$ for all $n \geq 1$. Central for Chapter 44 on the RH reformulation.

Bombieri–Lagarias 1999 *Complements to Li's criterion for the Riemann hypothesis*, J. Number Theory 77:274–287. Extensions of Li's criterion to Dedekind zeta functions and Selberg class; refinements used in Chapter 44 Remark on multi-L-function versions.

Voros 2003 *Zeta functions for the Riemann zeros*, Ann. Inst. Fourier 53. Explicit computation of first few λ_n. Verified numerically.

Coffey 2005 *Toward verification of the Riemann hypothesis: application of the Li criterion*, Math. Phys. Anal. Geom. 8:211–255. Numerical verification of Li positivity to $n \sim 10^5$.

Weil 1952 *Sur les "formules explicites" de la théorie des nombres premiers*, Comm. Sém. Math. Univ. Lund; reprinted Oeuvres Sci. II:48–61. Weil's positivity criterion $W(f, f) \geq 0$ for suitable test functions f, equivalent to RH. Referenced in Chapter 44 Table 44.1 for comparison.

The VB* converse (Chapter 57) establishes Hamburger determinacy of the symmetrised zero-moment sequence as the sharpest primary-source form of the VB* reduction. Li 1997 and Weil 1952 give RH-equivalent positivity statements; the arithmetic use of Hamburger determinacy requires the separate operator comparison (Theorem 57.4.22 under Hypothesis 57.4.21).

A.23 Positselski, Iwasawa

Positselski 2011 *Two kinds of derived categories, Koszul duality, and comodule-contramodule correspondence*, Mem. AMS, arXiv:0905.2621. See the full entry in App. A.5; cited again here for its role as a field-coefficient model for the integral comparison question in Chapter 33. Its coalgebra hypotheses are distinct from a module's μ-invariant.

Ferrero–Washington 1979 *The Iwasawa invariant μ_p vanishes for abelian number fields*, Ann. Math. 109. Proves vanishing for the cyclotomic Iwasawa modules of abelian number fields. Applying it to a proposed Heisenberg coefficient module requires an identification with such an arithmetic module, as explained in Remark 43.5.2 and Question 51.2.8.

A.24 Operator Theory: Moment Problem, Self-Adjointness

Akhiezer–Glazman 1981 *Theory of Linear Operators in Hilbert Space* (2 vols.), Pitman / Dover reprint. Ch. VI.3 on the Hamburger moment problem. Used in Chapter 44 Corollary 44.3.9 and Chapter 51 for the failure of the moment-problem equivalence in the unbounded-operator case. The moment problem is determinate for bounded self-adjoint operators on a positive-definite Hilbert space; in the unbounded

case, Carleman's sufficient condition for determinacy is $\sum_n \lambda_{2n}^{-1/(2n)} = +\infty$, and without it two distinct operators can share the same moment sequence.

Reed–Simon 1980 *Methods of Modern Mathematical Physics*, Vol. I (Functional Analysis), Academic Press. Ch. VIII on unbounded operators, self-adjoint extensions, spectral theorem. Standard reference for the domain-theoretic care demanded by the arithmetic Hilbert–Pólya hypothesis (Hypothesis 44.3.2).

Tomita–Takesaki 2003 *Theory of Operator Algebras II*, Springer EMS. KMS_β modular involution cited in Chapter 51 Theorem 51.2.9 as the specification of the Bost–Connes involution on the dual.

The Connes 1999 (arXiv:math/9811068) adele class space spectral realisation and the Deninger 1994 motivic cohomology regularised-determinant programme anchor equivalent formulations of H-P^{Ar} (Theorem 57.3.14). The reduction closes the operator-theoretic domain problem via the Friedrichs extension (Theorem 57.3.2); the determinant-divisor and trace-compatibility condition, requiring the normal zero-divisor operator to have divisor div $\xi_{\mathbb{R}}$ and Weil–Connes trace equal to the non-trivial zero distribution, remains the genuine Hilbert–Pólya content (Remark 57.3.16).

A.25 Restricted Direct Product, Flath, Godement–Jacquet

Flath 1979 *Decomposition of representations into tensor products*, in *Automorphic Forms, Representations, and L-Functions*, Proc. Symp. Pure Math. 33, Part 1, pp. 179–183. Flath's theorem on irreducible admissible automorphic representations of $GL_n(\mathbb{A})$ as restricted tensor products of local admissible representations. This decomposition does not construct the arithmetic placement of $\mathcal{V}^{\mathrm{prim}}$; that map is part of (K2) in Theorem 51.2.9.

Godement–Jacquet 1972 *Zeta Functions of Simple Algebras*, SLN 260, Springer. Local functional equations and standard local L-factors. The spherical Whittaker norm in Lemma 56.7.4 uses its declared multiplicative Haar measure and has factor $m_p(1 + p^{-1})L_p(1, \mathrm{Ad})$. A functional equation does not supply the arithmetic pairing map of (K5).

Gelbart 1975 *Automorphic Forms on Adele Groups*, Annals of Math. Studies 83, Princeton University Press. §3.1 on sph-finite automorphic representations and their restricted-tensor-product decomposition.

Kneser 1966 *Strong approximation*, in *Algebraic Groups and Discontinuous Subgroups*, Proc. Symp. Pure Math. 9, pp. 187–196. Strong approximation for simply connected semisimple algebraic groups. In the GL_2 application it applies to the derived group SL_2; the determinant idele-class quotient is the separate Tate component. Cited in Chapter 51 Theorem 51.2.4 ($\mathrm{L_{ACD}}$.4).

Platonov–Rapinchuk 1994 *Algebraic Groups and Number Theory*, Academic Press. Modern reference for strong approximation and related arithmetic results.

A.26 Cross-Volume Primary Sources

The arithmetic branch draws on results from the three preceding volumes. The relevant primary sources from those volumes are cited in the entries above at the point of use; the cross-volume dependency structure is:

Vol. I Five-theorem structure (Theorems A, B, C, D, H), bar-cobar adjunction, SC-formality, and the chiral Koszul duality framework. Invoked in Chapters 33 and 38.

Vol. II Holomorphic-topological twist $\mathsf{SC}^{\mathrm{ch,top}}$, 3D HT QFT, and 3D quantum gravity. Invoked in Chapter 37 for the arithmetic Chern–Simons comparison.

Vol. III Two-stage factorisation $\Phi_d = \mathrm{Sp}^{\mathrm{ch}} \circ \Phi_d^{\mathrm{FA}}$; Borcherds/BKM universality $\Phi_N = c_N(0)/2$. Invoked in Chapter 41 for the six-window synthesis.

Appendix B

Arithmetic Trace Comparisons

The following primary-source families concern structural hypotheses about $\mathcal{V}^{\mathrm{prim}}$. The source families concern different structural obstructions and proposed trace comparisons, with distinct hypotheses. The table records the source class, obstruction, and chapter reference. Sections B.2–B.6 record the obstructed structures, the remaining constraints, three-way gluing comparisons, and the missing arithmetic maps.

B.1 Primary Source Families

Source family	Angle	Reference/Result
Drinfeld+ Kapranov	Finite-place fields	26: formal fields. Arithmetic coefficient comparison required
Kazhdan+ Beilinson	GL_1 Adams vs GL_2 Hecke	27: Satake pair on rank-2 Heisenberg
Gelfand+ Borger	Λ-ring axiomatic precision	28: polynomial Adams and divisor actions; integral Hall lattice
Connes+ Soibelman	Bost–Connes vs $\mathcal{V}^{\mathrm{prim}}$	29: Bost–Connes $\otimes$ universal Heisenberg
Costello+ Gwilliam	Adelic factorization axioms	30: (F1)–(F5) on $\mathbb{C}_\infty$
Etingof	Prime-indexed Macdonald and Hall models	Section 14.9: tensor pairings, shuffle products and geometric comparison
Nekrasov	Arithmetic instanton Z	31: Degenerate $(\log p, \infty)$ limit
Segal	Arithmetic modular functor	32: Modular functor = Tate
Beilinson–solo	Arithmetic coefficient bar	33: residue and chiral comparisons require their operation maps
Witten	TQFT / BKL / Langlands triangle	34: Automorphic vertex, not TQFT vertex
Polyakov	Local charge and global residue	35: rank residue $r_\zeta = 2$. Conformal comparison separate
Gaiotto	4D-gauge to VA arithmetic lift	37: Kim arithmetic Chern–Simons $[\mathbb{G}_m, 1]$ classical boundary shadow
Bezrukavnikov+ Bernstein	Langlands spectral side	38: Iwahori Hecke Hochschild trace
Kontsevich+ Soibelman	E_n formality / CoHA	39: E_1 integral, E_2 over $\mathbb{Q}$

Drinfeld–solo	Arithmetic Yangian / R-matrix	40: Bethe algebra, Langlands = Bethe ansatz

B.2 OBSTRUCTIONS ACROSS SOURCE FAMILIES

The following comparisons concern specific algebraic and geometric constructions. Positive models and obstructions retain their own carriers, coefficient topologies, and hypotheses:

(i) The Hochschild trace class $\mathcal{V}^{\mathrm{prim}}$ does not itself specify a vertex algebra. Local Heisenberg fields exist, while the prescribed infinite Sugawara sum fails on its algebraic vacuum. Chapter 35 also records the prime-zeta natural boundary, separately from the rank-residue calculation and the remaining conformal comparison.

(ii) Abstract common field extensions of all $\mathbb{Q}_p$ exist, as in Observation 26.3.1. Such a field does not supply continuous local embeddings or an adelic topology. An arithmetic restricted tensor still needs its coefficient and representation maps.

(iii) The p-adically completed tensor $\mathbb{Z}_p \widehat{\otimes}_{\mathbb{Z}} \mathbb{Z}_p$ is $\mathbb{Z}_p$. The ordinary tensor has a nonzero multiplication kernel, as proved in Chapter 26. These are different completions of the diagonal problem. Neither calculation constructs the required arithmetic collision operations.

(iv) T_n does not lift Adams operations to GL_2 Hecke operators. The explicit Kazhdan–Beilinson computation gives $T_p^2(a_{-1}^{(p)}|0\rangle) - p \cdot a_{-1}^{(p)}|0\rangle \neq T_{p^2}(a_{-1}^{(p)}|0\rangle)$.

(v) The index-shift Adams maps fail the Frobenius congruence on the polynomial Newton-generator lattice, whereas they satisfy it on the integral Hall lattice of symmetric functions. The divisor substitutions T_p still fail on that Hall lattice. These are distinct integral carriers and operations, as proved in Chapter 28. Neither lattice calculation supplies a Λ-structure on the arithmetic trace class without a compatible arithmetic comparison.

(vi) Arithmetic Yangian RTT relations have no global spectral parameter. The Yang-Baxter spectral parameter $u - v$ has no analogue across distinct primes; there is no meromorphic 1-form on $\operatorname{Spec} \mathbb{Z}$.

(vii) A 4D class-$\mathcal{S}$ gauge boundary does not transplant to $\overline{\operatorname{Spec} \mathbb{Z}}$. The Hitchin base $\bigoplus_i H^0(\Sigma, K_\Sigma^{d_i})$ uses a holomorphic canonical bundle on a complex curve. The Arakelov dualizing line on $\overline{\operatorname{Spec} \mathbb{Z}}$ is not such an object.

(viii) The curve-theoretic category of $\mathcal{D}$-modules on Bun_{GL_2} does not arise from $\operatorname{Spec} \mathbb{Z}$ itself. The moduli stack $\mathrm{Bun}_{GL_2}(\operatorname{Spec} \mathbb{Z})$ is $BGL_2(\mathbb{Z})$: one coarse point with arithmetic stabilizer. This stack has representation theory of the stabilizer, not the geometric Hecke correspondence of the curve case.

(ix) The integral E_2-chiral-centre enhancement is not obtained by replacing the chain operad $C_\bullet(E_2; \mathbb{Z})$ with $\mathrm{Ger}_{\mathbb{Z}}$. Dyer–Lashof and Kaledin-type p-curvature classes obstruct that strictification, not the existence of an integral E_2-algebra.

B.3 COMMON STRUCTURAL CONSTRAINTS

The proposed arithmetic realization has the following structural requirements:

(i) The arithmetic curve is Arakelov-compactified $\overline{\operatorname{Spec} \mathbb{Z}}$, not $\operatorname{Spec} \mathbb{Z}$ (across source families).

(ii) The finite-place incidence poset does not supply formal collision coordinates. Formal Heisenberg fields can nevertheless be constructed over $\mathbb{Q}_p$, as in Chapter 26. Comparing them with arithmetic coefficient objects requires actual operation maps.

(iii) The Steinberg relation $\{p, 1-p\} = 0$ holds in Milnor K-theory. Comparing its residue complex with chiral collision operations requires a common carrier and maps preserving the operations, as in Chapter 33.

(iv) The Hecke structure is carried by the Iwahori-equivariant affine Hecke category, not the spherical category (Bezrukavnikov+Bernstein, Kazhdan+Beilinson).

(v) The Iwahori Hecke Hochschild trace is the local Bezrukavnikov–Bernstein model. Its global identification with $\mathcal{V}^{\mathrm{prim}}$ is the arithmetic BZN input F3. Kim arithmetic Chern–Simons (Kim arXiv:1510.05818) provides the classical boundary torsor construction, and the adelic factorization algebra lives on $\mathbb{C}_\infty$ (Costello+Gwilliam).

B.4 Three-Way Gluing of Presentations

Three proposed presentations of $\mathcal{V}^{\mathrm{prim}}$ require arithmetic comparison maps. The table names their carriers and corresponding chapters.

Presentation	Source family / Chapter
Arithmetic Chern–Simons classical boundary shadow for $\mathcal{V}^{\mathrm{prim}}$	Gaiotto, 37
$\mathrm{HH}_\bullet(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}) \xrightarrow{\mathrm{F3}} \mathcal{V}^{\mathrm{prim}}$	Bezrukavnikov+Bernstein, 38
$\mathcal{F}_{\mathrm{CG}}(\mathcal{V}^{\mathrm{prim}}) \in \mathrm{FactAlg}_{\mathbb{C}_\infty}(\mathrm{Mod}_{\widehat{\mathbb{Z}},\psi})$	Costello+Gwilliam, 30

Ben-Zvi–Nadler (arXiv:0904.1247) identifies $\mathrm{HH}_\bullet(\mathrm{D}(G/G)) = \mathcal{O}(\mathrm{LocSys}_G(S^1))^{\mathrm{flat}}$ over $\mathbb{C}$; the triangle relating arithmetic Chern–Simons, the Hecke category, and the Hochschild trace is the complex-geometric model for the three-way arithmetic comparison. The arithmetic identification remains conditional on the full Weil/(φ,Γ)-module target and a quantum boundary category.

B.5 Distinct Comparisons

The comparison questions concern different algebraic and geometric structures, even when their bibliographies overlap. Disjoint citations do not establish independence of mathematical hypotheses or construct a common object. The identification requires the maps in the following compatibility observation.

B.6 Compatibility and the Arithmetic Construction Problem

Remark B.6.1 *(compatibility of specified identifications).* Suppose the proposed arithmetic presentations are constructed in a specified common category. Suppose each has a specified isomorphism $f_i : X_i \to V$ preserving the stated operations and arithmetic data. Then $f_j^{-1} f_i : X_i \to X_j$ identify these presentations and satisfy $(f_k^{-1} f_j)(f_j^{-1} f_i) = f_k^{-1} f_i$. Transporting a six-window conclusion to V requires a proved source statement and comparison maps preserving its hypotheses and structures. Conjecture 41.1.1 does not supply that source statement.

The composite of two structure-preserving isomorphisms preserves those structures. The displayed identity follows by cancelling $f_j f_j^{-1}$. Any property transported to V must be among the properties preserved by the specified maps.

Question B.6.2 *(arithmetic trace comparisons).* Construct the global arithmetic Iwahori Hecke category, its Hochschild trace complex, and the proposed arithmetic boundary and factorization objects. Specify their coefficient rings, gradings, tensor products and completions. Construct the functors or chain maps

relating their specified common carriers, with compatibility for central and Hecke actions, local gluing and the claimed trace pairings. The local-to-global categorical and spectral comparison is F1, the finite-place enhancement is F2, and the arithmetic trace comparison is F3 in Conjectures 42.1, 42.2, and 42.3. Their existence and mutual compatibility are the missing inputs to a common arithmetic realization.

Several starting constructions have different, explicit carriers. Chapter 28 constructs the polynomial divisor and Adams operations and the integral Hall lattice. Chapter 29 constructs gauge Hochschild classes on its specified Bost–Connes algebras and analyzes their domains. Chapter 54 computes finite-algebra extension products and regular Hochschild homology. None of these calculations by itself supplies the arithmetic functors in the preceding question.

B.7 SIX SOURCE FAMILIES IN GENUS g

The initial genus-g ansatz was: "a genus-g arithmetic surface with almost complex structure carrying the cohomological signature of a genus-g algebraic curve." Six primary-source families concern this ansatz. Their proposed arithmetic-modular comparisons require the maps and hypotheses stated in Chapter 102 (all-genus arithmetic Koszul duality) and Chapter 103 (3D arithmetic Chern–Simons via the ordered incidence bar and conditional Beilinson–Drinfeld/Costello–Gwilliam comparison).

Primary Source Families

Source family	Source list	Proposed comparison
Source family 1: Arakelov	Arakelov 1974; Faltings 1984; Gillet–Soulé 1990; Bost–Künnemann 2010	Window I: arithmetic amplitude generating function AAGF_g (Chapter 102.2), arithmetic surface X/O_K, Hasse–Weil functional equation
Source family 2: Deninger / Connes–Consani	Deninger 1998; Connes–Consani 2014–2016; Bost–Connes 1995; Bost–Connes–Marcolli 2004	Window II: Minkowski torus over totally imaginary K of degree $2g$, Dedekind $\xi_K(s) = \xi_K(1-s)$
Source family 3: Fargues–Scholze	Fargues–Scholze 2021; Bhatt–Scholze 2022; Emerton–Gee 2019; Caraiani–Scholze 2017–2019	Window III: Ordinary crystalline Emerton–Gee stack $\mathcal{X}_{2g}^{\mathrm{crys,ord}}$, prismatic Frobenius as J
Source family 4: Mochizuki / Hodge–Arakelov	Mochizuki 1999 Publ. RIMS; Kapranov–Smirnov 1995; Durov 2007	Window IV: Arithmetic Teichmüller with theta-structure; Hodge–Arakelov comparison

Source family 5: Homotopical bar-cobar	Beilinson–Drinfeld 2004; Francis–Gaitsgory 2012; Ben-Zvi–Nadler 2009–2013; Lurie HA; Positselski 2011	Window V: $\mathcal{V}^{\mathrm{prim,surf},g}$ with E_2-chiral structure via Dunn additivity
Source family 6: Kudla–Rapoport / Shimura–Siegel	Kudla 1997; Kudla–Rapoport 2011; Bruinier 2002; Li–Liu 2021; Arthur 2013	Window VI: Siegel–Shimura genus-g datum SSG_g (Chapter 102.2), Siegel spin L-function with $\Lambda(s) = \epsilon\Lambda(2g+1-s)$

Obstructions

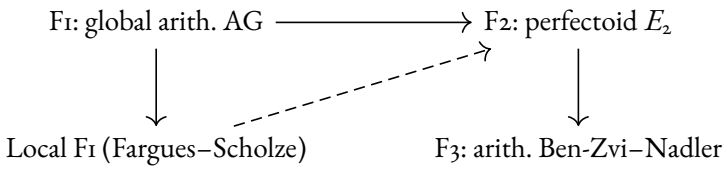
The six source families jointly obstruct six readings of the initial ansatz (Chapter 102.3 indexes the full list): the category-error reading of "almost complex structure on an arithmetic scheme" (no real tangent bundle on Spec $\mathbb{Z}$; Newlander–Nirenberg automatic on real 2-manifolds); "arithmetic Euler characteristic $= 1-g$" (Gillet–Soulé analytic torsion term); Künneth factorisation in arithmetic Chow (Bost–Künnemann Bott–Chern term); finite genus of $\overline{\mathrm{Spec}\,\mathbb{Z}}$ in the Deninger frame (Deninger-genus $= +\infty$); conflation of curve-genus with Siegel-genus (distinct integers); and the $\kappa + \kappa^! = 2 - 2g$ Euler-shift (Koszul sum preserved at 0; genus enters via rank, not shift).

Proposed Arithmetic-Modular Datum

The arithmetic genus-g datum $\mathcal{D}_g = (\mathcal{B}_g, \mathcal{E}_g, \varphi_g)$ (Chapter 102.1.1), with the essential conditional $\kappa_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) + (\kappa^!)_{\mathsf{G}}^{\mathrm{Ar},g}(\mathcal{D}_g) = 0 \Leftrightarrow \Lambda_{\mathcal{D}_g}(s) = \epsilon_{\mathcal{D}_g}\Lambda_{\mathcal{D}_g}(w_{\mathcal{D}_g} - s)$ (Chapter 102.4.1), with $w_{\mathcal{D}_g} \in \{1, 2, 2g+1\}$ window-indexed. The functional-equation clause is not a zero-placement theorem. The all-genus F-RH corollary (Chapter 102.5.1) contains the corresponding zero-placement clauses only after the relevant spectral-positivity input is imposed: RH for ζ, Hasse–Weil RH for Jacobians, Dedekind-zeta GRH for totally imaginary fields, and Siegel-spin RH for GSp_{2g} cusp forms.

The arithmetic-modular extension sources the finite-level arithmetic Chern–Simons state sums and the conjectural renormalized $GL_2(\widehat{\mathbb{Z}})$ limit on the étale $\overline{\mathrm{Spec}\,\mathbb{Z}}$ of Chapter 103. The finite-level boundary category is defined there after the finite cobordism input, and the ordered E_1-bar complex is constructed there; the identification of the Hochschild boundary trace with $\mathcal{V}^{\mathrm{prim}}$ and the partition-function identity with ξ remain conditional on profinite renormalization and local trace comparison. The functional equation then appears as the involutive symmetry of the partition function; zero-placement remains the separate positivity condition.

Comparison Boundary



The six genus-g presentations concern different carriers. A common arithmetic-modular datum requires their specified comparison maps and compatibility with the operations used in each presentation.

Appendix C

Three Structural Conjectures

The comparisons F1, F2 and F3 concern the arithmetic spectral recipient, factorization operations and the global trace. Their proposed relation uses specified local inputs and global comparison maps. The following diagrams organize those maps. They do not prove logical independence of the hypotheses.

C.1 The Graph

The local constructions of Fargues–Scholze and Emerton–Gee supply different inputs to F1 and F2. They do not alone give the displayed global equivalences or the required Iwahori factorization operations. F3 additionally needs the global trace comparison on its specified arithmetic carrier.

C.2 F1: Global Arithmetic Arinkin–Gaitsgory

Conjecture C.2.1 *(restatement of F1).* For $G = GL_2$ and the Selmer-derived global spectral stack $\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}$ (the derived moduli stack of Selmer deformations of a residual representation $\bar\rho$ with determinant condition det and cyclotomic twist datum $\mathcal{L}$, as in Chapter 42):

$$\mathrm{D}([GL_2])^{\text{sph-fin}} \;\simeq\; \mathrm{IndCoh}_{\mathrm{Nilp}}\big(\mathcal{X}^{\mathrm{Sel}}_{\bar\rho,\det,\mathcal{L}}\big).$$

Local inputs.

(i) Fargues–Scholze arXiv:2102.13459 (local geometrization and spectral action, not the displayed EG equivalence).

(ii) Caraiani–Scholze arXiv:1511.02418 (unitary Shimura variety case).

(iii) Emerton–Gee stack construction arXiv:1908.07185.

Global condition.

- Proof of the local automorphic-to-Emerton–Gee $\mathrm{IndCoh}_{\mathrm{Nilp}}$ comparison, including small primes and central-character families.
- Compatibility of local comparison functors under restricted-tensor-product gluing over primes.
- Identification of the Whittaker model across all places simultaneously.
- Functional-equation-level compatibility between spectral and automorphic sides.

Hypothesis. This is a global comparison theorem.

C.3 F2: PERFECTOID E_2-ENHANCEMENT

Conjecture C.3.1 *(restatement of F2).* The local Iwahori Hecke category $\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ carries a canonical E_2-monoidal structure from the perfectoid Beilinson–Drinfeld Grassmannian over $\operatorname{Spec}\mathbb{Z}_p$, and the restricted tensor product $\otimes'_p \mathrm{Hk}^{\mathrm{Iw}}_{GL_2,p}$ inherits a globally-defined E_2-monoidal structure.

Local ingredients (theorem).

(i) Perfectoid affine Grassmannian (Fargues–Scholze, Scholze diamonds).
(ii) Witt-vector affine Grassmannian (Zhu arXiv:1603.05593; Bhatt–Scholze arXiv:1507.06490).
(iii) Equal-characteristic BD Grassmannian E_2-structure (Mirković–Vilonen; Beilinson–Drinfeld Grassmannian factorization).

Global condition.

- Diamond-gluing of Iwahori Hecke categories across primes.
- Compatibility with Satake and Whittaker equivalences.
- Perfectoid Dunn-additivity argument producing E_1-algebra structure on the Hochschild trace.

Hypothesis. This is a mixed-characteristic factorisation theorem.

C.4 F3: ARITHMETIC BEN-ZVI–NADLER

Conjecture C.4.1 *(restatement of F3).* $\mathrm{HH}_\bullet\big(\mathrm{Hk}^{\mathrm{Iw}}_{GL_2,\mathrm{glob}}\big) \xrightarrow{\sim} \mathcal{V}^{\mathrm{prim}}$ as E_1-algebras.

Ingredients.

(i) Conjecture F1 (for the spectral side identification).
(ii) Conjecture F2 (for E_2-enhancement of the local Hecke factors).
(iii) Ben-Zvi–Nadler arXiv:0904.1247 (for the $\mathbb{C}$-version, which F3 arithmeticises).
(iv) Explicit computation matching the Hochschild trace character to $\zeta(s)$.

Consequences of F3.

- F3 implies the Gaiotto Chern–Simons identification (Theorem 37.4.1).
- F3 implies the Bezrukavnikov–Bernstein Hochschild identification (Theorem 38.5.1).
- A comparison with the coefficient bar additionally requires its algebra and operation maps. Theorem 33.8.2 proves the coefficient construction, not its identification with a geometric or trace target.
- F3 implies the arithmetic six-window placement (Conjecture 41.1.1).

Hypothesis. This is an arithmetic trace theorem.

C.5 Independent Conjecture: The G-Row Complementarity

Question C.5.1 *(central classes and Mellin reflection).* Construct the arithmetic object, its dual and scalar central invariants κ^{Ar}, $(\kappa^!)^{\mathrm{Ar}}$. Construct a common coefficient space, an involution J, a defect identity and an evaluation E such that

$$v - Jv = (\kappa^{\mathrm{Ar}} + (\kappa^!)^{\mathrm{Ar}})w, \qquad E(w) \neq 0,$$

with $E(v) = \Lambda(s)$ and $E(Jv) = \Lambda(1-s)$. Here $\Lambda(s) = \pi^{-s/2}\Gamma(s/2)\zeta(s)$. These maps would give the intended equivalence

$$\kappa^{\mathrm{Ar}} + (\kappa^!)^{\mathrm{Ar}} = 0 \quad \Longleftrightarrow \quad \xi(s) = \xi(1-s)$$

by Theorem 43.5.1.

The scalar functional equation is proved by Poisson summation. The question asks for its arithmetic central-class realization and for detection of the defect by E. A co–contra equivalence alone does not identify those maps. Any dependency on F1–F3 must be determined from the proposed arithmetic realization.

C.6 Chain of Implications

The arithmetic branch has the following implication form:

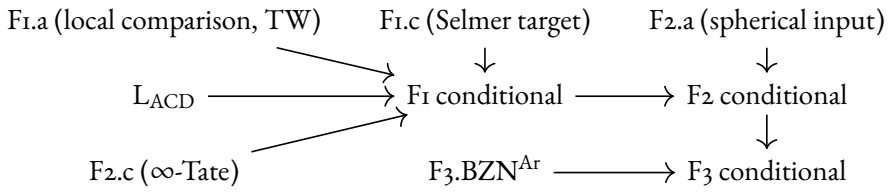
(i) The G-row conjecture (Question C.5.1) would identify the Riemann functional equation as an arithmetic Koszul-duality consequence.

(ii) F3 conditional on F1 and F2 unifies the three presentations of $\mathcal{V}^{\mathrm{prim}}$.

(iii) F1 is the global arithmetic Arinkin–Gaitsgory input.

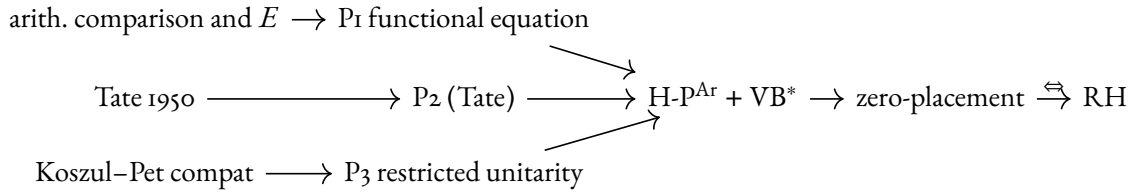
(iv) F2 is the perfectoid E_2-enhancement input.

(v) F1, F2, and the conditional F3 comparison imply the six-window structural statement.



C.7 Connection to Vol III

Vol III's B-row $\kappa + \kappa^! = 8$ (Mukai-enhanced K3 Heisenberg via Bruinier Heegner Chern-class reciprocity) has an arithmetic avatar (F4, Chapter 42 §3). Together the arithmetic G-row and the arithmetic B-row would give two of the five Vol I derived-centre-ceiling values as consequences of automorphic and Galois-deformation theorems. The chiral centre is then constrained by arithmetic comparison data.



C.8 Extended Graph with F-RH

The conjectures F1, F2, F3 of the preceding sections address the six-window placement of $\mathcal{V}^{\mathrm{prim}}$. A second cluster of conditions, independent of F1–F3, governs the connection to the Riemann hypothesis. Chapter 43 provides the structural branch; Chapter 44 states F-RH, whose zero-placement clause is RH and whose other clauses are the positive Hermitian, Koszul, and Zhu structures on $\mathcal{V}^{\mathrm{prim}}$. The arrows are:

F1–F3 structural branch (six-window placement).

four-input RH branch.

The dependency partitions into two branches:

F1–F3 structural branch (six-window placement, RH-independent). L_{ACD} (the adelic comparison and descent lemma relating the global spherical category to the restricted tensor product of local Iwahori categories) → F1 → F3.BZN^{Ar} (the arithmetic Ben-Zvi–Nadler functoriality for the loop space of the global spectral stack) → F3. The sub-conjecture F2.c has a restricted pointed central-unit theorem in Chapter 50; the mixed-characteristic Iwahori E_2 local input (F2.b) remains conditional. The F1–F3 structural branch states the six conditional windows of $\mathcal{V}^{\mathrm{prim}}$.

four-input RH branch. Here P1 is the functional-equation branch (the statement that the adelic Pozitsel'ski bar complex has the functional-equation symmetry of $\xi(s)$); P2 is the Tate-adelic computation (Tate 1950); P3 is restricted Koszul unitarity (the Koszul–Petersson compatibility on the spherically-finite cuspidal core); and H-P^{Ar} is the arithmetic Hilbert–Pólya determinant-trace problem (existence of a self-adjoint operator whose normal translate has regularised determinant divisor div $\xi_{\mathbb{R}}$). The P1 implication requires the actual arithmetic comparison, central-defect identity and detecting Mellin evaluation. Koszul–Petersson compatibility implies P3 on its stated domain. The inputs P1, P2, P3 and H-P^{Ar} imply zero-placement under VB*.

Here VB* must include the specified positive spectral realization, its common operator domains and the arithmetic trace comparison. A positive measure or Hamburger determinacy alone does not identify its spectrum with the zero divisor of ξ. With that identification, self-adjointness forces real spectral ordinates and hence critical-line zero placement. A primary Virasoro representation and a vacuum-compatible positive sector remain separate constructions, as in Chapter 51.

The F1–F3 branch concerns construction of the arithmetic trace object. The spectral branch concerns its independently specified zero-divisor and positivity comparisons. Neither branch supplies the other's maps.

C.9 BOUNDARY CONDITIONS

Input	Branch	Size	Present form
L_{ACD} (adelic descent)	A	global theorem	Conjectural

Input	Branch	Size	Present form
F2.c (∞-Tate product)	A	mixed-characteristic theorem	Restricted pointed central-unit theorem; full mixed-characteristic statement conditional
F2.b (mixed-char Iwahori E_2)	A	mixed-characteristic theorem	Conditional
F3.BZN^{Ar} (arith. BZN)	A	trace theorem	Conjectural
arith. co–contra	B	categorical comparison	Integral recipients and adjunction required. Completion criterion proved
Koszul–Pet compat	B	automorphic theorem	Computed local forms; arithmetic placement and form comparison required
VB* (arith. Virasoro positivity)	B	Unknown	Positive spectral condition implies RH

Table C.1: Boundary conditions for the structural and RH branches.

C.10 A Sufficient Path to RH

The sufficient implication to RH uses an arithmetic realization of P1, Koszul–Petersson compatibility, H-P^{Ar} and the positive VB* spectral condition. The coefficient bar construction and the local pairing models provide positive algebraic input. Their arithmetic interpretation requires the co–contra functors and the central-defect and Mellin-evaluation maps of Question C.5.1.

Arithmetic Koszul–Petersson compatibility on the spherically finite cuspidal core also requires the placement and form-preserving maps of Hypothesis 67.1.1. Determinant-trace realization, full-sector P3, mixed-characteristic Iwahori E_2 and VB* positivity remain separate conditions.

Refined Boundary List

Input	Branch	Size	Present form
L_{ACD}.0, .1, .2, .3	A	each large theorem	Partial reductions; global glue remains conditional
(BC-diamond-glue).core	A	global theorem	Conjectural, single cross-prime Bernstein compat
F2.c (pointed E_n datum)	A	–	Restricted result of Theorem 50.1.3; mixed-characteristic Iwahori E_2 input separate
F3.BZN^{Ar} R1.fin-type	A	–	Smooth affine Perf(A) trace calculation; arithmetic comparison separate
F3.BZN^{Ar} R1.formal.a	A	–	Completed trace and support comparison required; a categorical colimit alone is insufficient
F3.BZN^{Ar} R1.formal.b,c	A	pro-étale theorem	Pro-étale loop-space and flat-locus hypotheses
F3.BZN^{Ar} R2 (Selmer target)	A	Selmer theorem	Target and tangent complex fixed; Noetherian and nilpotent-support hypotheses remain
F3.BZN^{Ar} R3 (full target)	A	–	Conditional; the inertia shadow is not the Weil/(φ, Γ) target

Input	Branch	Size	Present form
F3.BZN^{Ar} R4 wild $p \in \{2, 3\}$	A	–	Local arithmetic categories and trace maps open; full tensor includes mixed terms
Wild Langlands functoriality	A	–	Open comparison (Question 54.6.1)
arith. Positselski C1–C5	B	–	Specified coefficient models. Arithmetic functors and invariant maps required
arith. Positselski (abelian Heis.)	B	–	Scalar functional equation. Central-defect realization and detection separate
Koszul–Pet K5 (local pairing comparison)	B	–	Computed model norms; arithmetic placement and adelic comparison required
Koszul–Pet compat	B	–	Conditional on arithmetic placement and form identity; full-sector extension separate
H-P^{Ar}	B	–	Friedrichs domain theorem; determinant divisor and trace matching open
VB* $\Rightarrow$ zero-placement	B	–	Conditional implication from P2, P3, H-P^{Ar}, and positive trace
VB* (main direction)	B	–	Positive spectral condition; determinacy alone is insufficient
VB* converse	B	–	Strictly finer than RH; 4-way equivalence (Ch. 57)

TABLE C.2: Refined boundary conditions.

Sufficient RH Path

A sufficient implication to RH within the arithmetic formalism is the four-input conditional conjunction on the four-input RH branch:

(i) **Arithmetic comparison**: the integral recipients, co–contra functors and completed coefficient bar on their specified domain. The P1 interpretation requires the central-defect identity and detecting Mellin evaluation of Question C.5.1.

(ii) **Koszul–Pet compat** (the four-input RH branch): the normalized local forms are constructed. Even on a sph-fin cuspidal core their arithmetic interpretation requires the placement and form identity of Hypothesis 67.1.1. Full V^{prim} compatibility and global KMS$_1$/GNS identification remain open.

(iii) **H-P^{Ar}** (the four-input RH branch): the independent Hilbert–Pólya determinant-divisor matching problem.

(iv) **VB* main direction** (the four-input RH branch): the positive spectral realization with its arithmetic trace and domain comparisons.

The F1–F3 structural branch remains RH-independent: (BC-diamond-glue).core, F2 trace continuity, and arithmetic BZN formal-loop compatibility affect the construction of $\mathcal{V}^{\mathrm{prim}}$, not zero placement. The equivalences involving VB* in Chapter 57 retain their spectral-realization, positivity and determinacy hypotheses. Hamburger determinacy alone is not equivalent to RH. The primary-Virasoro and vacuum-sector comparisons remain distinct from a self-adjoint zero-divisor operator.

C.11 Dependency Boundary

Three hierarchically ordered conjectures (F1 → F2 → F3) and one independent conjecture (G-row) govern the synthesis branch. On the RH branch: P1 (functional equation), P2 (Tate adelic), P3 (restricted Koszul unitarity), H-P^{Ar} (Hilbert–Pólya determinant-divisor matching), and VB*, with its positive spectral realization and explicit trace and domain hypotheses. The restricted pointed central-unit theorem gives the proved part of F2.c, and the strict abelian primary arithmetic Positselski bar supplies the P1 forward direction. The arithmetic branch as stated (Chapter 43, Chapter 44) reduces the RH-strength condition to H-P^{Ar} determinant-trace realisation and the full positive spectral VB* hypotheses. A primary Virasoro realization requires its own compatible operators and invariant domains.
